Dr Davis was an outstanding man in his profession, very scientific, he was the possessor of one of the first electrocardiographs in the State He contributed a number of scientific papers on diseases of the heart, was an untiring member of the State Medical Association, a Fellow of the American Medical Association, and had been a Fellow of the American College of Physicians since 1926

Dr Davis had one of the largest practices in Fairmont, and was a consultant with patients from a large part of the State His skill, sympathy and charming personality endeared him to

his clientele and to his professional brethren

His death, due to an automobile accident near Coleville, California, while returning with a companion from a fishing trip has brought great sorrow to his friends and to the profession of the State

(Furnished by JOHN N SIMPSON M D , F A C P , Governor for West Virginia)

DOCTOR LORRAINE SCHWARTZ

Dr Lorraine Schwartz (Fellow), of Pittsburgh, Pa , died July 25, 1932, from brain injury resulting from a fall

Dr Schwartz was born in Slimesville, West Virginia, February 9, 1874 He attended Jefferson Medical College of Philadelphia, graduating in 1903 During 1903-04 he was an intern at the Mercy Hospital of Pittsburgh and to the time of his death was on the staff of that hospital His list of appointments included Dermatologist and Syphilographer, Mercy Hospital, Columbia Hospital and Rosalia Foundling Asylum Dr Schwartz was a member of the Allegheny County Medical Society, a member of the Pennsylvania State Medical Society, a member of the American Therapeutic Society, a Fellow of the American Medical Association, and a Fellow of the American College of Physicians (since 1920)

June 7, 1906, Dr Schwartz was married to Miss Maud Bishoff of Pittsburgh who survives him

Dr Schwartz was a Mason, a member of the University Club and of the

Pittsburgh Country Club. He was a member of the Third Presbyterian Church of Pittsburgh.

For several years before his death Dr. Schwartz had been in poor health and, during this period, traveled extensively in this country and abroad.

A genial companion and a prac-

itioner of outstanding ability in his chosen field, Dr. Schwartz is greatly missed by a wide circle of friends both within the medical profession and without.

NUMBER 6

The Manner of Onset in Acute Rheumatic Fever As Seen in New York City

By HARLOW BROOKS, M S , M D , F A C P , and CHARLES O'REGAN, B A , M D ,
New York City

IT IS universally recognized that rheumatic fever differs materially in its rate of occurrence, in its clinical picture and even in its complications in various parts of the world. Even with very slight variance in geographical distribution, the disease is strikingly modified in many of its most essential respects. Longcope has several times called attention to the fact that the disease as it appears at even so short a distance from New York as Baltimore is very different both in occurrence and in symptomatology. Rare in the tropics, and even in the subtropics, the disease is hardly recognizable to the student familiar with its picture as it occurs in the North.

Altitude and barometric conditions in general also profoundly alter almost all the evidences of the disease. Its seasonable appearance, its relationship to weather conditions and even to in-

dustrial states are still other evidences that factors beyond any single specific agent must be vitally concerned in its production. Familial occurrence and the evident rôle which allergic states play in the disease are still other indications that factors in addition to a single specific infectious agent must be concerned in the development of the condition. It seems very probable, indeed, that the reactions of the patient to the infection are more determinative in this disease than the characteristics of the essential infectious agent.

No experienced clinician, however, can now justify the older assumptions that the disease had essentially to do with disturbances of metabolism, or of diet, for all the clinical manifestations distinctly class the disease as a specific one and as one due to some transmissible infection, even though as yet little unanimity of opinion exists as to just what this specific organism may be. One must therefore be careful in respect to recognizing as specifically

From the Fourth Medical Service of Bellevue Hospital, and The Nursery and Child's Hospital, New York City

essential, organisms which may in truth be but associated biological factors, several of which we know to exist with great frequency in this disease.

Still other confusing factors are those of the rôles played by traumatism, exhaustion, exposure and of familial occurrence, all of which are too frequently seen as determinative or modifying factors in the disease to be dismissed by the student as mere coincidences

Notwithstanding the preeminence which the study of etiology has recently taken in this great problem, the clinical aspects still present much that requires further observation, study and conclusion

At the outset it must be recognized, that as before stated, the disease presents a character apparently determined in large part by locality and hence the description of any phases of occurrence will not apply to the problem as it appears universally

The disease is exceedingly frequent in and about New York City. Five hundred consecutive typical instances were selected from the records of the Fourth Medical Service of Bellevue Hospital as occurring within the past four years. This service represents but one-fourth of the census of the medical divisions of Bellevue, hence it can be seen how very common the disease is in this city. It is believed that the diagnosis of rheumatic fever is correct in each instance included in this series since all questionable cases were eliminated from our statistics.

It is believed by many that social conditions greatly influence the occurrence and character of rheumatic fever.

It is believed by many that social conditions greatly influence the occurrence and character of rheumatic fever. servers to be true of the infection as it occurs in New York City, though the questions of exhaustion and exposure and especially of weather, profoundly influence the cases which appear in this city. Nonetheless, so that we might, in so far as possible, avoid criticism on this score, our series of 700 cases has been consecutively selected, 500 cases from the Fourth Medical Service of Bellevue Hospital, which is our largest city hospital, devoted entirely to the service of the poor; and 150 consecutive cases have been taken from the private and consultation practice of one of us. Since infants are not regularly included on the medical service at Bellevue 50 cases have been taken from the records of the Nursery and Child's Hospital, with the permission and through the great courtesy of Doctor Schloss, Director of the Pediatric division of that hospital.

This present study covers only the problem of the manner of onset in rheumatic fever as it occurs in New York City. For obvious reasons many other phases of the problem are reserved for later presentation, for it is felt that only thus could we properly present the large and constantly increasing material at our command.

It is the belief of the authors that chorea represents but a special clinical picture of rheumatic infection, hence in this group of 50 cases taken from the records of the Nursery and Child's Hospital, but 22 cases were filed under the diagnosis of rheumatic fever and 28 instances were catalogued as chorea. All of the remaining cases were typical examples of rheumatic fever as seen in New York City. In 450

but a good many of these cases subsequently returned to the service with reinfections

SEX

Sex is believed by some to be a matter of importance in the occurrence of rheumatic fever. It is the opinion of the authors that this is true only because males are as a class more frequently exposed to the conditions which we believe to invite the infection. Particularly in this regard must one consider hard physical labor and exposure to adverse weather conditions, also the important factor of physical exhaustion. It is also probable that a greater degree of dissipation and self neglect on the part of the males in general may be a factor in this respect. Our statistics, however, show about the usual incidence in respect to sex, with 443 males and 257 females.

AGE

As in most other localities where rheumatic fever occurs frequently, the preponderance of cases appears at that period of life which demands the greatest physical activity, but they show also a relatively high percentage of occurrence in infantile life, when one takes into consideration the relatively smaller group from this service. The figures are as follows: First decade, 50 cases, second decade, 140, third, 210, fourth, 171, fifth, 88 cases, sixth decade, 26, seventh, 9, and the eighth decade, 6 cases.

FIRST SYMPTOM

Catarrhal inflammatory processes of the upper respiratory tract are pre-

ponderatingly the most frequent and usually the very earliest indication of the infection. Unlike the nasopharyngitis of the "common cold" as studied by most recent investigators, that of the onset of rheumatic fever as it occurs in New York is almost invariably accompanied by fever, often a very high one. No sharp differentiation is of course possible between nasopharyngitis and involvement of the adjacent cavities, but in 347 cases this condition was cited as a pharyngitis. This high rate was even exceeded by the diagnosis of tonsillitis, which was recorded 382 times. Simple "sore throat" was cited by 124 patients without specification of the precise lesion which was present. In 33 instances a paranasal sinusitis was diagnosed by the medical (not the special) staff. It is notable that the cases presenting medically recognizable sinusitis were particularly virulent and rapid cases.

ADENITIS

The very early appearance of adenitis in many cases was one of the surprises of our study. This lesion was strikingly present in 187 instances. Although most frequent in the lymph nodes of the neck, particularly in the tonsillar lymph nodes at the angle of the inferior maxilla, it was often widespread and it was found frequently antedating joint invasion in the groups of nodes draining from the involved extremities. In a few cases the adenitis was of rapid development and so pronounced that acute lymphatic leukemia was considered. Several of these cases showed in addition a most puzzling lymphocytosis but in the average instance at onset but a low grade

polynuclear leucocytosis was found. Streptococci were isolated from such nodes in several instances

FEVER

Fever was present in all cases at some early period of the onset. Occasionally it was very high, but usually not. It was accompanied by a proportionately increased pulse rate except when early cardiac involvement had taken place in which case the heart rate corresponded to, and was indicative of the cardiac process.

CHILL

Chill was infrequently seen or complained of during the period of onset as we have studied it. It was noted but 65 times and then chiefly as a patient's complaint. It occurred more frequently, however, later in the disease, particularly with the development of deep complications or in phlebitis. It has, however, never been an important evidence of the disease as we have seen it.

SWEATING

Sweating, which subsequently often becomes one of the most striking and annoying symptoms of the disease, is not so very common in the period of onset and it is rarely complained of by our patients, possibly because of more distressing symptoms which are present at this time.

EVIDENCES OF OCCULT INFECTION

In view of the present, perhaps excessive interest in this possibility of origin, it may be pointed out that tonsillitis was noted in 382 cases as already mentioned. It is well recognized

that such a general infection might also originate from the nasopharyngitis and sinusitis which are so very frequent, also, in the onset of this disease.

DENTAL INFECTION

The possibility of infection from bad or infected teeth must be admitted in 238 instances. All cases are included in this group in which this possibility had been sufficiently considered to bring about extractions for this cause, or in which a well established dental infection was recognized as a result of study of X-ray plates taken, or of cultures made from extracted teeth. This high occurrence of infected teeth must, however, be considered in association with the fact that in Bellevue Hospital probably an equally high percentage of bad dental status would be found in association with almost any other condition, traumatic, accidental or otherwise. It must be, however, pointed out that of the fifty instances from the Nursery and Child's Hospital, bad teeth, possibly infected, were noted in 16.

ARTHRITIS

Arthritis is the most constant outstanding diagnostic index of this disease as it appears in New York City. It was present in the period of onset or very shortly thereafter in 622 of our cases. Occasionally it is the very first indication of disease noted by the patient. In the patients admitted to the Bellevue service it was present in greater or lesser degree in every instance at the time that they sought admission to the hospital. It occasionally becomes definite before pharyn-

gitis or tonsillitis is discovered. It is distinctly migratory in type and there are few exceptions to the rule of polyarthritis. Monoarticular cases are very rare or entirely wanting as the disease of rheumatic fever occurs in New York City. Exceptions to this rule usually imply mistaken diagnosis with confusion, for example, with gonococcal or septic arthritis.

The clinical picture of the joint lesion need not be detailed here since it is familiar from text book descriptions. It is essentially a peri-arthritis, the large joints are most frequently involved, but by no means exclusively so. Occasionally there is a considerable effusion into the joint space itself, but this is not the usual thing. The synovial membranes are rarely eroded in the acute phases of the disease. Various microorganisms are frequently detectable in the joint fluid. Streptococci preponderate in most instances, but the authors do not as yet accept any of the organisms described as of proven etiological significance.

Sixty-two cases from the Bellevue series, were complicated by certain or possible gonococcal infection. The arthritis in such cases, especially at onset, is usually somewhat atypical. The two forms of arthritis may unquestionably be associated in the same case. Nineteen of the Bellevue cases occurred in the presence of chronic syphilis. This also causes a modification of the joint lesions in some but not all instances.

As a rule, with exceptions, when the arthritis attacks a previously involved joint, the older ones subside somewhat in activity but reinfection frequently follows. An increase in the

temperature commonly immediately precedes invasion of a new joint. The leucocytosis is not much altered as a rule, when migration takes place.

CARDIAC DISEASE

Of the total of 700 cases, 154 entered with initial complaints explainable only on the basis of cardiac disease, apparently caused by the rheumatic fever. Four hundred and ninety-three cases showed at their first examination definite cardiac disease believed to be rheumatic and detectable by the ordinary methods of physical examination. From our subsequent experience with the electrocardiograph we believe that practically all instances of acute rheumatic fever present evidences, electrocardiographic or gross, of cardiac involvement. Certain cases may recover sufficiently, under proper control and treatment, so that some of these lesions may entirely disappear. Even mitral endocarditis of rheumatic origin apparently may heal in children so that the lesion may not be detectable in after life, but these cases are rare. Our studies of the period of onset indicate that cardiac lesions appear in the disease seen in New York City very early in the infection.

Six hundred and six cases were ultimately discharged with clinically recognizable rheumatic cardiac disease. We know from follow up observation that a good many of the apparently free instances at the time of discharge subsequently developed gross cardiac disease, presumably attributable to the initial attack of rheumatic fever. Such lesions apparently may first appear weeks, months and perhaps years after the initial cardiac defect which may

occur without recognition by the usual method of observation. We thus corroborate the observations of Swift in this respect.

PULMONARY, BRONCHIAL AND PLEURAL DISEASE

Sixty-three cases entered with signs or symptoms of tracheitis, bronchitis, pulmonitis or pleurisy. Pulmonary pathology certainly develops in a much higher percentage of New York City cases than the usual text book description implies. As a rule even the type of frank broncho-pneumonia which develops in the course of rheumatic fever runs a rather milder course. Initial rheumatic pneumonia is often present but the clinical course of these cases appears more mild than in a similar degree of ordinary pulmonary disease, independent of rheumatism. Further study of these cases is certainly advisable before any sweeping conclusions be drawn either as to their course or pathology.

EVIDENCES OF ALLERGY

In 42 instances skin lesions, suggestive of allergic disorders, appeared early after onset. None of these seemed to have been excited by drug action, but we cannot be certain on this point. A history of familial or personal asthma was obtained with some frequency. We are as yet unwilling to admit its definite relation to rheumatic fever, however.

SUMMARY

Rheumatic fever is very frequent in New York City.

In the groups studied, it appears more frequently in the male

It is seen most commonly in the second, third and fourth decades, but may occur at any period of life.

Primary attacks are more frequent in this present series, but recurrence of the disease is probably the rule.

The most frequent prodromal or initial symptoms are tonsillitis, pharyngitis, simple sore throat or sinus infections; in short, a catarrhal disease of the upper respiratory passages. Sinusitis, while infrequently diagnosed on medical services, is probably very frequent.

Adenitis, not only of the cervical but also of other systems is a frequent introductory sign. It is of persistent character and prone to reactivation.

Initial symptoms of pulmonary involvement are not dominant in this group of cases. Pulmonary involvement is, however, probably more frequent and important later in the disease than is commonly recognized.

Occult infection, if introductory of the disease, may occur from the nasopharynx and the accessory sinuses, from the tonsil or possibly from dental infection. Infection from the tonsils or from the nasopharynx seems more definitely indicated by these studies.

There are some early indications of possibly allergic character, but they are not common in this group.

Fever is an early and constant symptom. Chill is not frequent. Sweating is not striking in the period of onset.

Arthritis is almost constant and is highly characteristic. It occurs early and as part of the onset. It is distinctly a polyarthritis and of a migratory character, highly diagnostic in appearance and course.

Cardiac involvement is exceedingly frequent, perhaps constant. It occurs early in onset. Few cases escape eventual cardiac invasion of some degree.

Involvement of the nervous system is very rare in the period of onset. Delirium is exceedingly infrequent.

Renal symptoms are very rare in

the period of onset, and subsequently

CONCLUSION

The onset of rheumatic fever, as it occurs in New York City, is highly characteristic and easily diagnosed as a rule. It is almost always associated with early cardiac involvement and a very characteristic type of arthritis.

An Introduction to Medicine

“TO the student the value of a persistent endeavor to correlate symptoms with lesions lies not so much in the number of facts which he may succeed in memorizing, as in the development of an attitude of mind which may color the whole of his future professional career. The clinical-pathological conference owes its popularity to the realization of this fact. Education can achieve no higher success than by leaving its abiding imprint on the mental outlook of those who come under its influence.”

“To the clinician who wishes to indulge in the periodic brain-dusting recommended by Osler there are few more valuable correctives than a renewed acquaintance with the facts of morbid anatomy as revealed in the postmortem room. It is more than one hundred and thirty years since Bichat wrote the following words, but they are as true today as they were then: ‘You may take notes for twenty years from morning to night at the bedside of the sick upon the diseases of the heart, the lungs, the gastric viscera, etc., and all will be to you only a confusion of symptoms which, not being united in one point, will necessarily present only a train of incoherent phenomena. Open a few bodies and this obscurity will soon disappear, which observation alone would never have been able to have dissipated. Dissect in anatomy, experiment in physiology, follow the disease and make the autopsy in medicine. This is the three-fold path without which there can be no anatomist, no physiologist, no physician.’”

(From *A Text-Book of Pathology: An Introduction to Medicine* by WILLIAM BOYD, Lea & Febiger, Philadelphia, 1932. See review in this issue.)

Observations on Obesity

By RUSSELL M. WILDER, M.D., *Rochester, Minnesota*, and FLORENCE H. SMITH, B.S. and IRENE SANDIFORD, Ph.D., *Chicago, Illinois*

IT IS repeatedly affirmed that certain men and women maintain themselves in weight equilibrium or even gain weight on less food than others require, and popular opinion attributes this to abnormalities of endocrine activity and resulting economies in energy production. It has been repeatedly demonstrated that the basal metabolic rate, measured in terms of calories of heat production for each square meter of surface area, is normal in obesity and that no economy of energy exchange is accomplished in this particular, but the total energy exchange is the crux of the matter, and whether economies can be expected in total metabolism from pituitary, gonadal or other influences, is still open to discussion.

The direct measurement of total metabolism involves an elaborate experimental machinery, a calorimeter large enough to permit the subject to lead a life with a normal amount, or at least some standardized amount, of physical exertion. It also demands several trained technicians to conduct uninterruptedly the necessarily large

number of gaseous and other analyses of consecutive twenty-four-hour periods. Relatively few experiments of this kind have been attempted and none has been entirely satisfactory. Indirect measurements of energy exchange which depend on estimations of amounts of food consumed are exposed to errors introduced by the questionable honesty of many subjects. They are also influenced by fluctuations of water balance, especially significant in obesity, and measurements of water balance involve very particular difficulties. A study of the total water exchange by Newburgh and his associates in connection with a study of the total metabolism in obesity revealed how completely the retention of water may mask the actual loss of tissue occasioned by submaintenance diets. The body weights of Newburgh's subjects inevitably fell to the values anticipated from the metabolic data, but periods intervened when the weights were stationary. The longest of these periods was sixteen days.

NEGATIVE PHASE OF METABOLISM

Our interest in obesity was renewed by the demonstration of Lauter and of Bernhardt of "negative phase" of metabolism occurring after the ingestion of food and after short periods

Received before the American College of Physicians, San Francisco, California, May 6, 1932. From the Division of Medicine, The Massachusetts General Hospital, and the Department of Medicine, University of Chicago, Chicago, Illinois.

of light muscular exercise Strang and McClugage have reinvestigated the heat production following the ingestion of food in normal, obese and thin subjects They were unable to demonstrate a consistent occurrence of a negative phase after a test meal, and they showed that whenever decreases in heat production occurred there was an abnormal elevation of the basal heat production This is, of course, in agreement with the early work of Benedict and Carpenter who not only pointed out the extreme importance of an accurate base line in such experiments but also demonstrated that a negative phase was not encountered after ingestion of food by normal subjects

It has been established that obese subjects expend at least as much and usually more energy for measured amounts of work than is demanded of individuals of normal weight, but Bernhardt, in cases of certain types of obesity and in cases in which individuals were regaining weight previously lost, was led to believe that the rate of heat production would fall immediately after the performance of light work to a level which was lower than the resting or basal level and remain below this level for a time sufficient to compensate for the extra energy expended in the work (figure 1) Here indeed was an economy which might permit an individual to hold his weight or gain on a food allowance smaller than that required for a total metabolism based on conventional calculations, and in fact Bernhardt reported that his subjects gained weight on diets designed to meet, but not exceed, their twenty-four-hour

basal metabolism, although they were up and about and thus expending "extra" energy for work

We have attempted to duplicate these observations, and our data are presented in tables I and II, and partly in figure 2 Our subjects were adults one man and six women One patient had anorexia nervosa (case 6) and was gaining weight rapidly, the others were in varying states of obesity In cases 1, 2, and 3 the patients had been hospitalized for several weeks, they were on basal caloric diets and were losing in weight at the time of the work tests In cases 4, 5, and 7 the patients were hospitalized approximately one week before the work tests were made and at the time of admission were gaining in weight

For the determination of the metabolic rates the gasometer method with analysis of the expired air in the Haldane analysis apparatus was used The details of the technic have been published by one of us elsewhere⁷ In order to insure as accurate results as possible each patient had several metabolism tests as preliminary training before the work tests were done, and from the satisfactory values an average base line was obtained which served as a check on the basal calories obtained on the day of the work experiments The subjects were fasting from the previous evening's meal and were afebrile They rested quietly in bed for at least half an hour before the basal calories each hour were determined in duplicate tests The patients in cases 1 and 2 had had numerous determinations of metabolic rate and apparently they were quite undisturbed by the procedures, there-

fore occasionally the basal calories each hour were determined only once. As can be seen from table 1 this was not satisfactory and later duplicate determinations were always done.

The exercise was of two types: the leg flexion exercise in bed used by Bernhardt and pedaling on a bicycle ergometer (Sevringhaus type), with or without resistance. After the basal heat production had been determined the subject was instructed to flex one leg, bringing it forcibly back to the buttocks eight times in a minute, timed with a stop watch. At the end of each minute the alternate leg was then

exercised. This was repeated for twenty minutes, at the end of which time the mask was tightly adjusted and expired air was collected for a period of from five to eight minutes, while the patient continued with the exercise. This gave the height of the metabolism during the exercise. The patient continued the exercise until the necessary readings were recorded and checked, samples of the expired air were collected in sampling tubes and the gasometer was prepared for another test. A second test was then run for eight minutes, and at the moment of starting it the patient was

Fig. 1. (Case 23, Bernhardt). Negative phase of metabolism after exercise. The curve shows the depression of the metabolic rate from the day's "basal calories" during

TABLE I
Effect of Exercise on the Rate of Heat Production

[illegible]

requested to stop the exercise This gave a measure of the heat production immediately following exercise Determinations followed 30, 45, 60, 90 and 120 minutes after exercise

When the bicycle ergometer was used the basal heat production was determined in bed and then the subject rode the bicycle with the mask in place The rate of pedaling with or without resistance was 58 to 60 revo-

lutions a minute timed with a metronome and stop watch At the end of twenty minutes' exercise the expired air was collected in the gasometer for a period of five to eight minutes, depending on the volume expired The mask was then removed and the patient returned to bed A determination of the heat production was made ten minutes after the exercise and thereafter as in the experiments with

the other type of exercise. In no case was the patient exhausted from the exercise. With the exception of cases 6 and 7 at least three experiments were done on different days.

Following light exercise there was a slight decrease in the heat production below the day's basal calories in only two instances in the experiments in case 2, March 30, and in case 5, July 10. However, the highest basal heat production was obtained in both of these patients on these days, for the former the increase over the average figure for calories each hour was 10.7 calories (13 per cent) and for the latter 6 calories (7 per cent) and, since a negative phase does not appear if the heat production after work is compared with the average basal metabolic rate of these two patients, we are led to conclude that the patients we studied did not manifest evidence of a negative phase in the heat production following light exercise.

With heavier exercise there was no evidence of a negative phase in cases 1 and 2. The single low value obtained in case 1 in the experiment on April 17, which was not confirmed by any of the other experiments done in this case, forces us to question the accuracy of the determination rather than accept it as a negative phase of only fifteen minutes or so duration. However, in case 7 there was decreased heat production occurring two hours after exercise in the experiment of April 28. Decreased heat production also occurred at the same time in the series of tests on the following day. At this time we were suspicious that the mask was not air-tight and

consequently immediately repeated the test (two hours and fifteen minutes after exercise) and the heat production was then only 3 per cent below the day's best basal heat production. The patient was a young girl who did not cooperate well.

The respiratory quotients in these experiments (table II) were elevated during or immediately after exercise in all experiments except one (case 1, experiment of April 17). This is probably explained by the quickened ventilation and consequent removal of carbon dioxide from the blood.¹⁰ The return of the respiratory quotient to the basal level was usually complete within thirty minutes after the exercise.

It has been pointed out by Benedict and Carpenter as well as by DuBois that any experiment involving repeated short period determinations of gaseous exchange after a change in basal conditions is subject to error from a variety of sources, but particularly because the actual basal condition, to which all other measurements must be referred, is extremely difficult to determine with the requisite precision. Strang and McClugage, in their very careful investigations on the specific dynamic action of food in abnormal states of nutrition also emphasize the importance of an accurate base line and state that negative phases exist only in so far as the basal values are elevated.

Bernhardt does not publish any data to show that his basal calories represent more than one determination and apparently only one of his patients was the subject of more than one experiment. In a later investigation con-

ducted in Bernhard's Laboratory at The Mayo Clinic, Bernhardt himself was the subject and he again in one experiment observed a negative phase at a time when he was regaining weight lost in previous periods.

BASAL CALORIC DIETS

Several of Bernhardt's subjects, those with a diagnosis of endogenous obesity, held their weights or even gained, it was stated, when subjected to diets with caloric value equal to

their twenty-four-hour basal metabolism (Grundumsatz) They were not confined to bed and their failure to lose was attributed to compensation or economy by negative phases of the resting metabolism

We were able to hold three of our patients (cases 1, 2 and 3) in hospital for a period of 162 days The basal metabolic rates were determined repeatedly and the diet of each subject was made to equal his or her average basal heat production as determined, with particular attention paid to satiety values and adequacy of vitamins, minerals and protein Each subject occupied an isolated room in the metabolism division and, for the most part, the physical activity was supervised in the laboratory Two of these subjects were temporarily engaged as assistants in the laboratory The food was rigidly controlled and periodic examinations were made of the nitrogen and creatinine content of twenty-four-hour collections of urine and feces The salt given was 8 gm, and the fluids were made to equal 1,500 cc

The protocols of these observations, and the case records are given herewith (cases 1, 2, and 3) The weight loss, as shown graphically (figure 3), was that which could have been predicted from the knowledge of the basal metabolism and estimates of the extra energy resulting from the degree of physical activity A later recalculation of the total metabolism of these subjects gives figures which represent 141, 140 and 148 per cent, respectively, of their basal energy exchanges computed from the DuBois standards for their respective sexes, heights and weights (table III)

It is evident, however, that short periods of observation would have given entirely erroneous impressions of the total metabolism in these cases In case 2 the weight remained almost constant for 28 days, from December 1 to December 28, at 148 kgm, then dropped to 144.9 kgm by December 31 and held at this level until January 24 In cases 1 and 3 somewhat shorter, but nevertheless long, periods of constant weight occurred

WEIGHT LOSS DURING REST IN BED

In case 2, during an eleven-day period when the subject was required to remain in bed, the weight loss each day averaged 464 gm as contrasted to a daily loss of 122 gm, the average for the entire period of observation The patient in case 3 lost 900 gm a day for four days when he was in bed, as compared to his average loss of 143 gm a day In case 1 the average daily loss, during seven days in bed, was 614 gm, whereas the average loss each day for the entire observation was 103 gm This at first sight seems paradoxical With less energy expended by confinement to bed the rate of fat loss must decrease and weight loss should be retarded However, rest in bed serves to release water and thus temporarily at least the diminished rate of fat loss is obscured The phenomenon is the exact counterpart of what occurs with patients whose hearts are decompensated and one wonders how near to cardiac decompensation some of these very obese persons may be Direct measurements in case 2 revealed a striking diminution in the size of the legs during rest although pitting edema was

FIG. 3 Weight loss and basal metabolic rate in obesity

not observed. It is not improbable that this circulatory factor is often overlooked by physicians who are attempting to reduce obesity by diet and exercise, and that many instances of supposed resistance to reduction are accounted for by mild circulatory failure and imperceptible edema.

WEIGHT LOSS DURING ADMINISTRATION OF INSULIN

A possible effect of insulin on fat metabolism is suggested by the results

tion of gain in weight that follows its use in cases of cachexia. The benefit in cachexia may be explained by the resulting hypoglycemia and the effect of this on appetite and thus on total food consumption, but some evidence, especially the very high respiratory quotients (exceeding unity) that are obtained when insulin is given with a rich carbohydrate meal, is suggestive of a more direct action on fat metabolism. We have in this laboratory made a study of the effect of insulin on the metabolism of

TABLE III

§ Computed from the Amb-DuBois standards for the given sex, age, height and weight

55 and 60 units respectively. In one case (case 3), retardation of weight loss was not observable during either of two periods of insulin of 27 and 37 days. In the other (case 1) with two periods of insulin of 12 and 30 days respectively, retardation was noted, but without additional data on the water balance its interpretation is not possible.

An interesting by-product of these experiments was the observation of a definite loss of tolerance for carbohydrate when insulin was withheld after it had been given for a time. It was demonstrated by a response to glucose test meals typical of mild diabetes. Tolerance tests made before the courses of insulin resulted in perfectly normal blood sugar curves. The abnormality resulting from the insulin injections persisted not longer than two or three days. The protocols are contained in the records of cases 1 and 3. The most plausible explanation of this would appear to be that during prolonged administration of insulin the islet mechanism is put at rest so that on discontinuing the injections the island cells are slow to respond to the stimulus of incoming carbohydrates. The phenomenon is analogous to that observed with other glands of internal secretion, the thyroid, the parathyroids and the anterior pituitary-gonad complex. Administering an endocrine product depresses the activity of the gland whose function it supplants. It is also analogous to the old phenomenon of vagabond or hunger diabetes and the diabetic-like reactions to glucose tolerance tests that are observed in nondiabetic subjects maintained on low carbohydrate diets.

That no actual involution or atrophy of the pancreas is involved is indicated by the rapid return to normal function.

ESTIMATION OF FOOD REQUIREMENTS

Estimates of calorie requirements have been based as a rule on the food consumption of groups of individuals, such as soldiers, or have been arrived at by adding to the calories of the basal metabolism a quota for the specific dynamic action of food and one for each of the various activities in which the individual is engaged. In either case considerable error is probably introduced. The figures obtained are often 100 per cent in excess of the basal metabolism, or from 3,000 to 4,000 calories a day for individuals of average build.

Another method is available when the subject is obese and on a sub-maintenance diet. This is to add to the calories of the food those accounted for by loss of weight. If the period of observation is long enough, and it should be extended over several months to avoid errors due to water retention, and if rigid supervision is maintained, so that the food consumption is actually known, this provides data which appear to be entirely reliable. It has been shown by Strang, McClugage and Evans that, when sufficient protein is supplied to obese subjects on reduction diets, the nitrogen intake and output remain in balance and tissue protein is not wasted. Also the creatinine excreted remains the same before and after the reduction, an indication that the muscle mass and the parenchymatous organs are not affected. It also appears from the observations of Strang, McClug-

age, and Evans, and from our own that the basal metabolic rate (heat production for each square meter of surface) is not lowered by weight reduction in obese subjects as it is in subjects of normal or less than normal weight (figure 3). The fat depots of the obese apparently serve as effectively as does ingested food in maintaining the normal level of heat production. All this being true, the weight loss provides a fairly accurate measure of the number of calories supplied by the organism, and these added to those allowed as food make a nearly accurate measure of the total metabolism.

An illustrative calculation in case 1 is as follows. A woman, aged 60 years, leads a sedentary life and is 156.3 cm in height. Her diet contains 63 gm of protein and has a total calorie value of 1,800. In a period of 162 days she loses from 147.8 to 131.1 kgm. Her mean weight is therefore 139.5 kgm, the total weight lost 16.7 kgm and the average weight lost each day 103 gm. Since the nitrogen of intake and output is balanced, the loss of weight is attributed to fatty tissue and if the water content of fatty tissue may be assumed to be 13 per cent (the average of the figures for human beings obtained by Bozenraad) then the daily loss of fat may be placed at 90 gm, which would contribute 837 calories to the day's energy expenditure. Adding this figure to the calories of the food gives 2,640 calories for the total metabolism, a value which exceeds by only 44 per cent the determined basal metabolism for twenty-four hours.

In table 3, estimates of total metabolism are made for the three principal

cases of this study. In two of them this exceeds 3,000 calories, but the surface areas of these subjects is relatively large, due to obesity; consequently the basal metabolism for 24 hours is large. Total metabolism, however, in no instance exceeds basal metabolism by more than 50 per cent. If we recalculate the data of table III, using standard body weights, the basal metabolism is found to range from 1,320 calories, for the inactive short woman aged 60 years, case 1, to 1,860 calories for the more active tall young man, case 3. If to these 50 per cent is added to cover total metabolism, the estimates are somewhat lower than those of the early students of metabolism and in better agreement with clinical experience. It has been our practice for many years to plan diets for patients with diabetes so that they will not exceed 50 per cent more calories than are needed for calculated basal requirements and with few exceptions this allowance has proved to be adequate for persons engaged in moderately active occupations, such as nurses and physicians.

REPORT OF CASES

Case 1. A woman, aged 60 years, was observed from October 7, 1930, to July 18, 1931. She was constitutionally obese, her height was 156.5 cm, and her weight 150.0 kgm, overweight 140 per cent. Her father was short and stout. A sister, 5 ft., 6½ inches in height, weighed more than 200 pounds, gained gradually, she had menstruated until the age of 65 years. Had been married twice, but had not been pregnant. Of five brothers one, short in stature weighed 250 pounds gained late in life. There were no familial diseases other than obesity. The patient's menstruation had always been irregular, at intervals of three to six weeks lasting one to two days (one period a month).

pain, and uninterrupted to date. At the age of 21 years she had weighed 135 pounds. Development of weight was normal until the age of 28 years. At the age of 36 years, she weighed 190 pounds, at 48 years, 325 pounds. This weight had been rather constant since then. She was engaged in active laundry work until the age of 48 years, afterward her life was sedentary. She complained of being unable to move quickly, of shortness of breath, palpitation on climbing stairs, often cough after exertion, and required two pillows at night. Edema of the ankles toward evening had been present in the last ten years. Her appetite was excellent. At the age of 55 years, on an attempt to reduce under a physician's care with diet and medicine, she lost 45 pounds in three months. On a second attempt to reduce at the age of 58 years, "eighteen day diet", no weight was lost.

The patient appeared to be intelligent. The blood pressure in millimeters of mercury was 150 to 120 systolic, and 110 to 70 diastolic. The Wassermann reaction of the blood and the Kahn test gave negative results. The concentration of hemoglobin was 100 per cent, leukocytes numbered 8,700 and erythrocytes 5,600,000 per cubic millimeter. Urinalysis gave negative results, the volume on unrestricted intake was approximately 1,500 c c. The hands and wrists were small, the

pituitary tumor. The average basal metabolic rate was -2 per cent.

Study of the metabolism extended over a period of 162 days (from February 6, to July 10, 1931). The patient was up and about the wards for daily walks. The diet consisted of 1,800 calories (determined basal expenditure), protein, 63 gm (1 gm for each kilogram of standard weight), sodium chloride 8 gm, and water 1,500 c c. The weight lost was 16.7 kgm. The average loss each day was 103 gm. The daily average of the nitrogen balance from March 2 to March 21, 1931, was $+0.87$ gm (nitrogen of feces not determined and nitrogen intake calculated as 10 gm daily). From April 9 to May 8, 1931, the daily average was $+1.08$ gm (nitrogen of feces and food determined). Daily creatinine determinations varied from 1.08 to 1.34 gm.

A maximum of 60 units of insulin was administered daily for 30 days (May 11 to June 10, 1931) with loss of weight of 0.8 kgm, the average loss each day was 27 gm. In another period a maximum of 55 units of insulin daily was administered for 12 days (July 2 to July 14, 1931). The total loss of weight was 0.8 kgm, the average loss each day 67 gm. The glucose tolerance* before and after the administration of insulin (63 gm of glucose given in the morning) was as follows:

DATE OF TEST	BLOOD SUGAR FASTING GM, 100 c c	BLOOD SUGAR ½ HOUR GM, 100 c c	BLOOD SUGAR 1 HOUR GM, 100 c c	BLOOD SUGAR 1½ HOURS GM, 100 c c	BLOOD SUGAR 2 HOURS GM, 100 c c	BLOOD SUGAR 3 HOURS GM, 100 c c

*Insulin given from July 2 to July 14, 1931, maximal daily dosage 55 units. No insulin was given before glucose test meal July 13, 1931.

forearm was slightly increased in size, and the upper arm greatly increased. The feet were small, the legs were greatly enlarged with edema, varicosities and fat. The thighs were even more enlarged than the legs. Varicose veins were very prominent. Roentgenograms of the heart showed that it was 38 per cent oversize. There was no evidence of a

The weight lost during rest in bed from June 17 to June 24, 1932 (seven days), was from 130.5 kgm to 132.2 kgm (4.3 kgm). The average loss of weight each day was 614 gm. From July 8 to July 13, 1931 (five days in bed), the weight lost was from 133.6

*Blood sugars by new Folin method

to 131 kgm (26 kgm) The average loss of weight each day was 520 gm Table I shows percentage deviation of metabolic rate during and after exercise

Case 2 A woman, aged 24 years, was observed in hospital from November 23, 1930, to May 16, 1931 It was suspected that the obesity followed encephalitis Her height was 173 cm, and her weight 152.5 kgm, overweight 135 per cent Her mother had died of carcinoma at the age of 30 years There was no marked obesity in the family The patient had menstruated regularly for five years, since the age of fourteen, the interval between menstruations was 28 days, and the duration was five days This period decreased after influenza until a single pad sufficed During the last two years menstruation had increased and now lasted for one or two days, periodicity unchanged The normal weight of the patient was 135 pounds, but at the age of 19 years she had gained 100 pounds in one year There was no previous history of overweight At the age of 19 years the patient had influenza, with high fever, drowsiness, loss of hair, and laryngitis and was in bed for two weeks Diplopia had not been observed Subsequent recovery was slow (two to three months), and she tired easily, was very drowsy, the muscles became rapidly fatigued, and the eyelids drooped The hair grew rapidly again, and although the appetite had failed during the illness it was followed by an excessive desire for food, and gain in weight was rapid The patient suffered from headache She was emotionally normal Two months before coming to the clinic she was unable to raise her eyelids for two days Vision was unchanged

The patient appeared to be intelligent Her activity was diminished by excess weight The blood pressure was 130 systolic and 90 diastolic The Wassermann reaction of the blood and the Kahn test gave negative results The concentration of hemoglobin was 90 per cent, the leukocytes numbered 9,800 and erythrocytes 4,800,000 Urinalysis gave negative results, the volume on unrestricted intake after twenty-four hours was 750 cc The glucose tolerance test (65 gm of glucose) revealed the following: fasting blood sugar, 0.113, after half an hour, 0.156 after

two hours, 0.122 and after three hours, 0.080 gm Tests of the urine were negative for sugar Roentgenograms revealed that the thorax was normal, the size of the heart, approximately normal, and an unusual shape of the bones of the skull (ape-like) with considerable enlargement of the sella turcica The average basal metabolic rate was -8 per cent

Study of the metabolism, while the patient was employed as a laboratory helper, extended for a period first of 51 days (from December 5, 1930, to January 25, 1931) The diet consisted of 2,200 calories (110 per cent of the basal energy expenditure as determined later), protein, 65 gm (1 gm for each kilogram of standard weight) sodium chloride, 8 gm, and water, 1,500 cc The weight lost was from 148.4 to 144.7 kgm (3.7 kgm) The average weight lost each day was 73 gm In a second period from January 25 to May 16, 1931 (111 days), the diet consisted of 2,000 calories (determined on the basal expenditure), the amounts of protein, sodium chloride and water were the same The weight lost was from 144.4 to 128.6 kgm (15.8 kgm), the average weight lost each day was 142 gm The daily average of the nitrogen balance from March 9 to March 18, 1931, was +1.75 gm (feces not included, food nitrogen calculated as 10.4 gm daily) Creatinine determinations varied daily from 1.38 to 1.26

The daily average nitrogen balance from March 31 to April 2, 1931, was +0.34 gm (feces included food nitrogen calculated as 10.4 gm daily) Daily determinations of creatinine varied from 1.19 to 1.12 gm

The weight lost during rest in bed from December 27, 1930, to January 5, 1931 (nine days), was from 148.1 to 144.9 kgm (3.2 kgm), average loss each day 356 gm From February 22 to March 5, 1931 (11 days in bed) the weight lost was from 139.6 to 134.5 kgm (5.1 kgm) average loss each day 464 gm April 6 to April 28, 1931 (22 days in bed), the weight lost was from 132.1 to 124.7 kgm (7.4 kgm), the average loss each day 245 gm

Case 3 A man aged 26 years was observed from January 20 to September 22, 1931 It was suspected that his obesity was

of cerebral origin. His height was 183 cm and weight 131 kgm on admission, overweight 72 per cent. His mother was 5 ft, 7 inches in height, weighed 180 pounds and had a goiter. His father was 5 ft, 7 inches in height, and weighed 180 pounds. The patient had a sister who was of normal weight. At birth the patient had been injured with forceps. He had been overweight since childhood. For the last ten years he fell asleep when at work, slept for one or two minutes then was wide awake, he fell asleep when standing. This had occurred two or three times daily at any time, he lost consciousness abruptly and only realized that he had been asleep when he awakened. He sleeps the normal amount at night. His appetite is good. "does not eat more than the average man". In 1929 and 1930 he had tried several forms of treatment including diet and drugs, tablets by mouth, and hypodermic injections of a pituitary preparation three times weekly.

The patient seemed to be intelligent. He was afraid of losing his work as laborer as he could not keep awake. The blood pressure was 126 systolic and 80 diastolic, leukocytes numbered 10,000, and erythrocytes, 4,480,000. The Wassermann reaction of the blood gave negative results. The concentration of hemoglobin was 90 per cent. Urinalysis was negative, the volume with unrestricted intake was 1,150 c.c. Roentgenograms revealed calcification of the pineal body and normal sella turcica. The average basal metabolic rate was -15 per cent.

When undergoing study of the metabolism the patient was engaged as a laboratory worker. In the first period of 109 days (from January 22 to May 11, 1931), the diet consisted of 2,340 calories (123 per cent of the

basal energy expenditure as determined later), protein, 73 gm (1 gm for each kilogram of standard weight), sodium chloride, 8 gm, and water, 1,500 c.c. The weight lost was from 128.5 to 115 kgm (13.5 kgm), the average loss each day was 124 gm. In a second period of 53 days (from May 11 to July 3, 1931), the diet consisted of 1,900 calories (determined according to basal expenditures), protein, sodium chloride and water in similar amounts. The weight lost was from 114.7 to 105.3 kgm (9.4 kgm), the average daily loss was 177 gm. In a third period of 71 days (from July 12 to September 21, 1931) the calories, protein, sodium chloride and water were the same as those given in the second period. The loss in weight was from 106 to 93.6 kgm (12.4 kgm), the average loss each day was 175 gm. The daily average nitrogen balance from March 19 to April 20, 1931, was +0.5 gm (nitrogen of feces not determined and nitrogen intake calculated as 11.6 gm daily). From April 23 to May 4, 1931, the daily average nitrogen balance was -0.85 gm (nitrogen of feces and food determined). Creatinine determinations varied daily from 1.80 to 2.50 gm.

A maximal of 55 units of insulin was administered daily for 37 days (from March 8 to April 14, 1931) with total loss of weight of 2.9 kgm, the average loss each day being 78 gm. A maximal of 55 units of insulin was administered daily for 27 days (from May 30 to June 26, 1931), with total loss of weight of 4.5 kgm, the average loss each day being 167 gm. Glucose tolerance* before and after the administration of insulin (76 gm of glucose given in the morning) was as follows:

*Blood sugars by new Folin method

*Insulin given from May 30 to June 26, 1931, maximal daily dosage 55 units. No insulin was given before the glucose test meal, June 25, 1931.

From June 21 to June 23, 1931, was a period of extreme heat. Activity continued and the patient gained weight from 107.8 to 109.9 kgm. When in bed from June 24 to June 28, 1931 (four days), he lost weight from 109.9 to 106.3 kgm (3.6 kgm), the average loss each day was 900 gm.

Case 4 A girl, aged 19 years, was observed in hospital from July 5 to August 8, 1931. She was constitutionally obese, her height was 163 cm, and her weight 78.3 kgm, overweight 40 per cent. One sister was obese until she married when she became normal. Her mother formerly was obese, and two maternal cousins were overweight. There were no familial metabolic diseases other than obesity. Menstruation had occurred at the age of 15 years, and the flow was scanty and at intervals of two to three months. She had been overweight since infancy, reduction had been attempted at the age of 12 years and again at 16 years. She stated that she did not eat more than her associates. She had had mastoiditis at the age of seven years, measles at 14 years, epileptic attacks at 14 years, one attack when 15 years, then more frequently until treatment was instituted with phenobarbital, grains 3, daily. Headache or polyuria had not been present. She had received treatment with thyroid extract at the age of 17 years, at which age she also had pneumonia. She had never had encephalitis or injuries to her head.

The patient appeared to be intelligent. The fat was distributed symmetrically. The blood pressure was 106 systolic and 70 diastolic, erythrocytes numbered 4,600,000 and leukocytes, 9,000. The Wassermann reaction of the blood and the Kahn test were negative. The concentration of hemoglobin was 87 per cent. Urinalysis gave negative results. The glucose tolerance test (56 gm of glucose) revealed the following: fasting blood sugar, 0.054, after half an hour, 0.106, after one hour, 0.116, after two hours, 0.071, and after three hours, 0.070 gm. Tests of urine were negative for sugar. Roentgenograms revealed that the sella turcica was normal. The average basal metabolic rate was -16 per cent.

Studies of the metabolism extended from July 20 to August 12, 1931 (twenty-three

days). The diet consisted of 1,350 calories, protein, 74 gm (13 gm for each kilogram of standard weight), sodium chloride, 8 gm, and water, 1,500 cc. The weight lost was from 75.7 to 74.2 kgm (1.5 kgm), the average loss each day was 65 gm.

Case 5 A woman, aged 31 years, was observed from June 8 to July 11, 1931. She was constitutionally obese and was gaining weight, her height was 167.5 cm, and her weight 121.2 kg, overweight 92 per cent. Her parents and seven brothers and sisters were all of normal weight, one sister weighed 200 pounds. There were no familial metabolic diseases other than obesity. Menstruation began at the age of 13 years, and flow was always scanty. She was "stout" as a child, weighed 180 pounds at the age of 19 years, and 240 pounds at the age of 25 years in her first pregnancy. She had had rheumatism at the age of 27 years, and a relapse with mental disturbance (chorea?) for one year afterward with loss of weight of 100 pounds. She regained her weight of 260 pounds when in her second pregnancy, and weighed 268 pounds at the age of 30 years. The patient had had "acute articular rheumatism" in 1927, which confined her to bed for three months. This was followed by mental disturbances for one year. There was no intolerance to heat, no polyuria, or nocturia. Her appetite is excessive, she likes sweets, fats and pastries. She has never tried to restrict the intake of food.

The patient appeared to be of mediocre intelligence. A cystic adenoma of the thyroid gland, 5 cm in diameter, and varicose veins of the legs were present. The distribution of fat was uniform. The blood pressure was 124 systolic and 80 diastolic. The Wassermann reaction of the blood and Kahn tests gave negative results. The concentration of hemoglobin was 80 per cent, leukocytes numbered 7,200 and the erythrocytes 4,740,000. The average basal metabolic rate was -13 per cent.

Study of the metabolism extended from June 8 to June 16, 1931, with the patient up and about. She was permitted to select her food for five days, and the average daily consumption was 1,730 calories. She lost weight from 119.8 to 115.4 kg (4.4 kg).

She was readmitted to hospital from June 28 to July 11, 1931. Diet contained 4,000 calories (determined on the basal expenditure +100 per cent), and protein, 60 gm. She gained in weight from 117 to 118.4 kgm.

Case 6 A woman, aged 32 years, with anorexia nervosa, was observed from October 13, 1930, to June 18, 1931. Her height was 165.5 cm, and her weight 39.2 kgm, underweight 37 per cent. There were no familial metabolic or mental diseases. Menstruation began at the age of 13 years, and had been regular until two years ago, then irregular and scanty from October 1, 1930, to April 1, 1931, following which it had been regular. The patient had been married for nine years and had one healthy child. There had been no other pregnancies. The loss of weight occurred in the preceding three years. The weight had been 67 kgm. Her appetite was good, but she restricted the intake of food because of distress after eating, this led to a diagnosis elsewhere of mucous colitis. Constipation was marked, and had been treated unsuccessfully elsewhere by diet, irrigations of the colon and desiccated thyroid extract.

The patient appeared to be acutely ill and cachectic. The blood pressure was 100 systolic and 60 diastolic, leukocytes numbered 5,100 and erythrocytes 4,140,000. The concentration of hemoglobin was 82 per cent. Urinalysis gave negative results. The Wassermann reaction of the blood was negative. Roentgenograms of the thorax, gallbladder, stomach and colon were negative. Roentgenologic examination of the colon and ileocecal region gave no evidence of stasis. The basal metabolic rates in December, 1930, were -23 and -22 per cent. May 1, 1931, the basal metabolic rate was -14 per cent.

Study of the metabolism extended over a period of 89 days (from February 22 to May 22, 1931) with the patient ambulatory. The diet contained 400 gm fruits and vegetables, 66 gm protein, 225 gm fat, calories 3,290. The weight gained was from 39.2 to 57.6 kgm (18.4 kgm) an average daily gain of 207 gm. Two hundred seven grams of body fat represent 1,674 calories. The total intake of calories, 3,290, minus 1,674 gives 1,616 calories for total expenditure, 1,616

minus 1,110 (basal expenditure) equals 506 calories for work, or 46 per cent of the basal expenditure.

Case 7 A woman, aged 23 years, was observed from April 16 to May 4, 1931. She was constitutionally obese, her height was 154 cm and her weight 80 kgm, overweight 51 per cent. There was no familial history of obesity or other disease of metabolism. Menstruation had begun at the age of 13 years, and was regular until two years before observation, then the intervals lengthened, and the flow decreased to a scanty discharge for one day only. Her weight had been normal at the age of 20 years, and gain began when she was convalescing from a fractured leg, and progressed intermittently, the most rapid gain was made shortly before observation. The patient had occasional frontal headache, and was easily fatigued and nervous.

The patient appeared to be intelligent. The distribution of fat was uniform. The blood pressure was 102 systolic and 72 diastolic, leukocytes numbered 6,600, and erythrocytes, 4,560,000. The concentration of hemoglobin was 89 per cent. The Wassermann reaction of the blood and the Kahn test were negative. Roentgenograms of the sella turcica did not reveal any abnormalities. The average basal metabolic rate was -14 per cent.

SUMMARY AND CONCLUSIONS

1 The heat production following light and heavy exercise of obese subjects studied by us does not tend to drop below the basal level at any time during the two hours after exercise.

2 Three obese subjects, chosen for their "endogenous" characteristics were held under strict supervision in the metabolism division of the hospital for a period of 162 days. Their diets were arranged to provide a total of calories which would closely approximate their basal metabolism for 24 hours, with particular attention paid to satiety values and adequacy of vitamins, minerals and protein. Re-

duction in each instance proceeded at a rate which was anticipated from conventional calculation of the total metabolism involved

3 The rate of weight loss was seldom regular. Periods of several days frequently intervened when the weight remained stationary or even increased. One such period was 28 days. That these are to be accounted for by water retention is indicated by the influence of enforced rest in bed. An accelerated rate of loss invariably accompanied periods of rest in bed and corresponding retardation of weight loss was seen in periods of increased activity. The paradox is explained by relative circulatory insufficiency.

4 Insulin in doses of 20 units before each meal failed to alter significantly the rate of weight loss in one

case and was of doubtful influence in another.

5 The administering of insulin for periods of from 12 to 30 days was followed by temporary loss of tolerance for carbohydrate, so that responses to glucose tolerance tests were obtained typical of diabetes mellitus. The phenomenon is explained by diminished irritability of the rested pancreas, analogous to that observed after periods of carbohydrate starvation. Recovery of normal irritability is a matter of only two or three days.

6 Estimates of total metabolism, based on long periods of observation of weight loss of obese individuals on submaintenance diets, are in better agreement with clinical experience than the higher estimates of earlier students of metabolism.

The Depression and Public Health

“THE progress of public health is influenced by many factors, social, economic, and industrial as well as medical, sanitary, and biological. The adverse effects of unfavorable economic conditions on individual and community health have been demonstrated so frequently that a financial depression such as has been experienced by the United States would be expected to have deleterious results on national vitality.

“To date the anticipated has not occurred. The year 1931 was, in fact, apparently one of the most healthy in our history. Not only was there no undue prevalence of disease and no widespread occurrence of epidemics, but death rates were lower. The mortality from tuberculosis, a disease peculiarly involved in social and economic conditions, declined from 71 to 67 per 100,000 population, and infant mortality, one of the most sensitive indices of sanitary progress, continued to show a favorable trend.

“This auspicious health record during two years of depression should not, however, be permitted to lull us into a false sense of security. The results of malnutrition, improper housing, inadequate clothing, insufficient recreation, unhealthy mental and emotional reactions, and the curtailment of necessary health services are not reflected immediately in the state of the nation's health, but these conditions, which unquestionably exist today, cause a definite lowering of the vital resistance of the people and may make them a ready prey to disastrous epidemics, should they occur. An outbreak of influenza at the present time might prove devastating.

“Although the incidence of communicable and organic diseases has not yet appreciably increased, there seems to be a demonstrable increment in mental disorders. No general rise in mental cases of institutional severity has been reported, but mental hygienists believe and social surveys indicate real evidence of an increase in nervous disturbances and the milder mental diseases. Paroles in all mental hospitals have fallen off and there have been decided increases in the admissions to institutions for the feeble-minded. The depression is unquestionably engendering fears and anxieties that are undermining individual and family security and taxing the adaptive capacities of all classes of the population. These conditions tend to become accentuated as the depression continues. The suicide rate in 1931 was considerably higher than in the previous year.”

Insulin in Malnutrition

Further Observations¹

By ROY D. METZ, M.D., *Detroit, Michigan*

WHEN Banting and Best² made their outstanding contribution to scientific medicine and changed the diabetic patient of today to a living and not a dying diabetic, they little dreamed that the usage of insulin would invade the entire realm of medicine. It was about one year afterwards that Pitfield³ made successful use of insulin in infantile inanition. He noted that diabetic patients on insulin treatment often gained weight at a phenomenal rate even when the food intake was not excessive. Then Marriott⁴ reported uniformly good results in infantile athrepsia with the usage of insulin. Almost coincidentally, Barbour⁵ reported the successful administration of insulin subcutaneously in undernourished non-diabetic children. In 1925, Falta⁶ reported the non-diabetic usage of insulin in adults with uniform success. Since then, numerous publications have been presented dealing with the non-diabetic usage of insulin in various forms of malnutrition, both primary and secondary. While some of the authors are very conservative in their predictions, most of them have been more or less enthusiastic in regard to the possibilities

of insulin in undernourished non-diabetic patients. Frank and Wagner⁷ have published recently a monographic review of the German literature in reference to insulin so used. They have discussed its theoretical aspects more thoroughly, it seems, than have any other authors.

While most publications have been based upon observations in the hospital where close observation was possible, there seems to be no particular reason why insulin could not be utilized safely and efficiently by physicians in general practice. Jacobsen,⁸ for instance, feels that the administration of small doses of insulin with extra food in order to prevent shock is adapted for use in private practice without deleterious effects. Ceccarelli,⁹ too, advises the administration of insulin in emaciation and cites an especially favorable result in a patient with marked emaciation following cholecystitis with calculus. Toscano¹⁰ has reported excellent results with the use of insulin. He found that patients with malnutrition and without other evident disorders reacted most favorably and that the sense of well-being which resulted was frequently of greater importance than the increase in weight.

Favorable results from the use of

Received for publication, January 15 1932

insulin in the treatment of the malnutrition of children were reported even before its usage was considered seriously in adults. Careddu and Giua¹¹ reported that insulin brought about a regular and constant increase in weight with the formation of good subcutaneous tissue and improvement not only of the general condition but also of the resistance of the child. They also reported an increased intestinal tolerance for carbohydrates. Amici¹² has reported the beneficial effect of insulin in infantile athrepsia. He secured a notable increase in weight in a short time, with rapid improvement of the general condition. He comments particularly on its stimulative influence upon the appetite and upon general activity. Roi¹³ summarized his observations by stating that insulin stimulated glycogenesis and glycogenolysis, and brought about greater utilization of carbohydrate with consequent increased appetite, increased tissue turgor and the formation of a fat reserve. He also concluded that it acted favorably on catabolism especially in a state of acidosis, corrected possible dysfunction of the pancreas favoring the absorption of fat by the intestinal villi and stimulated the whole endocrine system.

If these favorable reports are true, we must no longer limit the use of insulin to the treatment of diabetes alone. We may look upon it as a biologic product unrestricted in its action to one system or organ in the body. Its influence apparently extends over the entire organism to a degree which we do not sufficiently understand or appreciate. While it seems to have been beneficial in the case of

many patients with malnutrition treated in the hospital, its usage in ambulatory patients has been inaugurated with fear and hesitancy. This may be due to the fact that there is a certain amount of novelty and mysticism associated with its usage in non-diabetic patients.

It appears that the primary indication for the utilization of insulin is the presence of malnutrition from almost any cause. It must be remembered that best results may be expected in patients without outward evidence of organic disease. The first item to be considered is the degree of anorexia present. This is important, because patients with a good appetite appear to react most favorably to small doses of insulin. It seems to render more efficient the absorption and utilization of carbohydrates, perhaps through pancreatic stimulation and increased intestinal peristalsis. In those patients with greater anorexia, larger doses seem to produce better results in direct proportion to the degree of anorexia. This seems to be caused by gastric hyperperistalsis, with its consequent hunger contractions. In such a condition, Short¹⁴ advises, it is important to have a diet rich in fats, for oftentimes such hunger is quickly allayed with relatively small quantities of carbohydrate.

Other items to be considered are the amount and frequency of the doses. There are two acceptable methods of treatment. The first, probably the best adapted for ambulatory patients, is the injection of one dose daily before the noon meal. This should be given approximately 20 minutes before eating in order to allow sufficient time for

absorption with consequent lowering of the blood-sugar preparatory to the new supply of carbohydrates. This method is more convenient and probably minimizes the possibility of an accumulative action of insulin.

It is usual to begin with doses of 5 or 10 units of insulin and to increase to 15 or 20 units according to the tolerance. It is not advisable to cause a hypoglycemia, although this may be easily and quickly checked by the administration of carbohydrate. It is preferable to maintain a high dosage and encourage the patient to ingest more than the usual amount of food. In any case, the dosage should be kept within the individual tolerance. While the sympathetico-suprarenal apparatus seems to liberate sufficient glucose from the liver-glycogen to take care of the ordinary hypoglycemic condition, even if no carbohydrate is ingested, the reaction may have an unfortunate psychic effect upon the patient.

The second method of treatment is to give two or more smaller doses each day. Ten units of insulin may be given before each of any two meals or before each of the three meals. If it should be given 20 minutes before the meal, there will be little or no danger of hypoglycemia. Nevertheless, carbohydrate should always be at hand for its psychic effect if for no other reason. This method causes greater inconvenience to the patient and has not proved as satisfactory as the administration of one larger dose each day. Of course circumstances alter cases, and each patient must be treated individually.

In either of the above procedures,

the physician should personally initiate the treatment in order to ascertain the tolerance and optimal dosage for the individual patient. When this is accomplished, he may teach the patient how to administer the insulin to himself, particularly emphasizing the necessity for accuracy of dosage, the necessity for cleansing the field of injection, and the importance of varying the sites of injections in order to avoid causing local fibrosis and atrophy of the subcutaneous fat.

The patient may then go about his work as usual, reporting to the physician at regular intervals for a check-up and for any instructions or changes deemed advisable. Although the patient may continue his work, the rate of gain in weight seems to depend greatly upon the energy expended at his work. It seems that the clerical patient reacts more satisfactorily than the one doing hard manual labor. No deleterious effects have been noted even when the therapy was continued over a long period of time. The length of the course depends upon the individual reaction to its usage and the speed with which the exogenous insulin causes an increased endogenous production of insulin to bring about a satisfactory weight or a progressively increasing weight, however small this may be.

There are three possible complications which must be ever present in the mind of the physician who administers insulin. The possibility of inducing hypoglycemia is of primary importance. This is first manifested by a sense of weakness and extreme fatigue. It usually occurs about two hours after the injection. If the pa-

tient is walking, he feels that he cannot progress a step further¹⁵ Restlessness begins and the hands tremble Perspiration follows with an intense sensation of hunger There is impaired visual acuity, and some patients may even complain of diplopia There may be vertigo, ataxia, nausea, vomiting, and epigastric distress Mental confusion may be shown by incoherent speech, irritability, or some irrational action The sequelae are those of stupor and coma No patient should be permitted to progress to this stage There should always be available carbohydrate, such as cubed sucrose or candy, for immediate ingestion This is particularly important when the patient leaves his usual source of carbohydrate for a walk, an automobile ride, or for some other reason By the ingestion of such carbohydrate, any hypoglycemia can be quickly and efficiently counteracted

The second complication is allergy¹⁶ In patients with allergic manifestations, such as urticaria, hay-fever, or asthma, insulin should be given with greater caution Crystalline insulin¹⁷ has been prepared and its chemical properties studied It seems extremely probable that insulin is a well defined protein and that its physiologic activity is a property of the insulin molecule itself or of some special group within the complex molecule Grishaw¹⁸ has recently reported allergic manifestations to insulin He cited a definite reaction in a diabetic patient Through experimentation with insulin from different sources and by different producers, he concluded that the insulin itself was not the causative agent in the allergic manifestation but that the

latter was due to some precipitable substance contained therein

Although the foreign protein in insulin has been reduced to a minimum by our modern efficient producers, it still contains some, and a local or general reaction may follow its use The local manifestation is usually an erythematous area at the site of the injection This may progress to a wheal or even to a general urticarial eruption with edema of the face, intense itching, and gastro-intestinal distress It usually appears about ten minutes after the injection and is relieved satisfactorily by calcium lactate orally Epinephrine may be used, but it is rarely necessary In the future, it is hoped that the animal source of the insulin will be marked on its container Then, should the patient be sensitive to beef protein, pork protein may be well tolerated, and vice versa Should there be a hypersensitivity to all of the usual sources of insulin, desensitization must be accomplished by a series of intradermal injections of insulin Jeanneret¹⁹ reported a patient so desensitized with no reaction after the seventeenth injection

The third complication to be borne in mind is the condition of the myocardium, particularly in angina pectoris and aortic insufficiency Experiments have shown that insulin diminishes the quantity and viscosity of the blood, with a decrease in the blood pressure The heart may enlarge to the left with an acceleration in its rate Transitory diastolic murmurs may even appear A routine cardiac examination requires so little time that it should be done in all cases Myo-

cardial contraindications will be found very infrequently. If a hypoglycemia is prevented, there is little need of fear in reference to the myocardium.

While the beneficial effects of insulin in malnutrition seem to be conceded and proved, we must still resort to theory, conjecture, and speculation in order to explain how its effects are produced. Falta²⁰ believed that insulin checks the elimination of sugar in the liver and promotes its absorption by muscles and other tissues. Depisch and Hasenohr²¹ advanced the counter-regulation theory against insulin. In this, the counterregulation promotes the elimination of glucose in the liver and checks its absorption in the tissues. They theorized that the assimilatory insulin system with its nervous regulation stands in the center of carbohydrate metabolism and therefore promotes the absorption of glucose in the liver and in the tissues. Against this, there is the action of the sympathetic nervous system and the secretion of the suprarenals, the posterior lobe of the hypophysis, and the thyroid gland in the liver, and the action of the secretions of the suprarenals and thyroid in the tissues. Their idea was not at all unlike the conception of Cannon²² in which he explained the antagonistic action of insulin and epinephrine.

Columba²³ has recently made an interesting observation. He obtained an insulin-like extract from obese and undernourished patients. Experimentally, he noted that this extract was less potent in the obese, and he felt that the decreased potency should be regarded as an expression of a latent state of functional insufficiency of the

pancreas, or diabetes mellitus. His observation thus strengthens the conception advanced by Fonseca²⁴ that there is a more or less direct relationship between obesity and diabetes.

Instead of looking upon malnutrition as a state of hypoinsulinism, it may be considered a state of hyper-suprarenalism. Such a condition would have a tendency to free the glycogen from the liver and muscles into the blood stream, where it could and would be readily oxidized. Under such circumstances, the exogenous insulin in insulin therapy would not only help to counteract the supply of epinephrine present but it would also stimulate the islands of Langerhans to greater activity so that a more normal and delicate balance would result between these antagonists with an approach to normal of the entire body economy. While an imbalance is probably present, it has not been determined whether it is due to the endocrine glands alone, to the autonomic nervous system alone, to a combination of both of these factors, or to some other cause. Hyman and Kessel²⁵ have taken a rather pessimistic attitude when they considered autonomic imbalance congenital and specific therapy not clinically available because we are ignorant of the chemical and hormonal factors which control the autonomic nervous system normally and stimulate it in emergency.

Although our knowledge of the relationship of the various endocrine glands to carbohydrate metabolism may be insufficient and attempts to evaluate disturbances in these mechanisms may be clinically somewhat difficult, there is at present adequate

reason to assume that all carbohydrate enters the blood stream as glucose. Here a variable portion is oxidized directly or indirectly into carbon dioxide and water, while the remaining portion is stored in the liver and musculature as glycogen.²⁶ Liver-glycogen may be reconverted into glucose and liberated into the blood stream as such through the action of epinephrine according to the demands of the organism. In the musculature, epinephrine causes the trembling or the contraction of muscles or groups of muscles, with the formation of lactic acid from muscle-glycogen. This acid²⁷ enters the blood stream and is reconverted into glycogen by the liver, from which it may be liberated as glucose. It would appear, therefore, that the tremors and convulsions of a hypoglycemia are protective mechanisms for the organism. The muscles may thus be looked upon as a reserve supply for glucose when too great a demand is being made upon the liver.

It may be concluded that insulin may be used advantageously in the non-diabetic patient. It extends its influence over the entire organism to a degree which we do not sufficiently understand or appreciate. It is probable that the gain in weight and the improved general well-being is due to more efficient absorption and utilization of carbohydrates, but we do not know how these are accomplished. While the optimal results are obtained in the hospital, the treatment appears adaptable for employment in private practice in ambulatory patients with average intelligence. In the ambulatory patient, the general effect of the treatment is similar to that upon the patient

treated in the hospital with reference to the increase in weight and the improved general well-being, but it is apparently less rapid and less satisfactory. A few case reports will illustrate the beneficial effect of insulin upon certain ambulatory patients.

CASE REPORTS

Case I A mechanic, aged 39 years, entered the Marine Hospital because of cough, weakness, and loss of weight. He appeared ill and was definitely undernourished and anemic. A diagnosis of pulmonary tuberculosis could not be confirmed. He was constantly having small superficial ulcers on the buccal mucous membrane. His condition was more or less stationary when insulin-treatment was inaugurated before the noon meal. The anemia began to improve, the ulcers healed, and the cough became less marked. He became stronger with an average gain in weight of over 3 pounds a week.

FIG 1 Weight curve in Case I

Case II A Canadian automobile mechanic, aged 37 years, entered the Marine Hospital because of abdominal discomfort and distress particularly after a bulky meal. He had had several surgical operations in the past eight years without marked relief. Physical examination revealed an unstable nervous system, malnutrition, and several postoperative ab-

dominal scars. He was much discouraged when insulin treatment was started. His general condition began to improve immediately. Even with unusually bulky meals, his abdomen became progressively more comfortable. He became stronger and his philosophy of life approached normal. He was at first given 20 units before the noon meal. Because of several mild reactions, the dosage was decreased to 15 units. He was transferred to another hospital before the treatment was completed "feeling the best that he had felt in 12 years." His average gain was $2\frac{1}{4}$ pounds a week.

FIG 2 Weight curve of Case II

Case III A hotel manager, aged 52 years, entered the Marine Hospital because of weakness. His illness began one month before with an attack of influenza from which he did not seem to recover. He tired easily, had no appetite, and had lost 12 pounds in weight. Physical examination revealed anemia and malnutrition. Pulmonary tuberculosis was suspected but not found. The first month of observation revealed little or no change in his general condition with an increase in weight of one pound. Treatment with insulin was begun. His weight began to increase. The red blood cells soon increased almost a million, with a proportional increase in the hemoglobin. He became stronger with

greater endurance and was particularly grateful for his improvement. His average gain was over two pounds a week.

FIG 3 Weight curve in Case III

Case IV A salesman, aged 38 years, entered the Marine Hospital with a hypertrophic arthritis of 12 years duration. It particularly involved both knees and the spine. He was treated with analgesics and various physiotherapeutic procedures. Because of underweight and flabby musculature, insulin treatment was begun. His strength increased and his muscles became larger and firmer. While the insulin had no direct effect upon his arthritis, the patient's general sense of well-being was the best that he had experienced since its onset. Three months after the treatment was discontinued, he was holding the increased weight. His average gain was almost two pounds a week.

FIG 4 Weight curve in Case IV

Carotinemia Associated with the Ingestion of Pumpkin

Report of a Case

By A C CURTIS, M D, F A C P, and E E KLEINSCHMIDT, M D,
Ann Arbor, Michigan

THE association of a yellow discoloration of certain areas of the skin with cases of diabetes mellitus was first brought to the attention of the scientific world by von Noorden in 1904. To this condition he gave the name xanthosis diabetica. Since then it has been variously designated as pseudoterceris,¹ hyperlipochromemia,² xanthemia,³ and carotinemia.⁴ This last term has been adopted by the majority of workers since Hess and Myers described the entity as a new clinical picture. Their work, and that of other investigators notably Palmer,⁵ has shown this condition to be associated with the ingestion of foods rich in carotin,* a yellow plant pigment. The especial retention of this pigment in the blood serum, epidermis, and sweat glands of certain diabetic and non-diabetic patients has attracted wide attention in the last decade.

The association of carotinemia with the ingestion of specific carotin bearing foods has been shown by Palmer,

Hess and Myers, Stannus,² Hashimoto,⁶ Boeck and Yater,³ Inlow⁷ and others. In the German literature Gragger⁸ has reported a single case of carotinemia associated with the eating of pumpkin. A search of the American literature, however, fails to reveal a single case report. Since the following case represents a carotinemia following the ingestion of large known amounts of pumpkin over a known period of time and its rapid disappearance on a carotin low diet, we thought it worthy of reporting.

REPORT OF CASE

Mr. D. T., aged 23, a student, was seen in the medical outpatient department as a return diabetic and tuberculous patient on April 22, 1931. The patient felt perfectly well but was somewhat apprehensive about a yellowish pigmentation of his skin which had developed within the last two months. This was the patient's third admission to the hospital.

The symptoms of diabetes mellitus were first noted in November, 1927. Diagnosis of this condition was made in September, 1928. A modified diet without insulin was ineffectual and he came to the University Hospital October 31, 1929 for treatment.

The diagnosis of diabetes mellitus was confirmed. Examination of his chest and his x-ray films showed a minimal border line tuberculosis. He was confined to the Tuberculous

From the Department of Internal Medicine, Medical School, University of Michigan. Received for publication, March 26, 1932.

*Carotin = carotene.

Unit where he was also stabilized on a diet of 55 grams of proteins, 220 grams of fats, and 65 grams of carbohydrates with 45 units of insulin. The insulin was slowly decreased, after four months on the diet, until it could be dispensed with entirely. The carbohydrate of the diet was then slowly increased but as he gained an excess of weight it was necessary to reduce his calories. On May 15, 1930, he was discharged on a diet of 55 grams of proteins, 166 grams of fats, and 130 grams of carbohydrates.

He returned on September 15, 1930. His weight had been maintained at 160 pounds during this entire period. X-ray examination of the chest showed definite improvement. He had remained aglycosuric during this entire period so no change was made in his diet. He was advised not to return to active work but to gradually increase his activity at home.

From September 14, 1930, until April 22, 1931, a period of seven months, he had substituted baked pumpkin to the extent of 600 grams daily for his five per cent vegetables. It is of interest to know that he had partaken also of two eggs daily during this same time. His appetite for these foods remained undiminished at the time of his last admission on April 22, 1931.

Examination A generalized yellow tint of the skin and mucous membranes was found which was more accentuated in certain areas. This pigmentation was light picric acid yellow in some areas and extreme orange in others. This latter condition was present most noticeably in the palms of the hands. The lighter yellow pigmentation was seen on the forehead, soles of his feet, soft palate, nasolabial folds, inferior surface of the tongue, conjunctivae, dorsal surface of the hands, and lastly, patchy areas in the mid-abdomen and midlumbar regions. This pigmentation was everywhere diffuse and appeared more reddish yellow than in icterus. There was no tinting of the sclerae. No associated discomfort was present. Two small pea-sized lymph glands were palpated on either side of the neck in the region of the postcervical chain. The chest and heart examination was negative. Blood pressure was 124/76. The examination otherwise was essentially negative.

Laboratory Observations The blood count and differential smear were normal. The blood Kahn test was negative. Blood sugar was 104 mgm per 100 c.c. of blood. Blood bilirubin was 3.2 mgm per 1000 c.c. of blood. The blood serum appeared a cloudy ochre color. The urine showed nothing abnormal. An x-ray film of the chest showed no change from that taken on September 14, 1930. The test for carotin was positive. Using the method of Van den Bergh, Muller and Brockmeyer,⁹ the amount of carotin present was found to be equivalent to the color produced by 132 mgm of potassium dichromate in 100 c.c. of water. According to White's recent article on the estimation of carotin in the blood,¹⁰ this would be the color equivalent to 1.65 mgm of carotin in 100 c.c. of petroleum ether. After this determination the patient was placed on a carotin low diet for one month. On his return the yellow pigmentation had entirely disappeared and his blood carotin had fallen to 0.075 mgm of carotin per 100 c.c. of serum.

COMMENT

Carotinemia has been found in cases of diabetes mellitus, nephritis, and in adults and children whose diet contained large amounts of carotin containing foods. It is not a rare condition as may be seen by a study of almost any of the recent reviews of the literature.¹¹ The case reported here is interesting because the carotinemia resulted from the ingestion of a known amount of carotin-rich food over a definite and long period of time in a patient whose diagnosis was known. It also represents an extreme case of carotinemia since White¹⁰ states that "our experience has shown that even the most pronounced cases of carotinemia have values which lie in the lower segment of the graph"—namely less than 0.750 milligrams of carotin per 100 c.c. of serum. Our case had more than twice that amount. Furth-

ermore, it demonstrates how quickly the blood carotin falls to a normal level after the patient had been placed on a carotin low diet. White¹⁰ has shown in 18 normal individuals that a blood carotin mean of 0.063 mgm per 100 c.c. of serum was present. Our figures, in 17 normal people, show a blood carotin mean of 0.106 mgm per 100 c.c. of serum. The case reported here returned approximately to this level in one month.

SUMMARY

1 A case of carotinemia associated with the ingestion of pumpkin is presented.

2 The areas pigmented were the palms of the hands, soles of the feet, forehead, nasolabial folds, lips, soft palate, inferior surface of the tongue, conjunctivae, abdomen and lumbar regions.

3 The case is illustrative of the extent to which carotinemia can develop due to the ingestion of a food rich in carotin content over a period of seven months.

4 The blood carotin content at the height of the carotinemia was found to be 1.65 mgm per 100 c.c. of serum and one month later with a carotin low diet it was 0.075 mgm per 100 c.c. of serum.

A Comparison of Blood Pressure in Men and Women

A Statistical Study of 5,540 Individuals

By MACNIDER WETHERBY, M D, *Minneapolis, Minnesota*

A STUDY has been made of the routine blood pressure reading of all individuals admitted to the medical division of the out-patient department of the University of Minnesota Hospital. These records cover the three year period from December, 1926, to December, 1929. There are in this series 5,540 individuals, 3,258 women and 2,282 men. The readings have been classified by decades for systolic and diastolic pressures, and a comparative study has been made of blood pressures in men and women.

LIFE INSURANCE STATISTICS

There have been a number of statistical studies of blood pressure. The larger groups have been in accepted life insurance risks such as those of Goepp,¹ MacKenzie,² Fisher,³ Hunter,⁴ and Symonds.⁵ For the most part this material consists of men under 50 years of age.

The two largest series of cases are those of Hunter⁴ and of Symonds,⁵ and these show very much the same

averages of systolic pressures for the corresponding age groups. Hunter's series represents about a quarter of a million individuals, and Symonds has a group of 150,419 men and 11,937 women. Symonds noted that under 40 years of age, the systolic pressure of women is one or two mm Hg less than that of men, and that after 49 years of age it equals or exceeds that of men by one or two mm Hg. Adams⁶ cited figures of G. W. Exton, director of laboratories and longevity service of the Prudential Life Insurance Company. He has submitted a record of 5,727 blood pressure readings from accepted and rejected risks in men and women. Unfortunately, average pressures for sex and age group are not given but the percentage of systolic pressures exceeding 150 mm Hg and of diastolic pressures exceeding 100 mm Hg are given. This shows a marked relative increased incidence in the occurrence of systolic and diastolic pressures at higher levels in women over thirty years of age.

Life insurance tables are of great practical value to their respective companies. These are largely made up of accepted risks, and represent much the same figures as our clinical tables of

From the Department of Medicine and the University Hospital, University of Minnesota, Minneapolis, Minnesota.

Received for publication December 22, 1931.

averages, if we eliminate nearly all readings of 150 mm Hg and over. Even in those tables including rejected risks, it must be remembered that presumably healthy individuals apply for life insurance. The financial factor also brings some errors into insurance figures.

BLOOD PRESSURE IN CHILDREN

Blood pressure studies in children up to 17 years of age have been made by Judson and Nicholson,⁷ and Faber and James.⁸ They have found the average blood pressure by age groups to be about the same for boys and girls.

BLOOD PRESSURE IN COLLEGE STUDENTS

There have been rather extensive studies of young college students as in Alvarez's^{9, 10} series of University of California freshmen and in the series of Diehl and Sutherland¹¹ at the University of Minnesota. From both sources it seems evident that the average systolic pressure in men from 17 to 30 years of age is higher than for women of similar age. Alvarez recorded as high as 22 per cent of the young men with a systolic pressure exceeding 140 mm Hg and only 2 per cent of the young women exceeding that pressure. These were single readings, and with the men were taken after a shower bath. Diehl and Sutherland¹¹ found 16 per cent of the men examined in 1922 to have a systolic pressure exceeding 140 mm; but on taking precautions to eliminate nervousness and excitement they found 9 per cent over 140 mm in their 1923 and 1924 groups. On reexamination

they found only 1.6 per cent of the total group with a persistent pressure of 140 mm Hg or more. The significance of a transient elevation of blood pressure in young men has not been determined. Diehl¹² has since studied systolic blood pressure in 976 young women in whom he has found a mean pressure of 116.70 mm Hg as compared with a mean of 122.7 in the young men. In the young women 7 per cent exceeded 140 mm Hg as compared with 9 per cent of the young men.

BLOOD PRESSURE IN MEN AND WOMEN

A comprehensive study of blood pressure has been made by Saller¹³ in a group of over 4,000 individuals examined at the Universitäts Klinik at Kiel. In his group there are 2,468 men and 1,743 women, ranging in age from 3 to 89 years. He has shown that the average systolic pressure tends to be slightly higher in men than women under 36 years of age. In all age groups beyond 36 years there is a marked increase in the systolic pressure of women as compared with men. As an example it is noted that in the men from 51 to 56 years of age the average systolic pressure is between 126 and 127 mm Hg, while for the women of the same age group the average systolic pressure is 148 mm Hg. Similarly there is noted a greater range of variability in the pressures of the women as compared with those of the men in similar age groups over 36 years of age. He has also shown a tendency for the average diastolic blood pressure of women to exceed that of the men. In the groups over 50 years

of age diastolic pressure is about 10 mm higher in the women than in the men of similar age groups

Gelman¹⁴ has presented a study of blood pressure in 3,761 individuals. This group was largely composed of presumably normal working people, 2,641 men and 1,120 women. In his series he found more men than women with systolic pressures exceeding 141 mm, however, there were very few individuals over 50 years of age in his series. There were only 35 women over that age. Under 30 years he found many more men than women with pressure exceeding 141 mm. In his group from 30 to 39 years of age, he found 11 per cent of the women and 6 per cent of the men with systolic pressures exceeding that figure. In his group from 40 to 49 years he found 19 per cent of the women and 15 per cent of the men with systolic pressures exceeding 141 mm. Gelman¹⁴ classified blood pressure in relation to age and occupation and showed strikingly increased incidence in the percentage of hard laborers showing systolic pressures exceeding 141 mm, and this was particularly true of the foundry workers.

Alvarez⁹ has recorded systolic blood pressure readings in 1,000 office patients showing pressures in the men higher than women under 40 years of age, and definitely higher in the women after 40 years of age.

Gager¹² has recorded pressures in 2,000 consecutive individuals seen at the Cornell Clinic. These consisted of 1,000 men and 1,000 women. In individuals under 30 years of age he found more men than women with systolic pressures of 140 mm or greater. In

the group from 30 to 39 he found the incidence much the same. In the groups from 40 to 59 years of age he found a markedly increased incidence of women over men with pressures of 150 mm and greater. In the groups of sixty years and over he found about the same incidence, however, the number of individuals in the latter groups was not sufficient to allow for error. In considering diastolic blood pressure Gager found that the sex-age distribution of individuals exceeding 90 mm was relatively much the same as for systolic pressure.

Riseman and Weiss¹⁶ recorded the incidence with which the diagnosis of hypertension was made in the wards and the medical out-patient department of the Boston City Hospital. The blood pressure readings were found to be 160 mm Hg or over in 91.6 per cent of the out-patient group on whom the diagnosis was made. In the group of ward patients 95.3 per cent had a systolic pressure of 160 mm or greater. It is of interest that in a group of 28,906 out-patients a diagnosis of hypertension was made in 1,620 instances and that on a basis of corrected sex incidence 29.5 per cent of the patients were men and 70.5 per cent of the patients were women. This relative incidence was about the same in a group of hospital patients.

BLOOD PRESSURE IN OLDER INDIVIDUALS

Wildt¹⁷ has reported the blood pressure readings of 248 chronic hospital patients ranging from 60 to 89 years of age. There was a definite trend for the average systolic and diastolic pres-

tures of the women to be greater than those of the men under 80 years of age. From 80 to 89 years, it was about the same in the small group of 14 individuals. He also showed a tendency for the average blood pressure to increase with advancing age prior to 90 years. Four individuals over 90 years of age showed a marked drop in the average systolic and diastolic pressures.

Bowes¹⁸ has recorded pressures in a group of 150 individuals from 65 to 95 years of age. He, too, showed a definite increase in the average systolic pressure of the women as compared with the men and as in Wildt's group showed a drop in the pressure of seven individuals over 90 years of age.

Richter¹⁹ in a study of blood pressure of 165 individuals from 60 to 89 years of age found 83 with a systolic pressure of 150 mm Hg or over.

Davis²⁰ has reported blood pressure in 50 white males over 75 years of age at the Johns Hopkins Hospital and has cited records of 102 white men over 75 years from the Royal Hospital, Chelsea. The systolic averages are about the same. Fifty per cent of the Hopkins group have a pressure exceeding 150 mm, with a mean systolic pressure of 158.3 ± 3.2 mm.

UNIVERSITY OF MINNESOTA OUT-PATIENT RECORDS

The patients admitted to the outpatient department are largely from the lower and lower middle classes. All individuals are interviewed as to financial eligibility before admission.

The charges are nominal and in some cases no charge whatever is made. The patients are from both the city and country and are largely laborers, farmers, housewives, and working women. Many had no medical complaint but were examined as a routine procedure. These patients are ambulant and many have minor complaints or have physical examinations as a routine procedure preliminary to tonsillectomy or hospital employment. A very small percentage come in because of symptoms suggesting hypertension. All patients admitted to the medical clinic were included and routine blood pressures taken as a part of each patient's study. The only cases excluded from the list were the clearcut cases of glomerulonephritis and aortic insufficiency. It has been interesting to notice the infrequency with which a diagnosis of true nephritis has been made. Consideration has not been given to obesity, although it is well recognized that the overweight individuals tend to have a higher pressure.

TECHNIC EMPLOYED

The blood pressure in all instances was taken with mercury manometers and by the auscultatory method. The diastolic pressure has been considered as the fourth phase. Most of the readings were taken in the sitting position. Patients had been sitting from thirty minutes to two hours prior to the examination and the blood pressure was taken after the history and near the end of the examination. In this way the factor of physical exertion was eliminated and the element of excitement reduced to a minimum.

STATISTICAL ANALYSIS

An analysis has been made of the blood pressures of 5,540 individuals, 2,282 men and 3,258 women. These have been considered in two groups, the total group and a group consisting of systolic pressures of 150 mm and over, and diastolic pressures of 100 mm and over. There are certain tendencies to error in any consideration of average blood pressure. One is the frequency with which readings are made on the divisions of ten and another is that manometer scales are marked off at two millimeter intervals.

(a) The means are arithmetic averages based on 5 mm groupings of blood pressure.

(b) The standard deviations of the distribution are the root mean square deviations of these groups about the mean.

(c) The probable error of the mean is the standard deviation divided by the square root of the number of cases.

(d) The probable error of the standard deviation is the standard deviation of the distribution divided by the square root of twice the number of cases.

(e) The coefficient of variation represents the standard deviation of the distribution expressed in percentage of the mean.

(f) The probable error of a difference is the square root of the sum of the squares of the probable errors of the constants between which the difference is taken.

(g) A difference is regarded as significant if its ratio to its probable error is three or more.

(h) A measure of difference is given by Pearson's χ^2 test (Pearson, Karl, on the test of Goodness of Fit, *Biometrika*, 1922-23, xiv, 186).

(i) P gives the probability that a given χ^2 would occur in a normal variation of one sample.

Figures 1 and 2 show for the men and for the women separately the frequency distribution of systolic blood

pressure in percentage of their respective age groups. The charts have been constructed by grouping the readings in intervals of 5 mm Hg. The charts further show a practically symmetrical distribution of the readings within the three lowest age groups, as contrasted with a skewness of the material in the fourth and fifth groups and with a more diffuse spread of readings within the sixth and seventh groups.

Table I shows the mean values, standard deviations and coefficients of variability of the systolic pressure for the entire material, arranged according to sex and according to age, the latter expressed in decades (except for the age group 15 to 19). Both for men and for women there is a steady rise of the mean pressure from one age group to the other. From the ages of 15 to 39 the rise is slight. In the fifth decade (40 to 49) there is for the women a sudden rise of 14 mm, being just twice the rise in the preceding decade. This rise brings the women 12 mm above the men, a difference which is not only maintained but slightly increased during the following decades. A sudden rise corresponding to the one just described occurs, to be sure, among the men; but one decade later than in the women. During this decade, the sixth, the mean pressure for the women has again risen. Thus, as was just stated, the mean pressure of the men never catches up with that of the women.

This, in a way, is the main finding brought out in the present study, and the following discussion serves further to elucidate this point. Attention is called to the fact that as this sudden break in the blood pressure curve

takes place, in the fifth decade for the women and in the sixth for the men, it is not only the mathematical mean that changes, but also the standard deviation and particularly the coefficient of variability, the latter becoming twice what it was in the first age groups. The coefficients of variability

whether this difference is significant or not. Such testing is also necessary for the larger differences already discussed. Applying the commonly accepted requirement that the ratio between the difference of the means and the probable error of the difference shall not be less than 3, it becomes

FIG 1 Percentage frequency distribution of systolic blood pressure by 5 mm groups for men

both for men and for women already show a definite rise in the decade preceding that characterized by the sudden rise in mean systolic pressure. It also is shown in table I that in the age group 30 to 39 the mean pressure for the women is already slightly

higher than the corresponding figure for the men, 2.88 mm. to be exact. Without a mathematical test it is impossible to have any opinion as to whether this difference is significant or not. Such testing is also necessary for the larger differences previously discussed. Applying the commonly accepted requirement that the ratio between the difference of the means and the probable error of the difference shall not be less than 3, it becomes

(the ratios for the age groups 40 to 49 and 50 to 59 being 12.05 and 11.24 respectively), and second, that even the small elevation of the mean pressure for the women between 30 to 39 above the corresponding mean for the men is of mathematical significance (the ratio being 4.64)

In order better to understand the meaning and significance of the

changes in the mean pressure in men and women, a brief discussion seems useful before the presentation of any further tables. As previously stated cause of the gradual elevation of the mean pressures. There is first the possibility that the pressure rises slightly in the population as a whole, further, it might be that the elevations of the means are caused by a certain

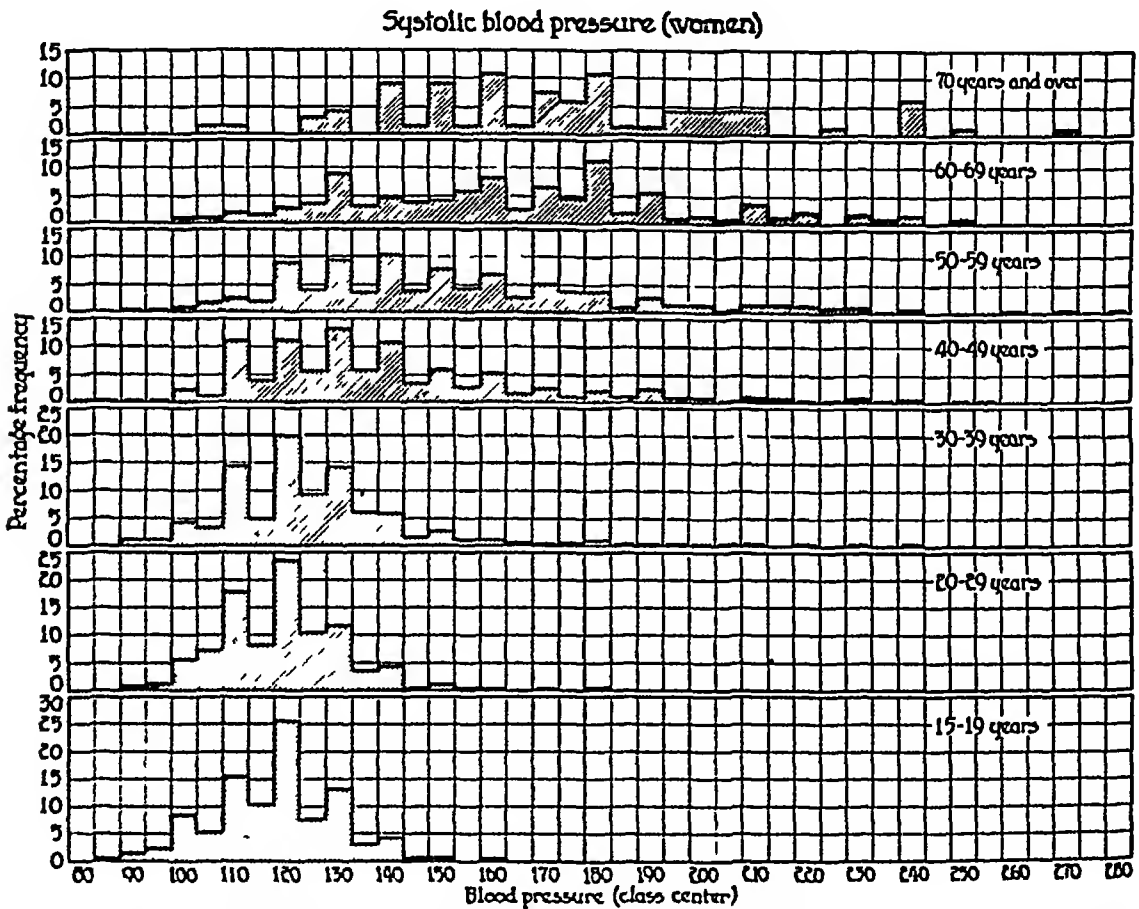

FIG. 2 Percentage frequency distribution of systolic blood pressure by 5 mm groups for women

the material under analysis consists of a practically unselected out-patient population, derived from both city and rural districts—only instances of aortic insufficiency and definite chronic glomerulonephritis having been eliminated. One might conceive of two different phenomena as the possible

number of definite hypertension mixed in with a large group of normal people, possessing pressures the same as in the groups below 30 for the women or below 40 for the men. Table VI shows that a noticeable number of cases of moderate elevation of blood pressure start to appear 10

TABLE I
Systolic Blood Pressure in the Total Material

years earlier among the women than among the men (30 to 39 group for women vs 40 to 49 group for men). This incidence of rather moderate elevation of systolic pressure increases rapidly among the women but more slowly among the men, as seen in table VI. Thus in regard to frequency of elevated systolic pressure, the women in the age group 40 to 49 are as badly off as the men 20 years later. This is well brought out for pressures above 150 and above 160 mm Hg.

A test of significance is made for the relative incidence of systolic pressures in men and women exceeding 150 mm Hg (table VII). Pearson's χ^2 test (h) gives a measure of difference which is interpreted directly on a probability scale. P (i) measures the chance that a given difference would occur in a normal variation. Thus in table VII $P = 0.8$ corresponding to a $\chi^2 = 0.1432$ in the 15 to 19 age groups for systolic pressure, meaning that there are eight chances in

ten that men and women in the given sample are not differentiated with respect to incidence of systolic blood pressure over 150 mm or that there are two chances in ten that they are so differentiated. The P's (table VII) indicate a small probability of sex difference for individuals under 30 years of age for systolic pressure. For the age groups over 30 years the probabilities are indicative that women have a significantly greater incidence of systolic pressure exceeding 150 mm.

Whether the elevated systolic pressures among women are of greater degree than among men is tested in table II which includes all individuals with a pressure of 150 mm Hg or more. If the means for the women are compared with the means for men age group for age group, and the differences tested as to significance in the usual way, no significant difference between these two sets of figures is found to exist.

Table III shows the mean values

standard deviations, and coefficients of variability of the diastolic pressure for the entire material arranged according to sex and age as in the systolic groups (See also figures 3 and 4) The diastolic pressure being of lesser magnitude fails to show as striking difference as the systolic. There is, however, a steady rise in the mean pressure by decades for both men and women. The pressures are about the

same in men and women until the fifth decade (40 to 49). At this point the women show abrupt rise, their mean pressure exceeding that of the men by 4 mm. In the sixth decade the men show similar elevation of the mean diastolic pressure. There is a continued rise for the women so that the mean diastolic pressure for the women is higher than for the men in all decades of life over 40 years. The

standard deviations and the coefficients of variability rise the same as for systolic pressure. The difference between the means for the women and the men are statistically significant in all age groups over 40 years, as shown in table V. The significance is definite though of lesser magnitude than for the systolic pressures.

Prior to 40 years of age about the same percentage of men and women

have diastolic pressures exceeding 90 and 100 mm (as shown in table VI). After 40 years there is a higher percentage of women than men with such pressures, the percentage of diastolic pressures at higher levels being about the same for the women as for the men one decade older. Pearson's test of significance (table VII) has been applied to the comparative incidence of diastolic pressures for men and

women exceeding 100 mm For the age groups higher than forty years the P's indicate a definite probability that the women have a significantly higher percentage of diastolic pressures exceeding 100 mm Hg

For individuals with diastolic pressures in excess of 100 mm the mean pressures are about the same for corresponding age groups of men and women (table IV) There are no significant differences (table V)

DISCUSSION

The preceding analysis is undoubtedly on a somewhat selected group of individuals as it includes all those admitted to our medical out-patient division Some subsequent studies have convinced me that the incidence of higher pressures is somewhat higher than that of the population as a whole The sex comparison however seems to be on an unselected basis

The analysis has revealed that

women exhibit an elevated systolic blood pressure more frequently than men, that this difference is noticeable already in the age group 30 to 39 and becomes more marked in the following decade, during which as many instances of elevated blood pressure are to be found among the women as one finds among the men who are 20 years older Among the individuals who show a systolic pressure of 150 mm Hg or thereabove, men and women do not seem to differ in any significant way as to the degree of the elevation of the pressure

We must remember that this is a statistical study of blood pressure and not a clinical study of hypertension consequently no record of the incidence of concomitant signs of hypertension (enlargement of the heart, retinal arteriosclerosis, etc) among the individuals exhibiting a pressure of 150 mm or more, has been worked up for inclusion in this paper Neither has

the constancy of the elevation of the blood pressure been studied in detail Caution must therefore be taken in discussing to what extent the difference between men and women, so clearly brought out by the analysis, represents a preponderance of chronic hypertension or only a greater lability of the systolic pressure among women That the labile character of normal and abnormal blood pressures alike constitutes the chief limitation of the significance of single as well as of serial blood pressure readings is by now well recognized and has been emphasized by O'Hare,²¹ Mosenthal,²² Kylin,²³ Ayman²⁴ and others If a greater blood pressure lability among women is the explanation for the difference brought out in this study, then it becomes necessary to introduce a new assumption, namely, the development of such an increased lability among women above the age of 29, since no trace of such a sex difference can be noticed in the two age groups below 30, where not only the mean pressure but also the standard deviations are the same for both sexes The writer does indeed hesitate to introduce such a new concept

There exist certain indications that chronic hypertension in its course and outcome behaves as a milder disease among women than among men In the out-patient service of the University Hospital where there is little difference between the number of men and women above the age of 50, there are a number of women with marked elevation of pressures, but very few men who have been followed over a period of several years Blackford, Bowers, and Baker, in a follow-up

study of patients with systolic pressures of 175 mm Hg or more found 65 per cent to be women, while their general group did not show any such sex preponderance. Their patients were followed from five and a half to eleven years and showed during this time a mortality of 70 per cent for men and 39 per cent for the women. The average length of life, after the diagnosis had been made, was longer for the women than for the men. Riesman²⁶ likewise comments upon the relatively benign nature of hypertension in women.

Applying these facts to our problem, a more benign course of hypertension among women would account for a greater accumulation of high blood pressures among women of more advanced age, probably starting at about 50 years, than among men. And such are indeed our figures (table VI). This explanation is not applicable for the most surprising result of our analysis, the early appearance of elevated pressures in the women between 30 and 39, neither is it applicable for the great difference in the age between 40 and 49, where out of the men there were only 12 per cent with pressure above 150 mm versus 41 per

cent among the women. There exists no mortality from hypertension or its sequelae among men of this age such as to produce this sex difference among the surviving.

It is a matter of importance to correlate with the findings of this study the results obtained from autopsies. We are fortunate to be able to compare with our blood pressure studies the detailed report by Bell and Clawson,²⁷ based upon a large autopsy material from the same community as our patients. Bell and Clawson used hypertrophy of the heart (in the absence of valvular lesions or chronic glomerulonephritis) as the chief diagnostic sign. (For details see original article.) Thus it is clear that only such elevated blood pressures as were sustained over a sufficiently long time and at a sufficiently high level to produce a marked hypertrophy of the heart, were included in the study of Bell and Clawson. In their total material of 4,578 autopsies on individuals between 21 and 80 years of age they found 420 cases of chronic hypertension. Among these they found the corrected ratio of men to women to be 14:1. For the whole hypertension group the causes of death are

given as follows myocardial failure, 45 per cent, cerebral accident, 19 per cent, coronary sclerosis, 16 per cent, renal failure, 9 per cent, miscellaneous, 11 per cent. In the group of coronary sclerosis the ratio of men to women was as 27 1. Eliminating the cases of coronary sclerosis, the ratio for the remainder becomes 11 1. In the study of Bell and Clawson about 15 per cent of the individuals who died at an age above 50 were afflicted with hypertension.

On the basis of the previous discussion it seems justifiable to state that elevated blood pressures are found both earlier in life and with greater frequency among women than among men. From the type of the curves and character of the tables presented there seems to be no support for any correlation of elevation of blood pressure in women with the phenomenon of menopause. It further seems obvious that there exists a rather large number of individuals with pressures temporarily or permanently in excess of average levels, who do not develop significant clinical or pathological sequelae from such pressures. There are probably a larger number of women than of men with such benign pressures at high levels.

Practically all discussions of normal systolic blood pressure in men have been carried on with the hope of being able to draw a definite line of distinction between normal pressure and an early pathological hypertension. The hope of being able to distinguish once and for all between a normal pressure and an early hypertension is a futile one. When cases of higher pressures start to accumulate in num-

ber as in the group of women between 40 and 49 for instance, they become significant in a different way, now they form to a great extent the lower pressures among a group of hypertensions as indicated in an indirect way by the enormous increase of the standard deviation of the mean for this group, and it is statistically impossible to determine the upper limit of a normal pressure for this age. We are at a loss, because there is no rule for a selection of our normal material, the needed dividing line being at the same time what we search for, and what we need to apply in order to find that for which we search. For practical purposes the way out of this dilemma is the one followed by the actuaries of the life insurance companies, the determination of the pressure above which the death rate rises above the rate known to hold for the same age groups without elevation of blood pressure. In this connection it is of interest that Fisher²⁸ found a normal mortality rate in 2,610 men from 40 to 60 years of age with an average systolic pressure of 142 mm. Fisher,²⁸ Rogers and Hunter,²⁹ and Frost³⁰ have shown an extra mortality in individuals with systolic pressure 10 to 15 mm above the insurance averages. They also show a marked progressive increase in extra mortality with each group showing further elevation of systolic pressure. Such averages, however, do not furnish a sharp dividing line between normal and abnormal blood pressure, but merely a line above which the pressure is more apt to be associated with significant organic changes.

CONCLUSIONS

1 The statistical analysis shows an increase in mean value of systolic and diastolic blood pressure with age, the most marked rise occurring a decade earlier for women than for men. The relative variation increases over the age period but has a tendency to rise abruptly and remain relatively constant between rises. These rises also occur one decade earlier for women than for men.

2 The absolute variation is greater for women than for men. There is a statistically significant difference in mean value for men and women after 30 to 40 years of age.

3 A statistically significant difference is also shown in incidence of blood pressure of higher groups for women in comparison with men. The

averages for men and women in the higher groups do not show a significant difference.

4 The clinical significance of blood pressure of equal degree must be considered independently in men and women. A given elevated blood pressure is more apt to be benign in nature and if of pathological consequence to run a longer course in women than in men. Hypertension as a cause of death is as frequent in men as in women even though the incidence of blood pressure at higher levels is significantly greater in women. In the older age groups this difference is partially explained by the shorter course of the condition in men.

(The author wishes to express to Miss Marie M. Ness his appreciation of her invaluable aid in the statistical analysis.)

The Action of Benzol, Roentgen-Rays and Radium On the Blood and Blood-Forming Organs

By EDWIN E OSGOOD, M D , *Portland, Oregon*

THIS paper is based on a review of over 1200 articles. This review, made in collaboration with Dr Laurence Selling, is to be published in "The Handbook of Morphological Hematology", P B Hoeber, Inc, and may be consulted for bibliography and detailed observations. Only the more clinically significant inductions with some suggestions for therapy derived from these inductions will be presented here.

It is well known that benzene, ar-sphenamines, radio-active substances, and roentgen-rays will, under certain conditions, produce the clinical picture of aplastic anemia. The other hematologic syndromes which may be produced are less well known. These syndromes include agranulocytosis, thrombopenic purpura, erythrophthisis, or any combination of these, and even anemia of regenerative type, leucocytosis, thrombocytosis, or polycythemia occasionally occur.

Under the term "benzol" are included a variety of mixtures of benzene (C_6H_6) and related compounds, but the chief action has been definitely

shown to be due to benzene, itself. The description of the action of the pure substance, therefore, applies to mixtures containing it as well. It is a volatile liquid with a boiling point of $80.3^{\circ} C$ and is used extensively in industry as a solvent, particularly for rubber. It is absorbed from the skin, the subcutaneous tissues, the gastrointestinal tract, and the lungs.

The effects produced vary with the dosage and individual susceptibility. Large doses produce acute poisoning with symptoms of cerebral irritation, followed by convulsions, coma, and death, or recovery within a few hours. Visceral hemorrhages occur but no marked hematologic changes have been reported. A somewhat smaller continued dose results in the development of the clinical and hematologic picture of agranulocytosis, purpura hemorrhagica, or both, after an interval of two or more days and death usually within twenty days, but the bone marrow shows complete or almost complete aplasia, although anemia is slight or absent. As the dosage is further decreased, the interval to the development of symptoms increases and the picture resulting may be that of erythrophthisis, agranulocytosis, or purpura hemorrhagica alone or in any

Read before the San Francisco Meeting of the American College of Physicians, April 8, 1932. From the University of Oregon Medical School.

combination, the marrow picture corresponding to that one would expect from the blood findings. Very small doses result in evidence of increased cell formation, such as the appearance of immature neutrophils and reticulocytes in the blood, leucocytosis, thrombocytosis and polycythemia, together with marrow hyperplasia. Even the development of leukemia or pernicious anemia has been reported but is not well substantiated.

The factors responsible for the great individual variations in susceptibility are largely unknown, but, in general, women are more susceptible than men and men more susceptible than the lower animals. Aplastic pictures are reported more commonly in man and agranulocytic pictures in animals, but this would seem to depend in part, if not largely, on the dosage. Hematologic changes may progress or develop as long as a month after exposure has ceased. The action is chiefly on the bone marrow and to a less extent on the lymphatic tissues. Opinions differ as to whether direct damage occurs to the cells in the circulating blood, if such damage does occur, it is certainly slight.

Industrial poisoning is not uncommon. Serious poisoning can be prevented by periodic hematologic studies, elimination of the more susceptible individuals, and reduction of exposure to a minimum by local ventilation and use of less toxic substitutes. The use of benzene in the treatment of leukemia is successful in producing reduction in the white blood cells and in retarding tumor growth, but its use is being questioned because of the possibility of producing aplastic anemia

or too great a fall in the white cell count, and because of the superiority in the clinical results obtained from the use of roentgen-rays and radioactive substances.

Drugs of the arsphenamine group, which contain the benzene ring, are known to have produced all of the above described findings; but the results in a given case apparently depend almost entirely on individual susceptibility rather than on the size and number of the doses. Hematologic changes resulting from therapeutic dosage are rare, difficult to anticipate, but likely to be serious.

The external application of radioactive substances and roentgen-rays will be discussed together, since the effects are produced almost entirely by the action of gamma rays. The tissue involved depends on the penetrative power, distance, filtration, and area exposed, and the effect on this tissue depends on the quantity of energy absorbed by it. When the penetration is sufficient to reach the bone marrow and the entire body is exposed, all the effects described for benzene may be produced, but lymphatic tissues and tissues unrelated to the hematopoietic system are much more severely damaged than by benzene, while complete aplasia of the marrow is more difficult to produce. The circulating lymphocytes show a correspondingly greater alteration. Local application of gamma rays gives a similar pathologic picture in the area exposed, but the compensatory response in the unexposed tissue alters the hematologic picture. For some unexplained reason, exposing the spleen alone may hasten coagulation, decrease the total white cell count, or

increase the platelets. True aplastic anemia rarely, if ever, results from therapeutic or occupational exposure to roentgen-rays if even minimum modern precautions are observed, but radio-active substances are somewhat more dangerous because of the greater penetration of the rays.

Gamma rays have been used in the treatment of almost all diseases of the blood and blood-forming organs. Such treatment gives very striking reduction of lymphatic tumors, such as enlarged thymus, Hodgkin's disease, lymphosarcoma and lymphatic leukemia. Lymphatic enlargements due to infection may also be decreased in size. It is debatable whether the length of life has been increased in Hodgkin's disease, lymphosarcoma and chronic leukemia, but it seems certain that the length of useful and comfortable life has been prolonged. Gamma rays seem valueless or contraindicated in acute leukemias. The clinical improvement in leukemias bears no direct relation to the fall in white blood cells. In myelogenous leukemia, opinion is divided as to whether therapy should be directed chiefly to the spleen or to the bone marrow. All are agreed that therapy should be stopped soon enough to avoid the development of a leucopenia. Gamma ray therapy is one of the most effective methods of reducing the red cell count and producing symptomatic relief in polycythemia. Small doses of gamma rays to the marrow have been reported to give favorable results in agranulocytosis but certainly an agent which is known to be capable of producing this syndrome should be used with caution. Gamma ray therapy to the spleen

sometimes causes cessation of gynecologic bleeding or the hemorrhages of purpura hemorrhagica but is not the method of choice.

The effects of radio-active substances internally depend almost entirely on the alpha rays. They are most marked on the bones and marrow because these substances show elective localization in the bones and the alpha rays have extremely slight penetrative power but tremendous destructive energy. The duration of action depends on the rate of disintegration of the particular radio-active substance. All forms with half-disintegration periods of more than a few days are extremely dangerous and should not be used internally. The dosage producing symptoms is extremely minute, a few micrograms having caused death and the interval between exposure and the onset of symptoms may be several years. Any of the syndromes described for benzene may result, but aplastic anemia is by far the commonest. It is usually associated with necrosis of bone and osteogenic sarcoma is a late sequel. Several cases of fatal poisoning have been reported among workers who have ingested luminous paint or have inhaled emanation or radio-active dust in the manufacture, handling or therapeutic use of radio-active substances. Alpha ray therapy has been tried in most of the diseases of the blood and blood-forming organs, but as it is much more dangerous and to date ineffective it has been discarded in favor of gamma ray therapy.

A few general comments are justified from the foregoing. Toxic effects from the dose of

must be excluded in the differential diagnosis in patients presenting the syndromes of agranulocytosis, thrombopenic purpura, erythrophthisis, or aplastic anemia. The fact that this group of syndromes or various combinations of them may be produced by any one of these agents suggests that they are closely related conditions and that the so-called idiopathic forms may also be related and due to the actions of toxins, possibly non-bacterial, on the marrow. The fact that resistance to infection is greatly decreased in all of these syndromes in which mature neutrophils are scarce in the blood stream suggests that the severe infections of mucous membranes characteristic of idiopathic agranulocytic angina, aplastic anemia, and acute leukemias may also be due to the scarcity of mature neutrophils in the blood, in other words, that the infection is secondary to the granulopenia and is not the etiologic factor of the disease.

Experimental work on the therapy of agranulocytosis, thrombopenia, and erythrophthisis could be done on animals in which these syndromes have

been produced by one of these agents, preferably benzene. On the basis of the evidence at hand, it would seem that the direction of therapy should be to supply an adequate number of white cells, red cells and platelets to the circulating blood until the marrow can be restored to activity. Repeated transfusions can easily maintain a normal red cell count, but if a sufficient number of transfusions is given to compensate for the more rapid destruction of white cells and platelets, a polycythemia results. This difficulty may be overcome by concentrating the white cells and platelets from a large quantity of blood. The action of pentose nucleotide and small doses of roentgen-rays on depressed marrow should be investigated further. The only hope for a real cure of leukemias would seem to lie in complete eradication of abnormal cells. Benzene or some related compound may have a sufficient specificity to accomplish this, if the patient can be kept alive during the period of complete aplasia. Investigation of these theories is in progress.

A Further Study of a White Family Showing Elliptical Erythrocytes

WARREN C. HUNTER, M A , M D , *Portland Oregon*

ALTHOUGH it is not uncommon to encounter occasional oval, elliptical or even rod-like erythrocytes in blood smears from perfectly healthy persons, a predominance of such forms in the absence of severe anemia is exceptional.

Two interesting and curious morphological abnormalities involving the erythrocytes may occur in healthy individuals, first, so-called sickle cell anemia which has never been found except in persons of negro extraction and second, a condition characterized by the predominance of elliptical or oval red blood cells and occurring in both whites and negroes. Of the two, sickle cell anemia is by far the more common, the incidence being variously estimated at from 0.6 per cent (Mulherin and Houseal¹) to 7.2 per cent (Cooley and Lee²). Huck and Bigelow³ were the first to demonstrate that sickle cell and elliptical cell deformities are entirely different conditions with hereditary transmission as the sole common feature.

Dresbach⁴ who was the first to recognize and record an instance of ellip-

tical erythrocytes in a human being suspected the congenital nature of the anomaly but was unable to prove the point since the one available relative of the patient had normal blood. The first suggestive evidence was furnished by Bishop,⁵ and Huck and Bigelow⁷ but full confirmation was lacking until the appearance of the study of Hunter and Adams,⁶ 1929, of van den Bergh⁸ 1931, and of Cheney⁹ in 1932.

In 1929 the author with the collaboration of Dr R. B. Adams reported the results of an investigation of the blood from sixteen persons of pure Dutch extraction. Of these twelve showed elliptical erythrocytes and were distributed as follows: a father, each of his eight children (five daughters and three sons) and three of his six grandchildren. In the third generation two girls and one boy were affected, these being the offspring of two daughters both of whom exhibited the abnormality. In contrast to previous reports by others several members of this family were more or less anemic and one had a well marked anemia of the secondary type with no obvious cause.*

After the publication of our work a communication was received from Professor A. A. Hymans van den Bergh of the University of Utrecht inquiring if any members of this family still lived in Holland. Upon learning the family name, Professor van den Bergh assigned a member of his staff, Doctor Rehorst, to locate those descendants residing in Holland and to examine their blood. The highly illuminating results of this investigation were presented before the Dutch Royal Academy of Sciences in 1931.⁷ The study of the Holland branch of the group was made difficult by reason of their dispersion throughout the country and further by the refusal of certain parents to allow the blood to be taken from their children. Nevertheless four additional examples of elliptical erythrocytes were encountered. Inquiry disclosed that the father of the man who emigrated to the United States, who was the grandfather of the girl in whom the anomaly was first discovered by us, had been married four times. There were no living descendants of the first marriage. None of the children from the second and fourth marriages nor the grandchildren and great-grandchildren issuing from either of these marriages had oval red blood cells. It thus appeared probable that the man living in America, who was one of several children from the third marriage, had not acquired the ab-

normality from his father but through his mother, the third wife.

Accordingly van den Bergh instituted a search for other children issuing from the third marriage and for relatives of the third wife who was not living at the time of the investigation. Upon inquiry it was learned that she was one of seven children, all of whom were dead. However, five of the eight children of a sister of the third wife of J. K1 were discovered and examined. Three members of this branch who had ovalocytes refused to allow blood to be taken from their children so that only the offspring of one son with, and of a daughter without ellipses, could be studied. The son had transmitted the anomaly to one of his two daughters. Of further interest was the absence of elliptical corpuscles in all of the three sisters of the man living in the United States in whom we had previously found such cells.

The present report is largely supplementary to the first⁶ and had its inception with the opportunity to study from the time of birth the blood of a baby daughter of Adriana S., in whom the condition was originally discovered. Also after the publication of the first paper⁶ I learned that a full brother of A. K1 living in Colorado had four children and that the wife of one of his sons was about to be confined. It appeared desirable, therefore, to continue the work and insofar as possible determine the incidence of elliptical erythrocytes in the entire family group.

Baby S., female, was born Dec. 22, 1931, at full term and proved to be normal and healthy in every respect.

⁷ The first 20 erythrocytes numbered 381-390 and were found to be normal in 13 per cent. The remaining 10 erythrocytes numbered 391-400 were found to be normal in 10 per cent. The remaining 10 erythrocytes numbered 401-410 were found to be normal in 10 per cent. The remaining 10 erythrocytes numbered 411-420 were found to be normal in 10 per cent. The remaining 10 erythrocytes numbered 421-430 were found to be normal in 10 per cent. The remaining 10 erythrocytes numbered 431-440 were found to be normal in 10 per cent. The remaining 10 erythrocytes numbered 441-450 were found to be normal in 10 per cent. The remaining 10 erythrocytes numbered 451-460 were found to be normal in 10 per cent. The remaining 10 erythrocytes numbered 461-470 were found to be normal in 10 per cent. The remaining 10 erythrocytes numbered 471-480 were found to be normal in 10 per cent. The remaining 10 erythrocytes numbered 481-490 were found to be normal in 10 per cent. The remaining 10 erythrocytes numbered 491-500 were found to be normal in 10 per cent.

Blood obtained from the umbilical cord at the time of birth was observed both in sealed wet preparations and in dried smears stained in the usual manner. In the sealed specimens a fair percentage of erythrocytes were oval and a few had a rodlike form. The exact number of each was not determined. The dried film contained a small number of oval cells but almost no greatly elongated or typical ellipses (figure 1). Three subsequent examinations of blood obtained by skin puncture on the day of birth and again on the fourth and twelfth days of life gave practically the same results. As is normal for a newborn child the number of erythrocytes and their hemoglobin content was high, 616

millions with 146 per cent hemoglobin (Sahl's Osgood-Haskins' standard), 62 millions with 138 per cent hemoglobin, and 60 millions and 127 per cent hemoglobin, on the days mentioned above.

As a control the blood from six other babies of the same age was examined over the same interval of time. In two instances both the cord blood and that obtained after birth were found to contain occasional oval erythrocytes but the number was insignificant. After leaving the hospital the parents of the baby moved to another city thus making periodic examinations impossible. However, at the age of three months it was possible to obtain one further specimen of blood

FIG 1. Baby S. Microphotograph of blood obtained from umbilical cord. 1 to 5 are oval erythrocytes, 6 is a normoblast.

which showed in fresh sealed preparations 44.4 per cent oval, 1.6 per cent elongated or irregular poikilocytes, and 54 per cent discoid cells. The percentage of abnormal forms in stained smears was not counted but comparison with the smears obtained during the first two weeks of life disclosed a very obvious increase (Figure 2). Many of the erythrocytes were now oval and in stained smears a fair proportion were rodlike with quite bluntly rounded ends. The number of erythrocytes and the hemoglobin could not be determined at this time.*

The placenta was placed immediately in ten per cent formalin and paraffin sections stained with hematoxylin and eosin were prepared. In the sections only a small percentage of oval

*I am informed that the baby died suddenly on April 30, 1932, while in apparent good health. A postmortem examination was not made.

erythrocytes could be seen in the maternal blood sinusoids, even where the cells were so widely separated that pressure artefact and tangential position could be eliminated. This finding is especially interesting in view of the very high percentage of abnormal erythrocytes in the circulating blood of the mother. The small size of the channels through the chorionic villi made it very difficult to find any erythrocytes which were not molded by pressure and nothing can be said as to the presence or absence of abnormal forms in the fetal side of the placental circulation. The same is true for the blood in the cord vessels. The placentas from ten other women fixed and stained in the same way served as controls. Oval erythrocytes occurred in two instances although the number was distinctly less than in the placenta from Mrs. S.

A study of the blood of the Colorado divi-

FIGURE 2. Blood smear from the mother of the child who died on April 30, 1932. The smear shows a high percentage of abnormal forms, including many oval erythrocytes.

sion of the family was made possible by the hearty cooperation of Dr James S Orr of Fruta, to whom the writer wishes to express his gratitude and appreciation for obtaining samples from the members of the family residing there

The Colorado group consists of Mr G K1 (full brother of A K1 of Montana), who has four children and two grandchildren, (Chart 1)

The blood of G K1 contains comparatively few oval red blood cells in sealed fresh specimens, the number computed on the basis of a count of one thousand erythrocytes being 82 per cent Still fewer occur in stained

films The total number of corpuscles and percentage of hemoglobin were not determined but Dr Orr informs me that the man is in good health

John, son of G K1, is a healthy male 28 years of age Fresh blood could not be obtained but in dried smears a small percentage of erythrocytes are oval in outline The red cells number 5,400,000, and the hemoglobin is 85 per cent (Tallquist)

Of the three remaining children a daughter, Neisje, has 108 per cent oval and 08 per cent irregularly formed poikilocytes in wet films and

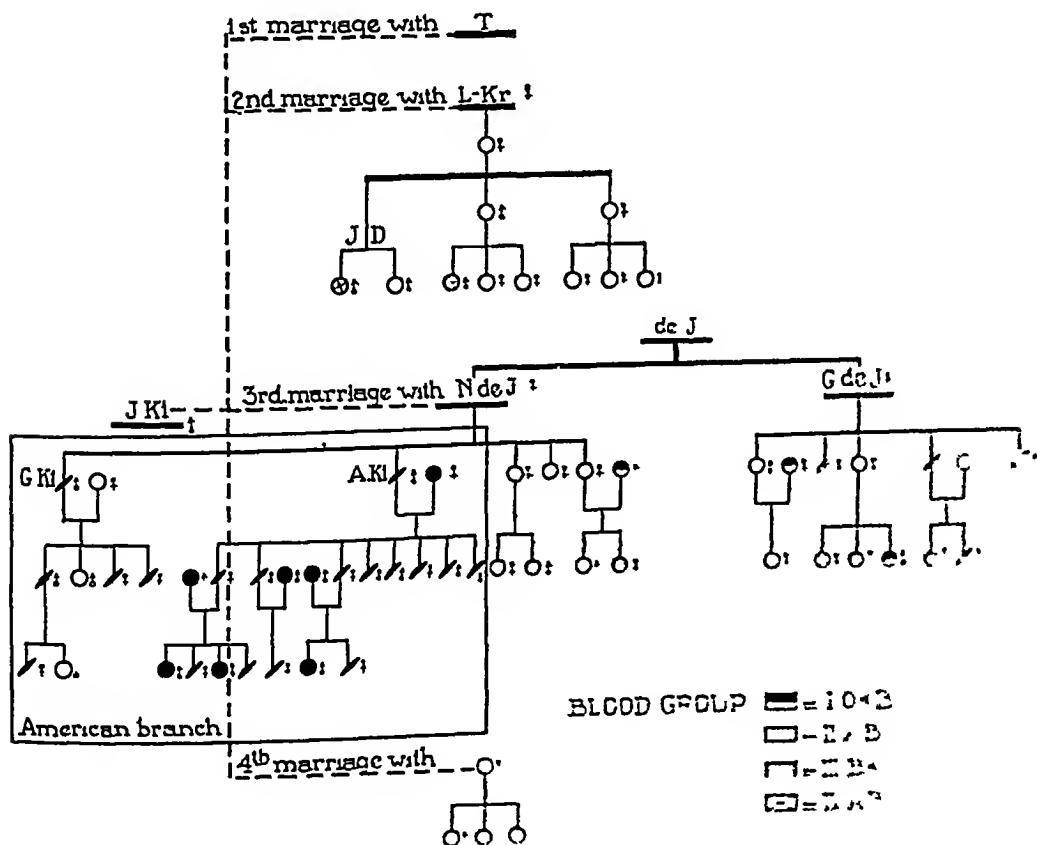

CHART I Occurrence of elliptical erythrocytes in three generations of the Colorado group. The American branch of the group has been set off by the rectangular frame in the diagram. The remaining members of the family, all of whom were, before being studied by van den Bergh. The chart shows the distribution of the blood group and indicates that it entered the family through the third generation. Individuals are designated by ellipses.

approximately the same number in dry smears. A sister, Mary, shows slightly fewer abnormal forms, 7 per cent oval and 0.6 per cent irregular erythrocytes. The fourth child (Ira) age unknown, has normal cells.

John Kl. is the father of two children, a boy four years of age who does not exhibit the abnormality and an infant daughter whose blood on the seventh day post-partum contained in dry smears a few distinctly oval erythrocytes.

After completing the study of these persons I noted in a very recent paper by Terry et al.⁹ a statement to the effect that in their hands pressure upon the cover slip over a drop of blood often resulted in a great reduction and sometimes an almost complete disappearance of oval forms, with replacement by circular cells. In my preparations pressure had been applied in each instance. This may readily account for the low percentages of oval forms present in the wet suspensions. Unfortunately no further specimens of blood could be obtained.

SUMMARY

The combined genealogical charts of Hunter and Adams⁷ and of van den Bergh, together with further corroborative evidence submitted herewith, indicate that in the Kl. family the condition of elliptical erythrocytes is inherited as a dominant trait, thus forming a striking example of inheritance of a peculiarity of a cellular component of the blood. Additional proof of the hereditary nature of elliptical erythrocytes is the occurrence in fourteen subjects of three generations

of the Italian-American family studied by Cheney.⁸

With one exception, that reported by Bernhardt,¹⁰ the abnormality has never been known to skip a generation but has appeared only in the offspring of affected persons and is transmitted with equal frequency by both sexes.

That the trait is truly a hereditary one is further shown by the presence of oval and rodlike erythrocytes in the blood of two newborn babies studied by the writer. In each instance one parent was similarly affected. In one of the babies from whom it was possible to secure several specimens, the number of abnormally formed red blood cells increased quite perceptibly between the age of twelve days and three months. According to Terry⁹ the adaptation of cells and serum to each other is still in progress at birth and continues for some time before permanent relations are attained and the blood group becomes established. Only on some such basis can one explain the striking increase of elliptic cells observed in Baby S. (figure 1).

Sections of the placenta from this case failed to disclose more than a few oval erythrocytes although the circulating blood of the mother contains a higher percentage of such cells than any other member of the family. Fixation in formalin may in part be responsible for the change in form. The occurrence of similarly shaped corpuscles in two of ten placentas from normal cases makes observations of this kind of doubtful value. Furthermore, in tissue sections it is very difficult to be certain that pressure from other cells has not altered the form of

erythrocytes In the writer's experience it is not uncommon to see numerous oval red cells in sections of many tissues and organs and little importance is attached to finding them in the case at hand

In a previous communication it was stated that the rôle of the erythrocytic anomaly as a cause of the anemia existing in several members of the KI family was problematical The present study has thrown no new light upon this aspect of the condition and we are in agreement with Osgood and Haskins¹¹ that the red cell form is probably exaggerated by anemia but does not predispose to it

Including the five new instances of

hereditary elliptical erythrocytes reported herein, 57 examples of this condition are now on record It is probable that the anomaly is less rare than formerly supposed and that with more careful examinations of the blood it will be found with increasing frequency

The present report is supplementary to those of Hunter and Adams⁶ and of van den Bergh⁷ and its chief purpose is to complete the study of one large family group Certain interesting and important experiments of Terry et al⁹ concerning the nature and behavior of elliptical erythrocytes have been omitted largely because of inability to obtain sufficient blood

Potassium Sulphocyanate: A Note on Its Use for the Painful Crises in Sickle Cell Anemia

By EDWARD G. TORRANCE, M.D., and TRUMAN G. SCHNABEL, M.D., F.A.C.P.,
Philadelphia, Pa.

SICKLE cell anemia is a disease of unknown etiology, its prognosis is uncertain and its treatment is entirely symptomatic. In its active stage it is noteworthy for its spontaneous remissions and relapses. Most observers have found that treatments thus far suggested do not materially alter the course of the disease. No therapeutic procedure seems to influence the degree of sickling *in vivo*. Blood transfusions bring about remissions with uncertain regularity, and are of temporary value when so induced. They do on occasions tide a severely anemic patient over a critical period.

Liver diet has been tried by Sydenstricker and others without any favorable effect. Levy² reported on the use of liver extract in three patients over a period of a year. This treatment apparently accounted for an increase in the number of red cells as well as the hemoglobin percentage. With the improvement of the blood picture there was a definite improvement in symptoms and a tendency to

inhibition of sickle cell formation. In one of these patients it is reported that the sickle cells disappeared from the blood and in another the number of such cells was reduced. Levy's report constitutes the only evidence in the literature of a favorable influence on sickle cell formation by treatment. Yater and Mollari³ reported a case in which liver extract was given for two weeks with no especial influence on the hemoglobin and erythrocyte pictures. The reticulocyte count rose from 28 per cent to 90 per cent, but fell to 0.6 per cent a few days later. One of us has noted the temporary influence of blood transfusions on the anemic state of a sickle cell patient, and at the same time some symptomatic improvement; but has not observed any effect from the use of a liver dietary or liver preparation in other patients.

Many of the hemolytic features of familial hemolytic jaundice resemble those of sickle cell anemia. It was not surprising, therefore, when Hahn and Gullberg⁴ reported in 1927 that they had done a splenectomy on a child four years old with sickle cell anemia. In 1928 Hahn⁵ reported another splenectomy for the same disease and at the

same time noted spectacular improvement in the patient operated upon in the previous year. Improvement in the second patient lasted for five months after operation. Stewart's⁶ patient showed no improvement while those of Bell, Kotte, Mitchell, Cooley and Lee⁷ improved only temporarily. Landon and Lyman⁸ reported the seventh splenectomy including that of Giddings cited by Bell et al. This was done in a child four years old and showed improvement nine months after the operation. The improvement observed was shown in the child's general condition, a lessening of abdominal pains with an increase in the hemoglobin percentage and red cell count. Fourteen months after splenectomy this patient still presented an anemia and the sickle cell trait. In a patient observed by one of us there was no amelioration of generalized bodily and abdominal pains after a splenectomy. There was observed however, an elevation in the hemoglobin and number of red cells, but the patient died after the lapse of a year of an unknown cause. No post-mortem examination was performed on this patient. It seems fair to state, then, that splenectomy has been disappointing as a therapeutic practice in sickle cell anemia in marked contrast to the results following this same operation on patients suffering with hemolytic jaundice. Splenectomy however, is followed by some temporary improvement in the blood findings and symptoms generally when the patient is the victim of sickle cell anemia.

There is a difference of opinion as to prognosis for the victims of this disease. Huck⁹ indicated that for those

with symptoms life rarely lasts longer than thirty years. Sydenstricker¹⁰ believed the prognosis to be good for adults but guarded for children. He found a high child mortality and much myocardial and renal disease in sickle cell families. His patients ranged in age from three months to sixty-seven years and all died of intercurrent disease—nephritic coma, meningeal hemorrhage, pyelonephritis, bronchopneumonia, and traumatic peritonitis. Josephs¹¹ found on the other hand that the mortality among sickle cell children and their families was not demonstrably higher than the average. He also noted that an infection was responsible for the transition in one patient from the latent to the active phase with a subsequent return to the latent condition. This is the only patient reported in the literature in whom latency developed when once an active phase had been established. Although death seems to be due generally to some intercurrent disease, Wollstein and Kreidel¹² reported two patients who seemed to have died of the disease *per se*. Franklin and Schwartz¹³ claimed that 50 per cent of patients with sickle cell anemia succumb to tuberculosis. Dolgopol and Stitt¹⁴ found that 52 per cent of 77 tuberculous patients revealed the sickle cell phenomenon. In addition, then to an unsatisfactory therapy we have in this disease a varied and uncertain prognosis. Anything which seems to offer the slightest hope of treatment would seem to be worthy of note and subsequent trial in other patients.

In accordance with this we wish to record our experience with

negro male patient 26 years of age. He was admitted to the Philadelphia General Hospital for the first time in October, 1926. His past history revealed that he had not been able to attend school regularly as a child because of frequent headaches, pain in the back and extremities. These aches and pains lasted two to three days and then would disappear for a month or more. They occurred more frequently in the winter than in the summer. On his first admission he complained of excruciating pain in the right leg and left arm. There was nothing especially noteworthy on physical examination except for marked tenderness over the right tibia and left arm. He had an evening rise of temperature to 102° F and a leucocyte count of 15,200. The differential count was normal. X-ray examination was reported as showing some slight osteosclerosis in excess of normal. A diagnosis of periostitis was made clinically; the periosteum was raised, and a small amount of sterile pus was evacuated. Pains continued in the left arm and right tibia in lesser degree after operation and at the end of three weeks he was quite well again. No record was made of the hemoglobin or red cell estimations during this hospital stay.

After the original admission he was returned to the hospital on four other occasions, all complaining of severe pain in the extremities, back and joints. On the last two admissions he had severe aching and dull pain in the right leg and left arm, but no tenderness or swelling. On the other two admissions he had no symptoms. He was discharged after the fourth admission, but returned to the hospital on the fifth admission because of the same symptoms.

attacks. These pains were especially perplexing during his second hospital stay for it was not until his third admission that sickle cells were reported as being present in his blood. Throughout his period of residence in the hospital and during his attacks of periodic pain it was difficult to make this patient comfortable, even by the use of morphine sulphate in fair-sized doses given at frequent intervals. Although it was appreciated that he was experiencing the abdominal crises which occur in sickle cell anemia patients, surgical consultation was requested at least twice. After both consultations it was agreed that there was no indication for laparotomy in spite of the fact that he was jaundiced, vomited, and at times the pain and rigidity occurred over the gall bladder area.

The records of physical examination for all admissions describe the patient as a young adult negro appearing younger and smaller than normal for his age. He was well nourished and well developed muscularly. The pubic hair showed a feminine distribution and he had no axillary hair. His cervical, epitrochlear and inguinal glands were enlarged. The conjunctivae were jaundiced. The heart was enlarged to the left and a systolic murmur was present at both the aortic and mitral areas. The former murmur was transmitted to the vessels of the neck. The liver and spleen were not palpable. He presented dried scabs which were excised during his fourth hospital stay. There were no abnormal fundal ocul findings.

At the time of the first admission the patient had no symptoms.

no sugar, an occasional trace of albumin and a few leukocytes. Phenolsulphonephthalein elimination amounted to 55 per cent for the first hour and 15 per cent for the second hour. A glucose tolerance test yielded the following findings: Fasting blood sugar 82 mgm per 100 cc, thirty minutes after 100 gm glucose, 131 mgm per 100 cc, one and one-half hours after glucose, 95 mgm per 100 cc, three hours after glucose, 74 mgm per 100 cc. The one and two hour urines showed 0.4 per cent sugar.

Hemoglobin values varied considerably at different times, ranging from a low of 8.1 gm per 100 cc to a high of 10.9 gm per 100 cc. Numerous red cell counts were recorded from 2,240,000 to 3,750,000. The hemoglobin values and red cell counts varied within short periods of time. Leukocyte counts ranged from 10,900 to 19,400. The average differential count was: polymorphonuclears, 57, lymphocytes, 39, large mononuclears, 4, and eosinophiles, 1 per 100 cells. Reticulocytes never exceeded 5 per cent in number. Sick-shaped cells were present at all examinations, varying from 6 per cent to 50 per cent of the cells counted. Nucleated red blood cells were present at all times. As many as 44 were seen while counting 100 leukocytes in a stained preparation. Platelet counts are reported from 2,800,000 to 4,800,000. The clotting time was 3.5 minutes on an average of three determinations. The fragility test showed beginning hemolysis at 36 per cent salt solution at one time, and at 30 per cent at another. Hemolysis was complete at less than 20 per cent in both instances.

Blood chemistry determinations yielded the following results: sugar 80 mgm per 100 cc, blood urea nitrogen, 12 mgm, cholesterol, 165 mgm, phosphorus, 4.6 mgm, and calcium 10.4 mgm per 100 cc. The P_H was 7.44. The van den Bergh test showed a delayed reaction on three trials. The icterus index varied from 8 to 15.

Test meal studies always yielded some evidence for the presence of free hydrochloric acid. The highest amount found at any time amounted to 25 in terms of decimal normal sodium hydroxide solution. The highest total acid value was 60.

X-ray studies showed normal pulmonary fields, the heart enlarged to the left, and no unusual observations made in the aortic shadow. The gastro-intestinal investigations by x-ray were negative as was the cholecystographic study. The bones generally showed the characteristic changes of sickle cell anemia.

In our effort to control this patient's abdominal crises we resorted to many drugs and therapeutic endeavors. We did not, however, transfuse him because his blood was never severely anemic. The variation in hemoglobin content and red cell count did not seem to bear any relationship to his pain. Besides this, our own experience coupled with that of others did not seem to warrant a trial which would only be temporary. We did not advise splenectomy because his spleen was not palpable. If this operation is to be of any value, it must appropriately be done in children in whom the organ is usually, but not always, larger than normal. These two factors were guided in this decision by the necessity

results which have followed splenectomy as reported in the literature

It is quite possible to accelerate or retard the sickling phenomenon *in vitro*. One such method consists in changing the PH of the suspension medium which contains the red cells. Hahn and Gillespie¹⁵ reported that the reduction of the blood PH from 7.3 to 7.25 causes immediate sickling. It is added, however, that while such an observation in application to the sickling phenomenon may be suggestive, it would seem to be of doubtful bearing on the genesis of circulating sickle cells. Nevertheless, with this lead we fed our patient for a period of time on a ketogenic diet and during another period added large doses of ammonium chloride. At still another time we prescribed massive doses of bicarbonate of soda. These practices had no apparent influence on the severity of attacks nor on their frequency. The same authors have shown that saturation of the blood with carbon dioxide will produce sickling and that the action can be reversed by saturation with oxygen. During an attack we placed the patient in an oxygen tent with no amelioration of symptoms. Indeed, nothing we did seemed to influence the amount of sickling as determined by counts done both on dried and wet preparations immediately after blood withdrawal. Hahn¹⁶ believes that there is a correlation between the severity of sickle cell anemia

and the number of sick cells in the circulation. In the studies on the patient reported here, the number of sick cells was not counted and the number of normal cells was not counted.

The patient's blood pressure during

attacks did not change the symptoms. There was some increase in the reticulocytes but no evident increase in the red cell count as the result of this therapy. Salicylates were exhibited in large doses with no appreciable effect on the pains.

During attacks we used nitroglycerin, atropine sulphate, and adrenalin chloride hypodermatically with no relief. These preparations were used with the thought that the pains might be vascular in origin or perhaps the result of some autonomic nervous system disturbance. There never was observed, however, any alteration in the blood pressure during attacks. The blood pressure averaged about 110 systolic, and 62 diastolic. During attacks we also gave some triple distilled water and calcium chloride intravenously without effect.

Examination of wet specimens of this patient's blood with dark field illumination (Dr S. W. Ludlum) showed an unusual degree of erythrocytic clumping. This phenomenon is closely related to that of rapid red cell sedimentation and probably results from relative dehydration, diminution of electrical charge and a lack of sodium and potassium salts. Graham and McCarty¹⁷ have found an increased sedimentation rate in sickle cell anemia. Dr Ludlum suggested the trial use of sodium and potassium salts together with potassium or sodium sulphocyanate in this patient, largely on theoretical grounds. Beginning on February 19, 1931, the patient received large daily doses of potassium citrate and sodium bicarbonate. He had previously received these salts previously with no effect.

able results, but now there was added one and one-quarter grains of potassium sulphocyanate given three times a day. On February 23, this dosage was increased to two and one-half grains three times a day and this medication was continued until March 6, 1931. During this time he was entirely free from pain and discomfort and was up and about the ward. He remained free from pain until March 11, 1931, when he again complained of pain in the shoulders and abdomen. Immediately on receiving the potassium sulphocyanate therapy there occurred again a prompt relief of symptoms. During the period of thiocyanate medication, no variations in the number of sickle cells were noted. He felt unusually well and on being denied the privilege of leaving the hospital in the regular way, he absconded April 16, 1931.

In view of the fact that no adequate explanation had been made for the pain symptoms occurring in sickle cell anemia, one of us has elsewhere ventured the opinion that they may be due to some transient alteration in the nervous system. This nervous alteration may be consequent upon the bone pathology which goes with this disease. Our patient presented extensive changes in his vertebrae and it may be that the pains are comparable to those occurring as the result of other vertebral diseases. On one occasion he seemed to obtain relief by the application of a tight torsal binder. No one has carefully studied at autopsy central, peripheral or autonomic nervous system material obtained from such patients. The pains are quite like the critical attacks observed with loco-

motor ataxia or perhaps the root pains occurring in various spinal diseases.

In this connection it is of interest to refer to the recent observations reported by Bancroft¹⁶ on the colloid chemistry of the nervous system. His studies together with others made in the Cornell laboratories tend to support Claude Bernard's theory as to the chemical mechanism production of anesthesia. This theory would attribute the anesthetic state to a coagulation of the nerve tissue colloids as brought about by all of the well known anesthetics. The thiocyanate radical has the property of peptizing these coagulated protein colloids so that following administration of a thiocyanate preparation after anesthesia, there occurs a more rapid return of the nerve tissue protein to its previous normal colloidal state than is true under the usual recovery condition following every day operative anesthetics. At least this is shown to be true for animals as reported in Bancroft's article. If transient anesthesia and paralysis occur as a result of some chemical change in nervous tissue a chemical mechanism may also be assumed for pain production. In any event it seems quite clear that sodium or potassium sulphocyanate might bring about a peptization of colloidal proteins under variable conditions. It is well known that the state of the body colloids is due largely to electrolytic ions. In the Hofmeister series the thiocyanate radical occupies the first position and is therefore the best disperser of electrical charges. When the matter would seem to rest on a highly theoretical ground there seems to be some justification for believing

that there is a rationale in using a thiocyanate salt with other salts of sodium and potassium under the circumstances which we assume to present themselves during the critical abdominal attacks as they occur in sickle cell anemia. This assumption is that the pains are due to changes brought about in the aggregation or dispersion of the body colloids in some way.

Naturally we can present no conclusions. We have herein set forth some therapeutic experiences with a patient having sickle cell anemia who

seemed to be promptly relieved of generalized bodily pains on two occasions after the exhibition of potassium thiocyanate, potassium citrate, and bicarbonate of sodium. In this disease, noteworthy for the spontaneous remissions and relapses which it undergoes, it is difficult to draw any conclusions as to the effects of therapy. We are therefore not prepared to say that our treatment was the effective agent. The results seemed to be significant, however. Further trial and observation are necessary before any conclusions may be reached.

An Assay of Goldenrod as a Cause of Hay Fever

By WARREN T. VAUGHAN, M.D., F.A.C.P., and RUTH W. CROCKETT
Richmond, Virginia

GOLDENROD, apparently our most popular aspirant for the title of "national flower" has in years past been reputed to be the principal cause of autumnal hay fever and asthma. Our modern concept of the etiology of pollen asthma has demonstrated that wind borne pollens are of far greater importance in this malady than are the pollens of those plants which are cross fertilized by insects. Indeed, the importance of wind distribution has been so emphasized, that prominent students of allergy have stated that goldenrod and other insect pollinated plants are of very little importance in the causation of pollen allergy. The idea is now quite general that goldenrod, like the rose and daisy, is always purely a local problem. If goldenrod be brought into a house for decorative purposes a sensitive individual may have trouble. Outside of this, the heavy sticky pollen is carried on the wind only for short distances and may therefore be easily avoided.

The summer of 1931, in Virginia at least, was an unusual one for plant growth, particularly for weed growth and the following observations have convinced the writers that under certain conditions at least, goldenrod

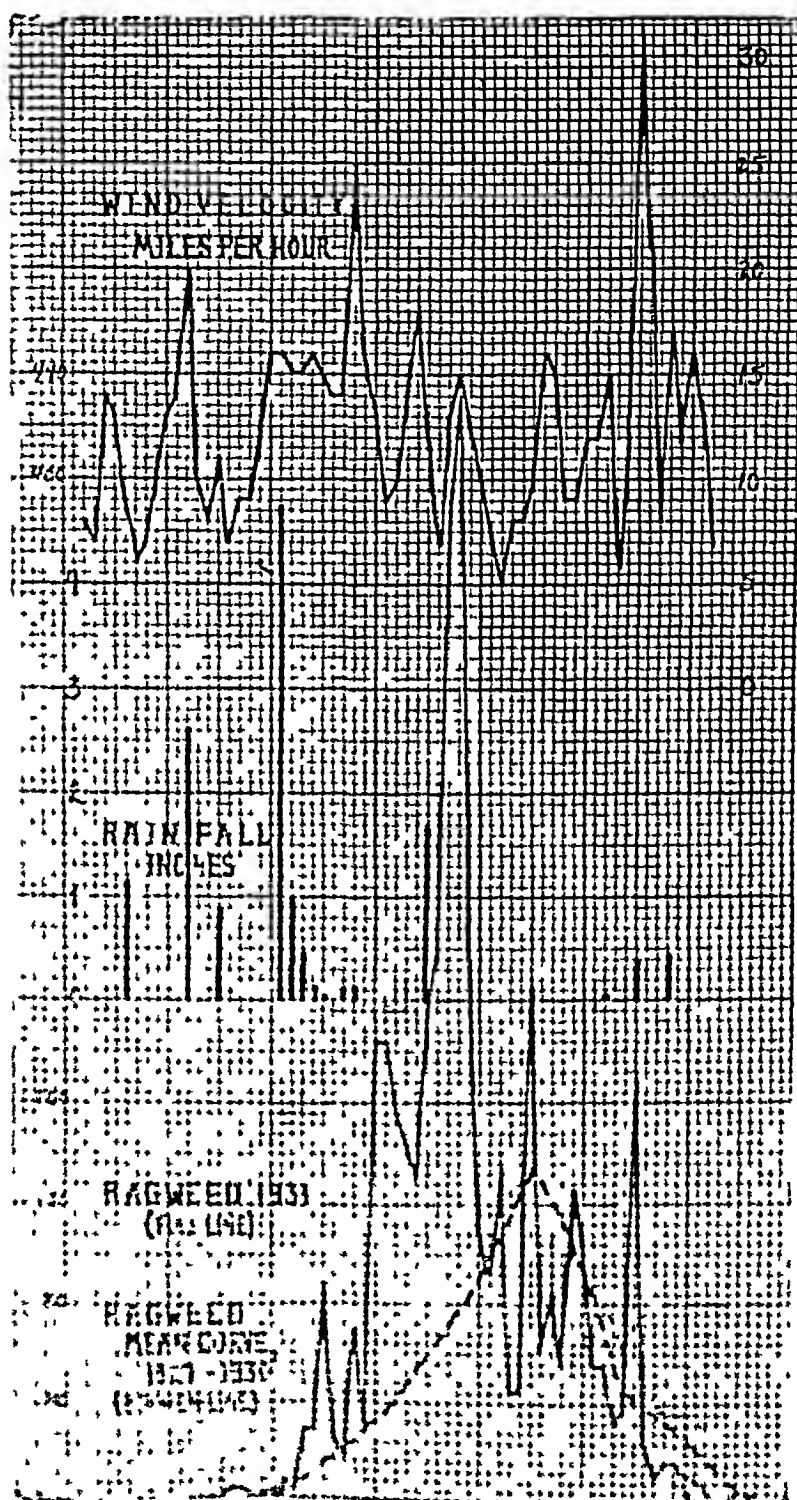

sensitization may be a factor requiring treatment.

HEAVY POLLIN PREVALENCES IN 1931

The ragweed curve for 1931 showed an unusually heavy pollen prevalence (chart I). We have kept daily curves of atmospheric ragweed pollen prevalence in Richmond since 1927. The average maximum prevalence for the four years, 1927 to 1930, was 116 grains per cubic yard of air. The highest prevalence prior to 1931 was 194 on September 22, 1928. The highest prevalence in 1931 was 138 on September 7. This is well over twice the highest daily prevalence in the preceding four years. Furthermore, the prevalence throughout the first half of the 1931 ragweed season was very much higher than in preceding years.

There were very definite meteorological reasons for this. In August, 1930 we had an unusual drought which delayed the onset of pollination for about ten days. On August 28, of that year there occurred a very heavy rainfall with 18 inches of rain in 24 hours. Within a few days pollen appeared in the places where it had been withheld. This was followed by a heavy prevalence so that the average for the preceding year

Received for publication April 1, 1932.

This is the first factor in explaining the very heavy prevalence of the succeeding year, 1931 a heavy distribution of ragweed pollen in 1930, presumably with a consequent heavy distribution of fertilized seed

July, 1931, had a normal rainfall in Richmond with an average temperature (80°F), two degrees higher than the usual average for July. With adequate rainfall and a high, but not too high, temperature, there were therefore good growth facilities in July. In August the temperature was average but we had an extremely abundant rainfall (11.4 inches), more than had been recorded for any August since the Richmond Weather Bureau was established in 1871. Finally, early in the ragweed season there were several days of high wind velocity which naturally carried large amounts of pollen into the air (chart I).

These four factors, wide distribution of seed in 1930, good growth facilities in July, 1931, abundant rainfall in August and high winds early in September, were responsible for the tremendous pollen concentration in September in the vicinity of Richmond, as exemplified by the ragweed curve.

Conditions in the country corresponded to conditions in the air. Ragweed, both giant and dwarf, seemed to be nearly everywhere. In the ditches along the roadsides wherever one might drive there was an unusual abundance of ragweed. But the wide distribution of vegetation was not limited to this particular plant. The other weed whose abundance was most striking was golden-

rod. It was every bit as abundant as the ragweed and as one would drive along the country roads entire fields would appear a golden yellow from masses of goldenrod. Conditions favoring growth had also produced unusually large individual plants. It was not at all unusual to see stalks of goldenrod over six feet high (figure 1). It became obvious that an indi-

FIG. 1. Goldenrod plants over six feet tall.

vidual sensitive to goldenrod could ride into the country without being exposed to heavy concentrations of this pollen.

But the observation which caused us to wonder whether pollen from too distant a source could carry pollen to the cover of pollen grains from the pollen of goldenrod or other plants in our pollen traps. The pollen grains

the eighth floor of an office building in the center of a city of nearly 200,000 population. It is at once obvious that this unusual pollen must have been carried to appreciable distances and that individuals even in the center of town were being exposed to it.

Goldenrod pollen is easily distinguishable from that of ragweed, but since there are many varieties of goldenrod and since the pollen grains differ in appearance in some of these varieties, some of the pollen was obtained directly from the goldenrod in the field for comparison with that found on the plates (figure 2). While the pollens appear to be the same, one cannot state absolutely, from morphologic resemblances, that the pollen on the plate is actually that of goldenrod. However, this appeared to be the case. In any event, an unusual pollen was being deposited on the plate. This indicated that hay fever sufferers were necessarily being exposed to this unusual pollen. The pollen appeared to

be that of goldenrod. Goldenrod was unusually profuse around the city and to a certain extent in the city.

THERAPEUTIC STUDIES

Allergists have known that it is not uncommon for an individual to react positively, on testing, to goldenrod extract. However, this has been overshadowed by the observations that goldenrod is insect pollinated, that the same individual is usually ragweed sensitive, and that ragweed desensitization alone usually relieves these persons of their symptoms. Therefore, in spite of positive reactions it has been customary not to desensitize with goldenrod.

In our experience, for every 100 persons sensitive to ragweed, 30 are found sensitive to goldenrod. In the majority of instances the goldenrod sensitive individual is also sensitive to ragweed.

Granting the frequency of goldenrod sensitivity, it becomes obvious that if such a person is exposed to golden-

rod pollen he may manifest symptoms and that if goldenrod pollen may be carried farther than we had supposed, this sensitivity may be an important one in the production of symptoms. With this idea in mind, as soon as the goldenrod-like pollen appeared on the plate, we investigated the records of those ragweed sensitive individuals who, following perennial or pre-seasonal treatment, had not obtained what they considered adequate relief. During the season there were 23 ragweed sensitive patients under treatment who had also been tested with goldenrod. Thirteen were negative to goldenrod and ten had reacted positively to it. Of the thirteen not sensitive to goldenrod, nine had received 90 per cent relief or better. However, of the ten who were sensitive to goldenrod seven had received 90 per cent relief or better, without goldenrod desensitization. Of the thirteen ragweed cases not sensitive to goldenrod eleven received 75 per cent or more relief from ragweed desensitization only. Of the ten ragweed cases sensitive also to goldenrod, nine received 75 per cent or more relief from ragweed desensitization alone. It therefore becomes at once obvious that even though goldenrod pollen appeared in small quantities on the plate during the ragweed season, it was not sufficiently concentrated to produce symptoms in the majority of cases. Two of the three ragweed and goldenrod sensitive cases who had received 75 per cent or less relief from ragweed desensitization alone were given coseasonal goldenrod desensitization therapy. One was promptly relieved of her remain-

ing symptoms while the other was not materially improved.

It would appear therefore that in a very heavy goldenrod year symptoms may be due to goldenrod even though there is no direct or near contact. This appeared in a heavy goldenrod year to be an unusual finding. Naturally, however, those who are known to be goldenrod sensitive must avoid close contact.

DISCUSSION

Past experience has shown that in average seasons, goldenrod sensitivity may be ignored, with the cautionary suggestion that the individual avoid close contact with the plants. In seasons in which the weed growth is heavy however it would appear that air borne goldenrod pollen may be responsible for symptoms. Certainly it is obvious that under such circumstances a ragweed sensitive individual also sensitive to goldenrod, who does not receive adequate relief from effective ragweed treatment should also receive therapeutic trial with goldenrod desensitization.

Our ideas as to how far pollen may be carried on the wind have of recent years required considerable expansion. Until recently Scheppegrell's¹ observations in the mountains of North Carolina have been the basis for the statement that ragweed pollen may carry as far as 15 miles. In 1931, however, Durham² concluded from airplane observations over Lake Michigan that ragweed pollen is nearly as concentrated 30 miles from shore as it is over the land. Block and Durham have reported that this pollen may be carried as far as 100 miles inland.

ernment study has been the authority for the statement that pollen from Alaska may be carried as far as the Northwestern United States⁴. It is therefore not at all surprising to find that we must consider it probable that the heavier pollens of insect fertilized plants may be carried in small quantities on the wind for a matter of three or four miles or more instead of the 300 or 400 feet usually allotted to them. If wingless insects are actually carried to elevations of several thou-

sand feet purely by the air currents⁵, the surprise is that the situation under discussion is not met with more frequently.

Aside from close exposure to the plant, goldenrod sensitivity is rarely responsible for symptoms, even during years of heavy prevalence. However it would appear that this pollen may be carried in small amounts to appreciable distances by the wind and may very occasionally produce symptoms in the absence of close contact.

The Present Status of the Ketogenic Diet

By D SCHUYLER PULFORD, M S , M D , F A C P , *Sacramento, California*

IT IS my purpose to outline the present status of the ketogenic diet rather than urge its use or disprove its value by reporting results on 75 treated cases of epilepsy. Sufficient time has now elapsed since Wilder's¹ introduction of this low carbohydrate high fat diet in 1921 to estimate its worth.

Ketosis is physiologically different from acidosis caused by a shift in acid base equilibrium and has other effects than dehydration. Therefore, in spite of the brilliant results of Fay² and McQuarrie³ and their followers with fluid restriction, diet-produced ketosis still commands our attention.

EPILEPSY A SYMPTOM NOT A DISEASE

Weed,⁴ Lennox and Cobb,⁵ Winkelman⁶ and others have advanced our knowledge of the anatomy, physiology and pathology of the central nervous system as related to convulsions so far that we now understand some of our failures to arrest epilepsy in the past. No longer is any type of epilepsy considered "idiopathic". Anatomists, physiologists, surgeons and pathologists have demonstrated conclusively the organic nature of the majority of cases studied. Dandy⁷ and others have shown at operation a "supra-cortical

laking" of fluid in the sub-arachnoid spaces not seen at autopsy because of the fall of cerebrospinal fluid pressure at death. This fluid is considered secondary to some cerebral lesion, probably an ischemia with resultant atrophy of the underlying cortex. Winkelman⁶ has demonstrated definite pathology of the arachnoid and Pacchionian bodies in eighty per cent of epileptic brains studied, be they of acute, chronic, "idiopathic", or symptomatic subjects.

Granted that all seizures are organic in origin, nevertheless physiochemical factors must explain their periodicity and the varying degree of susceptibility to such predisposing mechanical factors as hydration, increased pressure, tumors, etc. These in turn may be endocrine or even allergic in origin for all we know. But today even though we find certain organic lesions as predisposing causes we find ourselves even as in the time of Hippocrates, ignorant of the precipitating physiochemical basis of epilepsy and until this is found must believe with Doctor Fay² "That epilepsy will never be cured we are certain, but that it may be controlled in a manner similar to that we accept for diabetes is possible."

METHODS OF TREATMENT

In the evolution of the treatment of epilepsy we must not forget the

Presented at the San Francisco meeting of the American College of Physicians, April 6 1932

If all epilepsy is "symptomatic" and the continuing convulsions act *per se* as constant traumata to add to the organic basis it is important to stop them early. It occurs to me that the ketogenic diet is proving a means of telling how early or extensive a change we have in the central nervous system. The ketogenic diet alone of all the methods of treatment produces an arrest in convulsions which lasts long after the ketosis is abandoned. Does this not mean that progression of the brain pathology is arrested long enough for the patient to adjust to it, and that he can adjust successfully only to a slight lesion? When dehydration is necessary either supracortical laking or advanced brain changes are present to which the patient can never adjust. Therefore, it is necessary to continue the dehydration as long as one wishes to be convulsion free.

When ketosis fails we have an advanced cerebral lesion. Dehydration should then be resorted to either alone or combined with a mild ketosis and the patient told that it will probably be a lifelong procedure.

RESULTS OF TREATMENT WITH THE KETOGENIC DIET

Helmholz¹², Peterman,¹⁷ Talbot¹⁴ and Barborka¹⁵ early showed the value of the ketogenic diet in the treatment of epilepsy. Results reported from different quarters are surprisingly uniform. Epileptic convulsions disappear completely in about one-third of all children thus treated but the proportion of arrests in adults is smaller. The convulsion free state has persisted longer after the ketogenic diet than after dehydration when the rigorous-

ness of the two regimes is lessened. Many children after returning to an almost normal diet following six months of ketosis have been apparently normal for years. In September, 1930, Helmholz¹⁶ reported a series of 272 cases started on a ketogenic diet eight years before. Of a total of 171 who cooperated completely, 43 or 30 per cent, were free from attacks for one year or more, 32 or 23 per cent were improved, and 66, or 47 per cent were not helped. Talbot¹⁴ and Peterman¹⁷ recount similar experiences. Barborka¹⁵ noted poorer results with adults. Of one hundred non-institutional, supposedly "idiopathic" cases treated with a ketogenic diet, varying from 16 to 51 years of age and of from one to thirty-two years duration he reported 12 per cent controlled, 44 per cent definitely improved and 44 per cent not benefited. Combining the controlled and the definitely improved we have 56 per cent, or over one-half of the total, benefited. My experience corroborates this report and emphasizes that we should give patients of all ages a trial treatment.

In summary, we may say that with the ketogenic diet alone, without special attention to water or mineral metabolism, one-third of the cooperative intelligent epileptics can be made free from seizures. The best results are obtained in children and young adults who are just beginning to have seizures. Patients with frequent attacks of long duration respond less favorably.

The ketogenic diet is regarded as successful with *partial* seizures. Dehydration treatment has not been tried upon this phase of epilepsy.

which are in the order of their development:

- 1 Fasting,
- 2 Ketogenic diet,
- 3 Modification of mineral metabolism—shift of acid-base equilibrium,
- 4 Modification of water metabolism—dehydration

Fasting is impracticable and became unnecessary with Wilder's introduction of the ketogenic diet in 1921. Both of these methods result in imperfect combustion of fats, producing a fatty acid acidosis. They produce a shift in the acid-base balance (preventing an abnormal alkalosis), reduce the water volume of the body, and effect in some unknown way the irritability of the central nervous system.

Since ketosis was seen to produce a shift of the acid-base equilibrium, studies were undertaken to note the effect of modifying the mineral metabolism of the body. Peterman⁸ found that alkalosis itself did not explain susceptibility to convulsions for patients made attack free by the ketogenic diet did not develop seizures on taking alkalis to the point of alkalosis. Detrick⁹ emphasized the rôle of calcium ions in both dehydrating and reducing the irritability of the body cells, a reverse action to sodium ions which help retain water in cells and increase their irritability. Sodium chloride-free diets with high calcium intake with its mobilization, if necessary, with parathormone, together with moderate fluid restriction have in her hands controlled epilepsy without the use of the strict ketogenic diet.

After fasting, ketogenic diets and the proper shift in the acid-base equi-

librium, dehydration *per se* was next advocated in the treatment of epilepsy. Fay's² dehydration reports gave a most comprehensive review of the epilepsy problem and indicate "hydration" and "dehydration" to be the most important elements of cause and cure. He concludes "The predisposing factor concerned in a major convulsive seizure is due to a hydration state, however induced, whether local or diffuse, and proper control of this factor, when possible, gives rise to an attack free existence which may continue as long as the patient's water metabolism or fluid balances remain within the limits of proper compensation."

The precipitating factor remains an unknown quantity, even as in the etiology of goiter an unknown factor still baffles us. McQuarrie's¹⁰ hydration demonstrations, the inducing of seizures by increased water intake, combined with pituitary antidiuresis, confirm the surgeons' wet brain observations, Larson and Rowntree's¹¹ water intoxication studies, and substantiate the hydration state as being the principle predisposing factor in epilepsy.

The question whether dehydration is a superior method to the strict ketogenic diet is not fairly put, for they are so closely related. The ketogenic diet adds a sedative effect to dehydration so it might be likened to a mild dehydration plus luminal. It has been said that the sedative effect of the ketogenic diet is not better than that of luminal. This is not true for it has a dehydrating effect that luminal lacks, and clinically it arrests convulsions when the luminal alone has failed.

If all epilepsy is "symptomatic" and the continuing convulsions act *per se* as constant traumata to add to the organic basis it is important to stop them early. It occurs to me that the ketogenic diet is proving a means of telling how early or extensive a change we have in the central nervous system. The best results are obtained in children and in adults who are just beginning to have seizures. Patients with frequent attacks of long duration respond less favorably.

The ketogenic diet is not always successful with patients who do not respond to treatment by other means. Therefore upon this phase of epilepsy

MODERN METHOD OF TREATMENT

It has been my experience that for the successful handling of the epileptic symptom complex one cannot rely solely upon the ketogenic diet. Quite often ketosis must be supplemented by low NaCl, high calcium, intake and limitation of fluids. I have called back several patients who were only improved on a ketogenic diet alone, who with this combination treatment are now convulsion free. Each of the above methods, ketosis, sodium-calcium change and dehydration will arrest certain patients. Many of them need a combination of two or three of these systems of treatment. McQuarrie¹⁰ is in accord with this experience and Bauer¹⁹ placed 27 children who showed only 35 per cent cures with the ketogenic diet on Fay's method of dehydration with the result that "the same group over a period of one year under control showed almost 100 per cent symptomatic relief of attacks." Helmholz¹⁰ patients not helped by withdrawal of water when a ketogenic diet failed, were not reported in detail and may belong to the group which needs all three methods to arrest convulsions. Perhaps they even fall into the class of Howard West's²⁰ case of an epileptic child with an associated diabetes who even with impending diabetic coma with a low plasma carbon dioxide figure continued to have seizures. This case stands as a shining example of one of the 35 per cent of cases which ketogenic diet does not cure, probably because of an advanced organic brain lesion. Such an isolated experience should not discourage one from continuing with the ketogenic diet treatment but empha-

sizes the necessity of combining the newer methods with it.

It is often found practicable to give from one to three grains of luminal a day in the early stages of treatment though this is not always necessary. When stopping it, it should be withdrawn gradually.

CAUSES FOR FAILURE

Early epilepsy, particularly *petit mal*, apparently can be cured, *grand mal* when well established can be arrested, not cured. Advanced organic brain changes are the chief causes preventing successful treatment.

If there is a removable focal organic brain tumor, operation should not be delayed. Parker²¹ reported that in a series of 313 brain tumor cases seven per cent had no other symptom than convulsions for over a year. Twenty-one per cent had convulsions some time in their course, and a convulsion was the initial symptom in over half of these. Advanced degenerative organic lesions in the Pacchionian system or cortex, and developmental venous anomalies often defy treatment. A complete neurological examination including x-rays of the skull and ventriculograms should therefore be done on all convulsion cases.

Old age, chronicity, mental deterioration, psychopathies, and lack of intelligence or cooperative ability spell failure in direct proportion to their extent. Good physical and mental hygiene without the factors of fatigue and emotional stress and worry are essential. Mechanical factors such as mistakes in calculations, variation in foods, too little explanation to the patient, too small a degree of ketosis,

etc., must be considered. It is often necessary to increase the degree of ketosis over that necessary to give a slightly positive diacetic acid test in the urine. A fluctuation in the degree of ketosis may be due to an individual variation in the absorption of fat in different persons. When a high degree of ketosis fails, further water restriction or a change in the mineral metabolism should be effected.

DANGERS OF THE KETOGENIC DIET

Since the including of yeast and viosterol in the ketogenic diet, no deficiency diseases have been reported. No harm has been reported from a negative nitrogen balance which, if present on the low protein intakes used, is only transitory. Whether the two grams protein per kilogram of body weight as recommended by McQuarrie²² are necessary, or the one and one-fourth grams as usually given to growing children, sufficient, is not settled. Adults seem to do well on two-thirds of a gram of protein per kilogram body weight as Wilder has proven with diabetic diets. It is customary now to give calcium lactate to prevent the tendency to a negative calcium balance which high fat diets invoke, as well as for its dehydrating and sedative effects. In this regard it should be noted that calcium lactate $\text{Ca}(\text{C}_6\text{H}_7\text{O}_7)_2 \cdot 5 \text{H}_2\text{O}$ with a molecular weight of 308 in the process of metabolism gives an available glucose, $\text{C}_6\text{H}_{12}\text{O}_6$, molecule of 180. This means that the eight grams of calcium lactate which is often prescribed daily would develop in its metabolism 4.67 of anti-ketogenic glucose.

The hypercholesteremia of high fat diets has yet to be proved deleterious with epileptics as Joslin²³ holds it is

for diabetics. So with the giving of brewer's yeast, viosterol, and calcium lactate with the ketogenic diet, and with water restriction to twenty ounces the deeper states of ketosis are not often necessary to control convulsions and a sufficient supply of nitrogen and an unharmed amount of fat are consumed. Amenorrhea in women is prevented by the vitamin B of brewer's yeast.

THERAPEUTIC APPLICATIONS OTHER THAN EPILEPSY

It is common knowledge that the high fat diet, through its high vitamin A content, reduces the number and severity of infections such as colds and influenza. Prevention or attenuation of measles and scarlet fever is also noted. Higgins²⁴ has suggested that because of the lessened fecal bacterial content the ketogenic diet should be tried in arthritis or other diseases thought to be due to absorption from the colon. Clark²⁵ and Helmholz²⁶ have unpublished data to show the ketogenic diet to be a distinct adjunct in the treatment of certain types of urinary infection.

Wolbach and Howe²⁷ of Harvard, on animal experimentation, concluded that vitamin A deficiency allows injury to all epithelial structures, namely of the respiratory, alimentary, genitourinary systems and the cutaneous, and that the high vitamin A content of the ketogenic diet tends to strengthen this defense against bacterial invasion.

Migraine headaches have been treated with about the same degree of success as the epilepsies with the ketogenic diet. A few cases of asthma have been treated with the ketogenic diet. It is suggested that the ketogenic diet

MODERN METHOD OF TREATMENT

Higgins²⁴ has suggested that because of the lessened fecal bacterial content the ketogenic diet should be tried in arthritis or other diseases thought to be due to absorption from the colon. Clark²⁵ and Helmholz²⁶ have unpublished data to show the ketogenic diet to be a distinct adjunct in the treatment of certain types of urinary infection.

Wolbach and Howe²⁷ of Harvard on animal experimentation, concluded that vitamin A deficiency allows injury to all epithelial structures—namely of the respiratory, alimentary, genito-urinary systems and the eye and skin and that the high vitamin A content of the ketogenic diet tends to strengthen this defense lining against bacterial invasion.

Migraine headache has been treated with about the same proportion of success as the epileptic cases in which a few cases of asthmatic cough have been benefited. These last two are suggestive of allergy as the cause of the

lepsy Rather would we say that the shift in acid-base equilibrium of the body fluids was a predisposing cause to both the phenomena of "allergy" and epilepsy

It seems logical to treat all post-traumatic head injuries by some method of dehydration to prevent later complications such as epilepsy for permanent nerve changes can be initiated by a few hours intracranial pressure and its consequent anoxemia

We see, then, that the ketogenic diet has been found a useful adjunct in the treatment of

- 1 Migraine,
- 2 Asthma,
- 3 Infections of the urinary tract, and
- 4 As a prophylactic against the common acute infections and infectious diseases

SUMMARY

1 Ketogenic diet ketosis acts differently physiologically from acidosis caused by a shift in acid-base equilibrium, and has other effects than dehydration The ketogenic diet is still necessary, therefore, in the treatment of epilepsy

2 In the light of the studies of the last decade we must consider all epilepsy as symptomatic from organic changes in the central nervous system, and not "idiopathic"

3 Until the "precipitating cause", thought to be some physiochemical state, is discovered its cure is not possible The arrest of convulsions is obtained, however, in the majority of cases under controlled conditions of ketosis, sodium chloride-calcium ion balance and water balance

4 The results reported from the use of the ketogenic diet alone without

special attention to the water or mineral metabolism are surprisingly uniform About one-third of the intelligent, cooperative epileptics can be arrested, another one-third are benefited so that they wish to continue with the diet, but one-third are not helped Those that are benefited have only slight lesions

5 The ketogenic diet stops *petit mal* definitely in many early cases, dehydration not benefiting these patients *Petit mal* is, therefore, the one phase of epilepsy that may be cured

6 The modern method of treating epilepsy with a combination of ketogenic diet, dehydration and shift in the sodium-calcium ions arrests convulsions in the majority of cases A "cure", however, is no nearer now than in 1921, when the ketogenic diet was first introduced

7 The chief causes for failure are brain tumor, mental deterioration due to chronicity and old age, psychopathic states and lack of cooperation

8 The dangers inherent in the ketogenic diet such as nitrogen, calcium, and vitamin deficiency are controverted by yeast, viosterol, and calcium intake sufficient to prevent pellagra, amenorrhea, and negative nitrogen and calcium balance Fluid restriction permits a mild ketosis without a high degree of cholesteremia formerly found with a stricter ketogenic diet

9 The ketogenic diet has been found a useful adjunct in the treatment of migraine headache, asthma and urinary infections, and, in the persons who are receiving it, it acts as a prophylactic against the common acute respiratory infections such as colds and influenza as well as the acute infectious diseases of childhood

The Treatment of Cavities in Pulmonary Tuberculosis

By LEROY S. PETERS, M.D., F.A.C.P., *Albuquerque, New Mexico*

AFTER observing tuberculosis clinically for the past 26 years, you can hardly blame me for not becoming overly enthusiastic when some optimist suggests the expectant treatment of cavities, claiming that nature, with the aid of bed rest, hard pillows and plenty of endurance, will effect a result as often as those of us who advocate interference by means of various forms of compression therapy.

We have had the curability of tuberculosis sung from the housetops over so long a period of time that many medical men really delude themselves into thinking that it is a curable disease. To disabuse yourself, you need but scan the statistics gathered by competent men the world over. True, when the disease is diagnosed early and proper advice given, the majority of those patients get well. However, early diagnosis is a rarity as is evidenced by the fact that sanatoria over the country show the large percentage of their patients in the moderately advanced and the far advanced stages of the disease.

Let us then face facts and not fancies. We deal with a clinical entity and not a supposition contrary to fact.

Presented at the San Francisco meeting of the American College of Physicians, April 5, 1932.

When tuberculosis passes the early stage, cavitation occurs in the majority of patients, evidenced either by physical signs or x-ray examination. It may be present also in early tuberculosis, when the onset has been acute and the process exudative. But cavities are cavities, and should instill into the minds of the tuberculosis worker a wholesome respect for their presence, and a well grounded desire for their elimination. They are all too dangerous and the sooner we realize the possibilities of aspiration, extension, hemorrhage and milary spread, and then act upon the realization, the more we shall be doing to restore the health of an otherwise probably doomed consumptive. We are too prone to remember the patient who lived for 20 years with an open cavity, and forget the hundreds who are dead within 15 months of the time the cavity was diagnosed. Clinical impressions may have their place in medicine, although I doubt it, but facts form a much saner basis for successful treatment of disease.

The pathologist has worked out various types of cavities and has shown how and why healing takes place. He can tell you which cavities nature will heal and why nature can effect a result. He knows from the appearance of

the wall whether or not we can expect a collapse of a given cavity. He can tell you from the location in the lung whether mechanical interference is necessary or whether magic will do the trick. He has converted many clinicians who feel the urge to play a game of watchful waiting to see what an all-wise Providence may or may not do. I admit that small grape-skinned cavities situated beneath the clavicle offer better chances of spontaneous healing than large thick-walled cavities in a more mobile part of the lung. I also admit that nature at times performs marvelous feats, but I am cognizant also of the fact that she has made many failures.

Then, too, we must not lose sight of the fact that an economic problem is involved. Most patients can ill afford years of cure-chasing when some simple procedure may restore health in months rather than years. Since the depression, the world is full of the new poor, a situation which makes active resistance rather than passive doubly advantageous.

In glancing over the literature written by advocates of the watchful waiting policy, I cannot let pass unchallenged the article by Fales and Beaudet.¹ These authors claim better results by means of bed rest than I have been able to attain by compression therapy. They show healing in 66 per cent of small cavities, 23 per cent of large cavities, and 32 per cent of cases with multiple cavities, or an average healing of 40 per cent in all types. They chose to compare these figures with my percentages published in 1929² before intrapleural pneumolysis increased the averages markedly. Published reports

of my work³ were available at the time they made use of the less favorable figures. They elected to show that 39 per cent of my cases gave complete collapse by pneumothorax, and inferred that this was the end result in cavity healing. They should have averaged the percentage of healed cases in complete collapse, or 53 per cent, and the healed thoracoplasties, or 36 per cent, making a total of 45 per cent of healed cavities. The later statistics to which they did not refer, increase this to 57 per cent. In other words, compression therapy shows healing of cavities in 57 per cent of cases, and rest shows healing in 40 per cent—a 17 per cent advantage for compression treatment. Then, too, they forgot that the class of cases we treat shows large or multiple cavitation in the majority of patients, and that this class is the least benefited by the rest regime. They also attempted by combining the group in which cavities that are healed and that in which they are made smaller to make the results show to better advantage. Unless cavities are healed, they are still a grave menace and no apologies should be offered for allowing them to remain open.

In an analysis of 700 cases of artificial pneumothorax,² I showed the following results:

Complete compression
53% well 24% dead
Partial compression
25% well 44% dead
No free space
16% well 60% dead

A glance at these percentages shows conclusively that closure of cavities pays, since the complete compression cases with cavities closed show 53 per

cent well and 24 per cent dead, and the "no free space" cases—the ones on whom it was impossible to do a pneumothorax—show 16 per cent well and 60 per cent dead. These same failures were of necessity treated by bed rest. There was nothing else to do.

Many partial compressions are now made complete by intrapleural pneumolysis, and many of the pneumothorax failures are being given the benefit of extrapleural pneumolysis or thoracoplasty. In fact, everything is being done to eliminate the cavity.

I like Pinner's classification of cavities since it is simple and practical. He divides them into (1) honeycombing or multiple small cavities, (2) small round or slightly oval cavities with or without perifocal change, (3) irregular shaped cavities with thick walls. The second type offers best chances for compression therapy, although honeycomb areas collapse if not too near the apex where the lung is usually firmly adherent. The irregular shaped cavity with thick walls is hardest to collapse, and yet many times perseverance wins.

Let me here outline the various methods and their indications. First of all rest is utilized to see what the patient can do with small cavities or honeycomb areas. Enough cavities heal spontaneously to warrant this expectant treatment for a reasonable length of time, but for a reasonable length of time *only*. This period should be put at three months, and then if no attempt at healing has taken place, institute at once some form of compression.

Phrenicectomy is the method of choice in small round cavities with thin walls, the so-called grape-skin type. No matter where situated, this

form of compression should be tried first. Then if collapse is not attained, a pneumothorax may be attempted. The fact that a phrenicectomy has been done is no barrier to pneumothorax treatment—oftentimes it is an aid. This, too, is the method of choice when pneumothorax has proven a failure before resorting to extrapleural pneumolysis or to thoracoplasty.

Pneumothorax is by far the most satisfactory form of compression therapy in the majority of cases, and should be the method of choice when phrenicectomy fails, or in the cases showing multiple cavitation or large cavities with thick walls. After two or three months, if adhesions prevent the closure of the cavity, intrapleural pneumolysis, if feasible, should at once be attempted. This procedure converts many partial collapse cases into complete collapse, with resultant cavity closure.

Many cavities—situated in the upper third of the lung where adhesions cannot be burned—are suitable for extrapleural pneumolysis. This is fairly successful when the lung is held firmly from below by a pneumothorax or when adhesions are dense so that when paraffin is implanted the lung does not slip away thus defeating the purpose of the paraffin pressure.

Thoracoplasty falls next in methods of choice. The longer we are in this work, the more prone we are to do everything possible before resorting to radical surgery. More and more patients are given the benefit of pneumothorax, and less and less thoracoplasty. When proper selection is made and all other methods have failed, this surgical procedure proves effective and should

by all means be advised. Our results show 36 per cent made well but also 42 per cent dead over the years, and this is due to the fact that tuberculous patients are poor surgical risks at best, and thoracoplasty is *major* surgery.

Intelligent physicians should recognize the necessity of conservatism. Fads must be thrown into the discard at once, but progress in the treatment of disease can come only when we prof-

it by experience and learn to evaluate our own work and that of others. The man who temporizes with tuberculosis today, who treats advanced disease by bed rest alone, and the usual routine of twenty-five years ago, failing to utilize the methods of compression therapy at his command, is a menace to his patients, and is not giving the best the profession has to offer in the treatment of this disease.

Chronic Invalidism with Marked Personality Changes Due to Myxedema

By HENRY F. STOLL, M.D., F.A.C.P., *Hartford, Connecticut*

THE clinical aspect of myxedema was presented with such thoroughness by the special committee of the Clinical Society of London appointed in 1883 to study this disease that little if anything has been added to the clinical picture since that time. Among the 109 cases reviewed, it was found that slowness of thought and mental disorders of an irritable and suspicious character, with hebétude alternating with somnolence, were very common. Delusions and hallucinations occurred in one-half the cases and insanity was noted in about the same per cent. Acute or chronic mania and dementia were common with a marked predominance of suspicion and self-accusation.

Since the advent of simple apparatus for determining the basal metabolism, the condition is frequently detected, especially in hospitals and clinics where routine tests are performed. Yet the disease is often undetected for many years as the cases here presented illustrate.

One is impressed with the marked personality changes present in the advanced cases: irritability, untruthfulness, suspicion, delusions, retarded

cerebration, inability to concentrate, introversion and failing memory are conspicuous in the cases here reported. It is quite obvious that these patients are very difficult to get on with and as they frequently live many years, the home is sometimes wrecked as a consequence.

CASE REPORTS

Case I Nearly every pleasant afternoon after banking hours some twenty years ago, one could see a fine-looking old gentleman with closely cropped beard sitting in a buggy with the top thrown back, driving a rangy bay horse about the streets of Hartford. On the seat beside him was what to a casual observer might easily have been mistaken for an image of Buddha. The sallow, brown skin, the puffy, expressionless face and the sinister appearance in general, resembled closely the image of the great god. Whenever I saw them I was deeply interested because a few years before, while an intern in the Hartford Hospital, this woman, the wife of the banker, had been a patient of mine suffering from a badly infected arm. Her appearance at that time was essentially the same.

The arm healed slowly and as she was rather concerned about the fact that her hair was falling, I prescribed a "hair tonic." Her appearance suggested nephritis but a careful study did not reveal any renal lesions. Her speech was slow and monotonous. Everyone thought her "queer", however because of her universal suspicion of much of the treatment. It was very difficult to have her take her medicine as she was sure

she was being poisoned and surreptitiously she would telephone her husband to tell him she was sure she was being given poison. We then learned that for a long time she had acted queerly and had grown increasingly suspicious. That her symptoms were due to lack of thyroid secretion never occurred to any of us.

Some years later she came under the care of Dr I W Kingsbury who recognized the condition and attempted to administer thyroid. She was so psychotic however that she never could be made to take medicine with any regularity and consequently few, if any, beneficial results were obtained. A large part of her husband's life was spent in a futile endeavor to have her recover her health. There was no such thing as family life; the children grew up without the usual mother's solicitude and guidance and the family was all but wrecked, due to her years of invalidism.

Case II Shortly after the war, I used to see about the streets a man of middle age whose appearance fascinated me. He was about medium height, stocky and thick-set. He had a distinct pallor combined with a bloated appearance of the face and he was bald except for a few wisps of hair, here and there, that appeared to have sufficient tenacity to remain in place.

He walked with a plodding gait, lifting his feet but little above the sidewalk. When getting aboard a trolley car he would lurch forward and was able to get on only with great difficulty. As I subsequently learned, when going upstairs at home he would have to go up on his hands and knees.

He consulted me in July, 1919, complaining of weakness, shortness of breath and awkwardness in his movements. He also suffered from bleeding hemorrhoids, a not uncommon complication of myxedema. Because of his clumsiness in getting about and working, he was forced to give up a lucrative position in a shop as he no longer was sufficiently deft. He had recently attempted to support himself as an itinerant salesman of barber supplies. From his wife I obtained the following information:

"Until he was 26 years of age he had a good position in a shop and worked steadily

FIG 1 Case II Taken in 1900, before appearance of symptoms of myxedema. Note alert expression of eyes.

He was of a jolly, buoyant disposition and lived happily with his wife. When about 26, twenty-seven years prior to my seeing him, he began to have difficulty in doing his work as rapidly as hitherto. At 34 he had what was probably an abscess of the lung from which he made a good recovery. However thereafter he was able to carry on his work only with a great deal of assistance. He would outline a definite plan of action involving a large number of details that would require several days to consummate, if I did not watch him", said his wife, "and make out orders and keep track of everything connected with the business. When he was about half through, he would get things all mixed up so that he did not seem to remember when I tried to tell him what his first plans were. He was in poor health all the time and under some doctor's care most of the time. He began to grow stout but it seemed more like bloated than healthy flesh. He was in this condition for several years. The doctors consulted told him they could find no serious trouble but he seemed to grow fat. He grew an old man. About seven years ago I was positive that he had some trouble for he seemed changed in every way. Others did not notice this and I was not able to

FIG 2 Case II Taken about 1905 The tissues of the face have a thick puffy appearance and the lack of lines of expression is apparent

my women friends began to tell me that he had changed so much in his actions that they did not like to be left alone with him. About this time his attitude with regard to sexual relations towards me changed very definitely. He had hitherto been very considerate but now his demands were very excessive, so that I never remained alone in the room with him. At about this time there was a distinct change in his disposition. He had always been good-natured but now he began to fly into a temper over trifles and to appear to think I wished to get rid of him. He became very suspicious, especially when anyone was talking where he could not hear what was being said, as he was sure they were saying derogatory things about him. He refused to take medicine or even food unless I took some and he became very despondent.

He had spells that were like fainting, although he did not lose consciousness, he would fall down and lie perfectly still and at other times he would have a very stupid expression. He had been having these 'spells' for the past eight or ten years.

About two years before I saw him, his hair began to grow thin. At no time in his life had he ever perspired normally and he felt the cold extremely, in fact he remarked that it was the joke of the family because he was so cold. Photographs taken in 1900, when he was 18 years old, showed him as an alert individual. Those taken during subsequent years showed a distinct change in appearance, a bloated condition of the face and complete loss of all expression until finally, just before I saw him, his expression had lost all resemblance to that of a human being and his countenance was bestial.

It was not possible to have a basal metabolism test made at this time, but he was immediately put upon thyroid with most dramatic results. Within a month after treatment was started, his speech became very much more rapid, his ideas came more easily and there was a marked improvement in his ability to walk. For the first time in his life he began to perspire. Soon his head was covered with fine soft hair except for a small spot in the back where the hair usually becomes thin past middle age. He was no longer recognized by his former patrons, in fact, one barber asked him what had become

FIG 3 Case II Taken at the conclusion of treatment after patient has resumed his work. Note the alert expression

of the other fellow who used to visit him with the barber supplies. Before long, he returned to his occupation as an expert tool-maker where great skill and accuracy are required and he was rated as the best workman in the room of thirty.

The noteworthy points were the apparent good health up to the age of 26 years, notwithstanding the fact that the thyroid was functioning at a somewhat low level as evidenced by the fact that the patient never perspired, the gradual development of symptoms following an acute illness, the slowing up of mental processes, the development of delusions, attacks of unconsciousness, loss of a lucrative position and the almost complete breaking up of the family as his wife had been urged by friends to secure a divorce. Finally, the complete restoration to health following thyroid administration after over twenty years of semi-invalidism.

Case III A few years ago I was asked to see a woman of 70 years of age who was considered by her neighbors to be "not right" mentally and by her family as "bordering on insanity." For five years previously she had been in very poor health and for three years confined to her home by reason of weakness. She complained much of pain in the back of her head and neck, apparently following an attack of herpes zoster three years before. There had also been attacks of pain suggestive of gall bladder disease. She felt the cold intensely and complained so bitterly that the house had to be kept so hot that the other members of the family could scarcely stand it. As a child and young woman she did not perspire.

She exhibited poor judgment in meeting the events of everyday life and was most unreasonable, combative and difficult to get on with. She would repeat things over and over many times and was extremely egocentric. A grown daughter who was in business

always dreaded returning home from the office because of her mother's irritability. The patient's husband, just before his death a few years previously, told his daughter she would have need of all the patience she could muster to stand her mother's constant nagging and faultfinding.

Shortly before I saw her, some lay friend suggested that she might have myxedema, as a relative who had had this malady presented similar complaints and accordingly thyroid administration had been started without, however, any material change at that time. She presented a bloated expression with pallor of the mucous membranes, no axillary or pubic hair, the skin though bloated was somewhat wrinkled in places and very dry. Speech was slow and thick as though the tongue were swollen. Tactile and pain sense seemed to be much diminished over the legs, knee jerks were normal, the ankle jerks were not tested. She had a rather marked secondary anemia. With the improvement following thyroid administration, the change in her voice was so marked that it was not recognized over the telephone. (This occurred in another case not here reported.) Her daughter subsequently wrote me that she was a different person from the woman she had known all her life.

Case IV Three years ago, there was admitted to my service at the Hartford Hospital, a middle-aged woman complaining of nervousness. It was very difficult to obtain a history from her as she seemed confused. She stated that nine years previously she had a child that died at birth. She worried a good deal and felt that her illness dated from this time. From her son-in-law it was learned that when he first knew her ten years previously she was a strong, healthy woman, energetic, ambitious, doing all of her housework, not complaining or manifesting signs of nervousness. He had noted a marked change during the past few years. She became quite garrulous and her chief conversation was concerning her fears of the aches and pains which she felt growing in her body. At times she was unable to dream, saying that she had frequently nothing to think she was not able to sleep, well she was not able to sleep at all.

down much during the day. More and more she has neglected her housework so that she does very little. Occasionally she will start off with considerable energy but promptly becomes very tired and has to stop and rest. She is very easily upset about trivialities, as for instance, when her husband would ask her if a certain bill had been paid, she would break into tears and cry for a long time. She appears very slow in understanding and requires a long time to answer questions. Walking up to the store, a short distance from her home, she becomes very tired and on her return is completely exhausted. As he expressed it, "She has not been easy to live with and has not accomplished much in her housework."

Many physicians had been consulted and much medication prescribed apparently, however, without any real improvement. One physician whom she had consulted every few weeks for the past few years stated that he was giving her medicine which would help her "low blood." Six months before entering

the hospital, her teeth were all removed. Because of the pains in her feet she had x-rays taken and special shoes made but they did not relieve the pain nor improve the numbness in her legs. At all times she complains of feeling the cold very acutely and in hot weather never perspires. Finally, as she expressed it she "did not know whether she was going or coming." Confidentially she explained that she was sure there was pus still in the sockets of her teeth which were removed and this undoubtedly was caused by the "poisoned pills" which her previous physician had given her. She frequently referred during the early part of her sickness to the "poisoned medicine" that her doctor had given her.

It was difficult for me to realize that this sallow-complexioned woman with expressionless, bloated face and sluggish mentality was the same individual who 15 years before was an alert, bright and capable waitress in a restaurant where I often had lunch, but such was the case. The basal metabolic rate was

FIG. 1. Case IV. 'A' was taken before treatment and 'B' three months after treatment had been started. Note in the latter the absence of supraclavicular pads and of thickness of the feet. There has been also a marked change in the appearance of the hands and in the texture of the skin.

—43 She was given three grams of thyroid a day and the rate reached normal 15 days after the thyroid was started, only 56 grains in all being required to bring about the remarkable transformation

For the past three years she has been taking from two to three grains of thyroid daily, the metabolic rate varying from —5 to —20, according to the amount of thyroid, but no detectable clinical change accompanies the change in rate

Case V A woman of 69 consulted Dr Alexander Prince in February, 1923, because of failing vision. He was immediately impressed with her appearance and, suspecting that she had myxedema, sent her to me for examination and basal metabolism estimation. In addition to her poor vision, she had had "a cold feeling" for two years and for the past year this had been much worse. Her last child was born when she was 35. This

was followed by the menopause and since that time she had been in poor health. The first symptom noticed was the sensitiveness to cold and what she described as "choking spells". For years her speech had been thick, but this thickness has increased and now is accompanied by hesitation. Her memory is poor. For years she has not perspired. Especially distressing has been what she refers to as a numb feeling through her knees and at times they ache a great deal. Following the death of the child referred to, 24 years ago, her hair began to fall. Severe headaches were helped somewhat by glasses. She has become weak though gaining in weight, and has become exceedingly suspicious. She was rather pale, with puffy, expressionless face and exhibited a slight rocking of the head from side to side. The lower lip was thick, the speech slow and difficult to understand, the skin was dry. The basal

FIG. 5. Case V. A, taken on Feb. 1, 1923, with basal metabolic rate —22, or 60% below normal; B, taken on April 23, 1923, with basal metabolic rate normal.

metabolic rate was -24 . The rest of the examination was not remarkable. The most important data, as is usual in these cases, were supplied by a member of the family.

The outstanding features, according to her daughter-in-law, were her selfishness, deceit, and extravagance. As she did not like one of her daughters, to eliminate her from the home, she consented to her making an undesirable marriage, notwithstanding the protests of her husband, relatives, and friends. Her son was not able to remain at home because of the "everlasting nagging and bickering." Though faultfinding in her home, she was very boastful of her children when talking to others. She would suddenly decide to visit friends at most unusual and inconvenient times, leaving home without making any provision for someone to take care of the fires or the house. Untruthfulness was also a conspicuous feature. A curious eccentricity was a remarkable fondness exhibited towards her son-in-law notwithstanding the fact that he ill-treated his wife (her daughter). Finally, her husband, his patience utterly exhausted, left her.

Under thyroid administration she made a very satisfactory recovery and during recent years, though over 70, she has worked much of the time as a practical nurse.*

Attention has been drawn by Lund and Benedict² and later by Benedict,³ to the fact that patients with myxedema are unduly susceptible to morphine. They state that not only

does morphine cause a drop in the basal metabolic rate of ten per cent in normal rabbits but that in hypothyroid rabbits the drop is twenty per cent. They report several cases in which alarming results followed the use of morphine in patients with myxedema.

One instance is given in which the condition had been unrecognized for years, the patient received morphine three times for various operations, each time causing grave concern to the surgeon. Another patient who reacted badly to morphine when the metabolic rate was low, subsequently showed no untoward symptoms to the drug when the rate was above normal. One patient died. In this connection the following case is of interest.

Case VI Two years ago, a middle-aged Italian woman was admitted to my service, complaining of dizziness and weakness. She had not been able to work for seven or eight years. She was apathetic, rather obese, with moderate hypertension. Complete laboratory and x-ray investigation was negative except for basal metabolic rate which was -19 .

She showed much improvement after three weeks of thyroid feeding at which time the metabolism index was -11 , later it dropped to -16 . On the day the last test was recorded, she had a molar tooth, about which there was an abscess, extracted under gas-ether anesthesia. She was given one-sixth grain of morphine hypodermically, at 11 45 A. M. During the extraction she stopped breathing, at 1 10 P. M., and was pronounced dead at 1 30. Artificial respiration and intracardiac stimulation proved unavailing. Respiration ceased 85 minutes after the morphine was given. Autopsy was not obtained.

It is of course speculative as to the cause of death but in view of Lund and Benedict's work, it is at least suggestive that the combination of morphine and myxedema played a part.

*This patient died in September, 1932. An autopsy was performed by Dr. W. M. Allen. The microscopical examination of the thyroid showed that about two-thirds of the gland was made up of dense cellular fibrous tissue. There were small islands (2 mm.) of lymphocytic infiltration. In the center of these there remained a few atrophic distorted thyroid follicles. The epithelium was markedly atrophic and an occasional acinus contained a small amount of markedly eosinophilic colloid. There appeared to be no functioning tissue. The heart and liver showed fatty degeneration.

When morphine poisoning occurs in known or suspected myxedema, the intravenous use of thyroxin, as used by Lund and Benedict, is probably the best possible treatment

The anemia that accompanies myxedema may be of the so-called secondary type due to the low level at which the blood-forming system is operating or to blood loss as frequently occurs from bleeding hemorrhoids. Sometimes true pernicious anemia coexists and it is essential to administer both thyroid and liver to obtain complete amelioration of symptoms.

Mason, Hunt and Hurvath⁵ found that with true myxedema there was a marked elevation in blood cholesterol that did not obtain in low metabolic rates, unaccompanied by clinical evidence of myxedema. As the metabolic rate rises, the cholesterol falls and is below normal when the patient is hyperthyroid.

That there is a "myxedema heart" has been asserted and denied. Characteristic findings are described as being: "a heart enlarged in transverse diameter, prolongation of the interval between auricular and ventricular contraction, an inversion of "T" wave in all three leads, small "P" waves and slurring of QRS complex. White⁶ considers a flattening or inversion of the "T" wave in all leads "almost pathognomonic" of myxedema. When cardiac symptoms are present, thyroid should be administered but the initial dose should be small. These patients are often benefited but untoward results may occur.

Lack of perspiration is characteris-

tic of myxedema. Accordingly we were much interested a few years ago in a patient with this disease who perspired profusely on the palms of the hands. They were literally dripping wet.

Save for the occasional patient who is so psychotic that mouth medication cannot be carried out, there does not appear to be any reason for using thyroxin intravenously. The sudden and violent readjustment of the body can be avoided by the use of a potent tablet by mouth. Murray who appears to have been the first to administer thyroid to a patient with myxedema, used a preparation of sheep thyroid and his patient died at the age of 74 years, after taking the treatment for 28 years.

Though patients with spontaneous myxedema require thyroid all their lives, those with myxedema following radiation for toxic goiter often need it for only a few years, due presumably to regeneration of the gland.

Patients with myxedema often spend a great part of their lives and a large amount of money in a vain quest for health as their varied complaints take them in turn to nearly all the specialists in the healing art. Not infrequently they are committed to hospitals for mental diseases. The frequent failure to recognize the condition is particularly deplorable because the transformation of what Osler referred to as "a poor, unbecomingly, toad-like caricature of humanity" into an alert normal person by the administration of thyroid is one of the triumphs of medicine.

The Question of 'Primitive' Syphilis

"THAT the character of syphilis in the indigenous population of Asia and Africa differs in many respects from European syphilis can hardly be denied. In accounting for this marked difference, Bramsen repeats the usual suggestions of 'spirochetal strains', varieties of racial and social 'soil' 'lack of treatment', 'racial immunities', and the antisiphilitic action of tropical fevers, notably malaria. Mere mention of each suggestion reveals how little is known, and Bramsen indicates that the Orient offers itself as a laboratory not only on the history and epidemiology of syphilis, but also on its diagnosis, treatment, and control.

"There seems to be in the minds of writers on tropical medicine a concept known as 'pandemic syphilis', which, to quote one reviewer 'is contracted in childhood, the primary lesion passing not unnoticed but unnoted in a lowly living population among whom sores and ulcers are disregarded. Syphilis under such conditions may almost be regarded as one of the exanthems of childhood. Following the marked dermal reaction a considerable degree of immunity results and neuroparenchymatous syphilitic lesions do not develop.' In the mind of this reviewer this is 'acquired syphilis as seen in children', in which 'none of the well-known stigmata' of the congenital disease are present. Another pathologist prefers to call this 'endemic' syphilis, Butler writes of 'primitive' syphilis, and others refer to 'tropical' or 'indigenous' syphilis.

"There is doubtless general agreement that there exists among the lowly population of huge areas of the world a tremendous amount of treponematous infection, but when one begins to search textbooks and literature for a description of this pandemic syphilis, one finds almost no information as to its clinical character its serology and immunology, its epidemiology, its proper treatment, and the criteria for its cure.

"Most writers and reviewers of the literature of tropical medicine are taken up with yaws and with its differentiation from syphilis, to the exclusion of the larger subject as to the nature of syphilis itself in primitive peoples. Advocates of the duality of the two diseases overlook the fact that their strongest argument would be to delineate the symptoms and pathology of this pandemic syphilis which they state exists as a distinct disease side by side with yaws in tropical countries."

(Quoted from FETIS H. HUDSON, *Syphilis in the Euphrates Arab*, Am Jr Syph, 1932, vii, 447-469.)

Historic Montreal: Metropolis of Canada and Mother of the Cities of the West

By MAUDE E. ABBOTT, B A , M D , F R C P (Can),
McGill University, Montreal

FOR the first time in its annals the College is to meet in this beautiful metropolitan city that clusters around the slopes of Mount Royal and extends to east and west below these along the banks of the St. Lawrence as far as eye can reach. Snow-girt she will be then, and sparkling in her winter garment in air tingling with ozone that breathes of those mighty regions beyond of which she is at once the haven and the gate. For Montreal, the second largest seaport on this continent is the only one that lies 1 000 miles above the ocean to which her liners sail. She stands too at the confluence of the Ottawa and the St. Lawrence, those mighty river highways that lead, the one northward to its source, and the other inland by way of the Great Lakes to the heart of the American and Canadian West. It was this location, so favorable for the command of the water-ways as well as the intrepidity of her first *voyageurs*, that brought such phenomenal success to the early explorers from Montreal and the vicinity who first penetrated the vast fur-trading regions of this Continent and established outposts of civilization at many far-flung areas that have since become teeming centers of population both in Canada and the United States.

Moreover this great city which now

numbers some 1,200,000 inhabitants, had origin in a spirit of lofty idealism and a splendid fortitude that make its record a living force in world history today. Her foundations were laid amid thrilling scenes of Indian warfare and French heroism by a mere handful of devoted men and women, in whose hearts the zest of discovery and the love of adventure burned with a flame tempered by a profound religious faith to the steady light of a true consecration. Her boundaries extended and her resources multiplied with the years in spite of adverse trade conditions, devastating epidemics, internal dissensions and the many difficulties that marked the passing of the old *régime*. From these vicissitudes she has emerged today the fifth city on this continent in point of population, the commercial metropolis of the Dominion, the seat of twelve large hospitals and of two great Universities representative of that dual culture in which two nations live united under the British flag. For in this Province of Quebec which has rightly been called the nursery of the British Canadian as well as of the French Canadian race and their institutions modern Canada was hatched as well as ancient Canada preserved.

The history of Montreal is that of a

one of merely local interest, but concerns the entire American continent. For Montreal gave de La Salle, Marquette and Jolliet to the discovery of the Mississippi, Du Lhut, Radisson, Nicolet and others to the penetration of the middle West, de la Verendrye and his sons to the pathfinding of the Great Lake districts and beyond, Archibald MacDonald and John McLaughlin to the civilization of Oregon, Alexander Henry and David Thompson to British Columbia and the Canadian West, these and many others, including "Bienville, Iberville, Laclede, Cadillac, Mackenzie, and Fraser, whose revered names live in eternal history from Louisiana to the Atlantic Ocean and across the continent to the Pacific Coast. New Orleans and Chicago, St. Louis, Detroit, Fort William, Duluth, St. Paul, look hither for their originators."³ Montreal was the headquarters, too, of Lord Selkirk in his settlement of the Red River District in Manitoba under the Hudson's Bay Company and it was the seat of residence and operation in the early nineteenth century of those pioneers in commerce and education, the great fur magnates of the Northwest Company of whom James McGill was one.

From this colorful record of the pioneer achievements of so many brave men, one turns with no less vivid interest to the city's own past, and to the evolution of its hospitals and medical schools and of those outstanding physicians whose names are linked with each advance. For many generations the main life of the town centered around its religious and philanthropic activities. So that alike in the birth and growth of the early French hospitals and in the foundation of that first

great British-Canadian charity, the Montreal General Hospital, we see reflected the most conservative and representative elements of the community grouped in concerted action for the common weal.

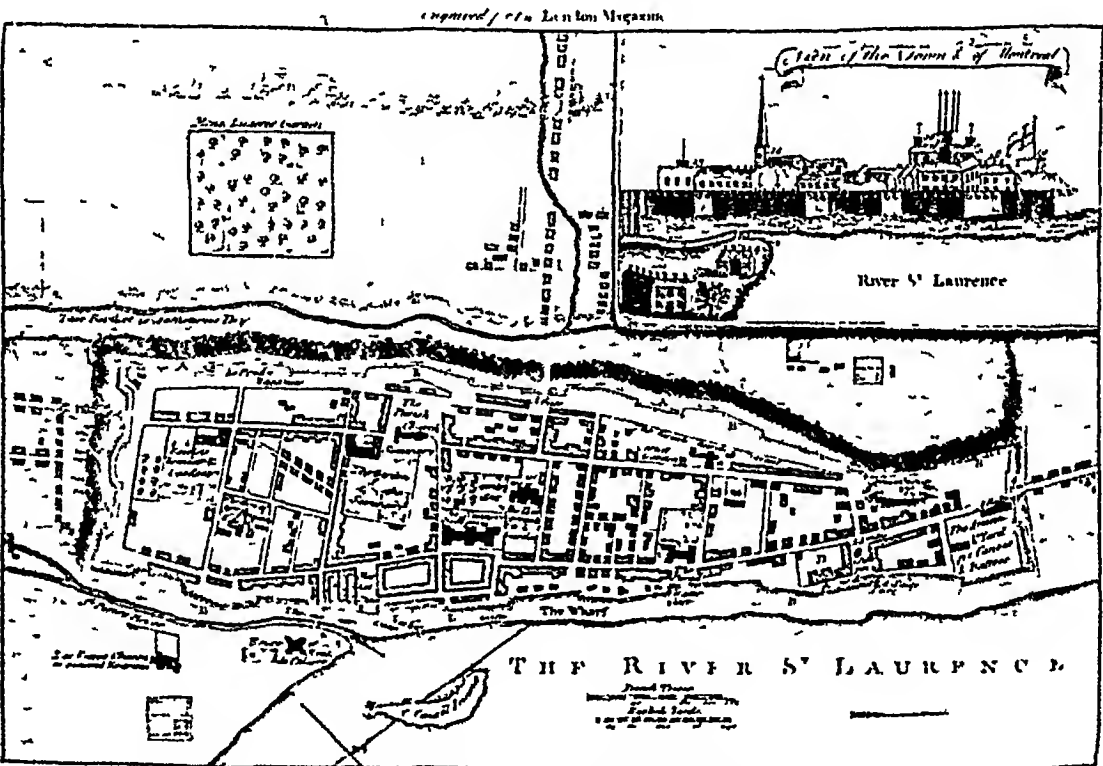

The first hospitals on the American continent were founded in Quebec Province, one the *Hôtel Dieu du Précieux Sang* at Quebec in 1639, and the other, the *Hôtel Dieu de St. Joseph* at Montreal in 1644. Indeed, this latter may be dated earlier, in 1642, with the foundation of Montreal, for Chomedey de Maisonneuve, with Jeanne Mance in his company, landed at the Pointe aux Callières (the present Custom House Square) in May of that year and in the log "habitation" erected by him on this spot and occupied by his little force in March, 1643, a couple of rooms were reserved for her and for the sick, and there was also a dispensary. The first Hotel Dieu building was erected, however, with funds from Mme de Bulhon, on land that is still the property of the nuns of St. Joseph on the corner of St. Paul and St. Sulpice Streets and was opened to patients in October, 1644. It had attached to it a modest farm of four *arpents* with two bulls, three cows and twenty sheep. There was a building 60 by 24 feet with two wards, a kitchen and a serving room, as well as a room for Mlle Mance who had sole charge of the sick until her return from France in 1659, when she brought with her three nuns of St. Joseph, to whom on arrival she made solemn transfer of her beloved hospital. Mlle Mance, however, continued to administer its affairs until her death in 1673. On two occasions she saved the little colony from impending dissolution by going to Paris and securing

FIG. 1. Statue of Jeanne Mance tending a wounded soldier, by Philippe Hébert. (Photograph from the clay model in the artist's studio, from which the bronze statue was cast in the courtyard of the present Hotel Dieu of Montreal was cast in 1880.)

in 1649, the reorganization of the tottering Société de Montréal, and again in 1651, obtaining there 22,000 livres to assist de Maisonneuve in the transportation of 100 men to hold the colony against the Iroquois. The terrible incursions of these relentless foes and the indomitable resistance presented by its defenders, together with the bitter cold of the Canadian winters in their imperfectly constructed building, make the tale of Jeanne Mance and these first hospital nuns who took over her work, one of almost unprecedented womanly heroism and a dauntless courage and self-devotion that has not often

found its parallel in history (See figure 1) This first hospital was burnt down in 1695, and again in 1721 and 1734, and was rebuilt thereafter as shown in figure 3. Until the English General Hospital was opened in 1822, the Hotel Dieu was the only medical hospital in Montreal, and it functioned as such through the great epidemics prior to that time and assisted in the military exigencies of the wars of 1760, 1765, and 1812. It was removed to its present site in 1861 and since then has had repeated extensions for purposes of modern equipment as shown in figure 13.

Plan of the Town & Fortifications of Montreal or Ville Marie in Canada

FIG. 2. Plan of Montreal in the year 1758. Showing the city surrounded by a wall which was four feet thick and nine feet high. At this time the town lay along the river front entirely below Craig Street which was then the bed of a small river and is seen here running from East to West near the top of the picture. The "old Hotel Dieu", entitled here "The Nursery Hospital", is seen lying on the upper side of St. Paul Street just to the left of the Seminary Gardens and the Parish Church above these. The Hôpital Général or the Freres Church occupies the site of the present Custom House Square, in the left foreground of the picture below the little river St. Peter. (From a print in the possession of the David Ross McCord Museum of McGill University.)

The *Hôpital Général* of Montreal, another venerable institution, was founded in 1694 as a House of Charity by François Charon in a building erected by him for the purpose near the river front at the foot of St Peter Street (see figure 2) After his death it fell into disrepute but was revived, with extended powers for the care of foundlings and the insane, in 1747 by Mme d'Youville, Head of the Order of Grey Nuns It functioned actively in these

distinguished authority on the local history of Montreal, have a mass of well indexed notarial material dating from the arrival of Maisonneuve in 1642, and are well worthy of a visit From these and from Mr Massicotte's publications a few notes are extracted here

The first medical names are those of *Louis Goudcan*, who is said to have accompanied Maisonneuve in 1642, and whose name is attached to the first notarial deed executed by Lambert Closse in 1642 and *Jean Ponp-*

FIG 3 The Old Hotel Dieu Hospital, situated on St Paul Street, between St Sulpice Street and St Dozier Lane Begun in 1644, it was demolished about 1861, when its successor the Hotel Dieu of today was opened on Pine Avenue at the northerst corner of Fletcher's Field

ways and on occasion also as a military hospital until the middle of the nineteenth century, but has now become, under the name of the *Grey Nunnery*, a huge charitable institution for foundlings and the infirm It removed in 1871 to the corner of Guy and Dorchester Streets and is no longer a hospital

MEDICAL PRACTITIONERS IN MONTREAL DURING THE SEVENTEENTH AND EIGHTEENTH CENTURIES

The Archives of the District of Montreal housed at the City Hall under the care of Mr E Z Massicotte,⁴ the

pee who officiated at the entrance into the world of the first children of European parentage born at Ville Marie These men must have helped Jeremie Vanez at her infant hospital but the first name officially attached to the Hotel Dieu is that of the *Abbe Surt*, first Sulpician cure of Montreal who had learned Medicine in earlier years and attended there from his arrival in 1657 to 1659 He was succeeded by *Etienne Beuchard*, a master-surgeon of Paris and a man of parts, who arrived in 1653 in the service of the Company of Montreal under an engagement for five years in return for an advance payment of 147 livres, he held the appointment of surgeon to the Hotel Dieu from 1659 to 1702 by a quaint deed under the great seal of the city with medicines two barrels of oil for Montreal for twenty years

per person so treated *Louis Chartier* also came out in 1653 in the service of the Company and was the friend and financial supporter of *Dollard des Ormeaux* but was himself drowned in the Ottawa in 1660 while defending the upper end of Montreal Island against the Iroquois

Bouchard was succeeded on the Hotel Dieu from 1674 to 1680 by *Jean Gaillard* and the latter by the two surgeons and medicolegal experts, *Jean Martinet* and *Antoine Forestier*, who were officially appointed in 1681 in

1681 *me Guertin*, midwife for the community. *Daniel Debonne*, who had taken medical degrees abroad, was physician to the Hotel Dieu of Montreal from 1770 to 1780

EARLY LICENTIATES UNDER THE ACT OF 1788

A very important French Canadian physician practising in Montreal in the years just succeeding the conquest was *Jean Bte Jobert* who took an active

FIG 4 Chateau de Ramezay on Notre Dame Street, once the residence of the French and Early English Governors Built in 1705, and now the Museum of the Montreal Antiquarian and Numismatic Society

an interesting deed which pledged them to "dress and treat the patients" in alternate quarters and to visit them diligently at 7 o'clock every morning and at other times when necessary at request "for 75 livres a year each, the remedies being supplied by the hospital". An important physician in Montreal in the next generation was *Dr Joseph Benoit*, surgeon and *medecin du roi*, who was on the staff of the Hotel Dieu from 1715 to 1719. Associated on it with him for a few years was the Irishman, *Timothée Sylvestre*, who obtained his license, under an order from the King, from the famous *Dr Michel Sarrazin* of Quebec by personal examination. A curious deed of this time reveals that the women of Ville Marie in solemn convocation assembled on Feb. 12, 1713 elected *Cette-*

part in the campaign then going on against the Baie St Paul disease, the malady, apparently an obscure epidemic form of syphilis, that was then ravaging the country from the Lower St Lawrence to the Upper Ottawa. His name is attached to a license dated 1788, granted by the first Licensing Board of the District of Montreal to *Henry Loedel*, father of H. P. Loedel, a member in the next generation of the first Medical Board of the Montreal General Hospital. With it are affixed the signatures of *Xavier Bender*, *Charles Blake*, *Robert Sym* and

FIG 5 The Montreal General Hospital in 1831, as seen from the rear, showing the central building erected in 1822 and the Richardson wing, before other additions had been made. From *Hochelaga Depicta*, 1839.

George Selby, a galaxy of well qualified physicians who practised medicine in Montreal in the latter part of the 18th century and who did yeoman work in the struggle for securing the medical legislation against quackery that resulted in the first Licensing Act of 1788. Dr Loedel entered later into partnership in Montreal with Dr Blake, who was a retired army surgeon and evidently a man of substance, for another interesting deed, dated 1785, records the sale to him by Elijah Cady of Boston, of three negroes "Tobi, Sarah and Boye" who remained in his possession a long time as attested by a notarial endorsement upon it thirteen years later.

An examination of early licenses in the Dominion Archives at Ottawa reveals many interesting facts. The first French-Canadian doctor to study abroad appears to have been Jacques Labrie, who took an Edinburgh degree

in 1807 and was granted the Provincial license for the District of Montreal in 1808. He wrote a history of Canada and practised at St Eustache some 25 miles from the city. On June 18 1795 a license bearing the signatures of Charles Blake, Robert Sym and John Rowand was granted to the famous Daniel Arnoldi called later the *Doyen* of the profession in Montreal who was long a member of the Board of Examiners, became the first President of the College of Physicians in 1841 and died in 1849.

Under the conditions engendered by the Act and from other causes the dawn of the nineteenth century saw a better class of physicians appearing in the Province. A new generation had arisen of Canadians (or in a number of cases Americans) born prior to 1800 who after receiving their professional training through a local apprenticeship proceeded to qualify for the Province.

cial Licentiate either by passing an examination before one of its District Boards or by obtaining a degree or diploma abroad. To these were added a few highly qualified British surgeons who had settled in the country after the war of 1812 and who played an important part in elevating professional standards and in formulating that demand for higher medical education that had already found expression in the organization of courses for medical students both at Quebec and Montreal as much as twenty years before the ultimate successful formation of the Montreal Medical Institution in 1823.

Thus it came about, that, in the second and third decades of the century, we find on the list of Licentiates for the District of Montreal a group of highly significant names, of men who, by their subsequent labors, set in motion an educational force that extended far beyond their own day and place. For these men, who became later the Founders of the future Medical Faculty of McGill, brought with them from their own school at Edinburgh, of which they were all four graduates, that precious gospel derived from Leyden, of clinical teaching at the bedside that is the keystone of the best medical education today. So firmly did they implant this doctrine in the principles of their infant institution and in the hospital from which it sprang, that it became for the successive generations of teachers here a living force. To it McGill's greatest graduate, Sir William Osler, owed and acknowledged his inspiration and he transmitted that early influence throughout this continent in his later years.

First on the list for the District of Montreal for the year 1816, stands the

revered name of *Andrew F. Holmes*, who later became the first Dean of the McGill Medical School. At that time he was a youth of 24, fresh from a classical education at Dr. Skakel's school and five years' apprenticeship under Dr. Arnold. Along with *John Stephenson*, his life-long friend and later co-worker on the McGill Faculty, he proceeded to London, Paris and Edinburgh where he graduated M.D. in 1819. Stephenson took a London degree in 1819 and one at Edinburgh in 1820, returning to receive the Provincial License in 1821, he became and remained for many years the Secretary of the Montreal General Hospital and Registrar of the McGill Faculty and has been universally acknowledged as "the man of all others who saved the bequest of James McGill to his University." In 1817 Dr. *William Caldwell*, a surgeon of the 34th Regiment of Dragoons, obtained his license, and *William Robertson*, a surgeon of the 59th Regiment, retired after the War of 1812, who was the fourth founder of the McGill School and long a member of the Board of Examiners for the District, fulfilled the necessary formalities in 1828. Another distinguished licentiate of the year 1828 was Dr. *Pierre Beaubien*, who graduated from the University of Paris in 1822, and after practising in that city for several years returned to Montreal to follow a career of great influence, especially upon medical education in the French-Canadian Schools. He is said to have introduced the use of the stethoscope into Canada. For many years he was a Professor in the *École de Médecine* of Montreal and later he became Dean of the Laval-in-Montreal Medical School and member for Mont-

FIG. 6. Montreal in 1852. View from Mount Royal, showing the Arts building and Bursar's Office of McGill College in the foreground, at left in the distance. The then country residence of James McGill, with its farm buildings and orchard occupying the center of picture surrounded by fields on what is now Burnside Place. The city proper lay below St Catherine Street, and Sherbrooke and University Streets are visible. The Montreal General Hospital with cupola and Richardson and Reid wings is seen in the left center and near the river-front is the Church of Notre Dame with its two spires and just to the left of it the old Hotel Dieu (From the Whitfield Print in the possession of the David Ross McCord Museum of McGill University.)

real in the Legislative Assembly. He left an illustrious name and founded an important family.

ORIGIN OF THE MONTREAL GENERAL HOSPITAL

This important development, which marks an epoch in the history of medicine in Canada, took form as a direct

stranded within her precincts. Failure of the crops during the summer of 1816 intensified the distress by impending famine, and in addition the lack of accommodation for the care of the sick poor made itself desperately felt, the Hotel Dieu being at that time the only hospital and provided with only thirty beds. In the winter of 1817 public

FIG 8 Osler in 1871, when a student at McGill University, from which he graduated in 1872

result of the distress of the poorer population in Montreal in the years immediately succeeding the battle of Waterloo. With the cessation of the European war there came a great influx of immigrants into Canada and this thriving little town then of some 16 000 inhabitants was overwhelmed by the flood of indigent and debilitated persons arrived from overseas whom the onset of the winter season left

legislation was enacted and private philanthropy engaged to meet this appalling crisis. It is an interesting historical fact that Montreal's first great civic charity, the English General Hospital, originated at this time through the initiative and activities of a small group of influential women who organized themselves for the relief of the "Distress of the Lower Class of the People" and "to alleviate those who

ful sufferings" of the indigent poor, under the name of the *Female Benevolent Society*

Two years later in the autumn of 1818, this Society succeeded in establishing a soup-kitchen to which was attached a small house of four rooms for the care of the sick called the "House of Recovery", situated on what is now Chaboillez Square. So successful was the work carried on there during the first twelve months of its operation that it was handed over to a group of business men and a larger house capable of accommodating twenty-four patients with three wards situated on Craig Street was leased and thrown open to patients on May 1, 1819, with "four professional gentlemen"* in attendance, one of whom (Dr John Stephenson) acted as house-surgeon. To this house the name Montreal General Hospital was given and here regula-

tions were framed, Quarterly Reports issued, and work carried on until May 1, 1822, when the present Montreal General Hospital on Dorchester Street was opened, the building at that time consisting only of the original central block surmounted by a cupola and protected in front by the iron railing that is still in place (see figure 5). This building had been erected at a cost of £5,856 of which amount a little over £2,100 was subscribed by the public spirited citizens of Montreal and the balance paid in the following year by the Hon John Richardson. Three other wings were added in the succeeding decades, in 1831, 1848 and 1874, and a smallpox building (since taken down) was erected within the enclosure in 1868, of which Dr Osler was put in charge in 1875 and himself became a patient there with this disease. It was on the basis of this experience that he wrote his "Initial Rashes of Smallpox". In 1874, also, he was appointed

*Drs Holmes, Stephenson, Caldwell and Robertson

FIG. 9. The first building of the McGill Medical Faculty in the university grounds, in which Osler lectured a professor of the Institutes of Medicine from 1874 to 1884. Erected in 1872 and destroyed, with its extensions, by fire in 1907.

Pathologist to the Hospital, there inaugurated the first systematic autopsy service in Canada, and performed during the ten years of his service 750 autopsies, thereby gaining most of the rich experience embodied in his Practice of Medicine. Some 150 specimens collected by him at these postmortems

actual headquarters of a medical school and for the instruction of students, who were to be admitted, following the example of Edinburgh, freely to the wards for clinical teaching and study. That this was understood as far back as 1819, is evident from the words of Dr. Charles Perrault of Quebec, speaking

FIG 10 The Central Medical Building of McGill University erected in 1910, and now in occupation. It contains Administration offices, Medical and Osler Libraries, Anatomical Medical, and History of Medicine Museums, and Departments of Anatomy, Histology and Public Health.

are preserved in the Historical Medical Museum at McGill and are interesting as the basis of many of his early publications.

RISE OF THE MONTREAL INSTITUTION AND THE MEDICAL FACULTY OF MCGILL UNIVERSITY⁶

From the first organization of the English General Hospital in 1819 it was clearly formulated, thanks to the insistence of its first Medical Board, Drs. Holmes, Stephenson, Robertson and Caldwell, and later H. P. Loedel, that the hospital was to be used as the

in the House of Assembly in support of Mr. Molson's motion "for the establishment of a public hospital at Montreal." He said, "Independent of the good which must result from the establishment of a well regulated Hospital to humanity at large another no less important object is obtained by establishing in such an institution a school for teaching the healing art in all its branches."

On October 20, 1822, Drs. Stephenson and Holmes were deputed by the Medical Board to draw up the regulations that seemed to a majority of

an endeavor at this Hospital" These considerations are couched in historic terms and read "The Medical Officers of the Montreal General Hospital, having seen the great difficulties which the student of medicine in this country has to encounter before he acquires a competent knowledge of his profession,

and considering that the Montreal General Hospital affords the student a facility of acquiring a practical knowledge of Physic never before enjoyed in these Provinces, . have met to consider of the possibility of founding such an institution in this city

They are further encouraged to attempt the formation of a medical seminary when they reflect that the medical school of Edinburgh, the basis of which they would adopt for the present institution, now justly considered the

first in Europe, is of comparatively recent formation—and the early history of the Royal Infirmary of Edinburgh is not dissimilar to that of the Montreal General Hospital" A week later (Nov 27, 1822) a copy of this memorandum signed by all five members of the Medical Board of the Hospital was forwarded to the then Governor General, Lord Dalhousie, with the suggestion that in order to give the new Institution status the Board of Medical Examiners should be reconstituted and made to consist of the Medical Officers of the Montreal General Hospital Lord Dalhousie, whose enlightened attitude on educational matters was well known, expressed his complete approval and sympathy and on Feb 22, 1823, a Commission was duly appointed consisting of the five Medical Officers of

Fig. 11. The Université de Montréal Medical School on St. Denis Street, which is about to be replaced by a large University and Hospital unit now under construction on the western slope of Mount Royal.

the Hospital "any three or more of you" to be the sole Medical Examiners for this District

Delay in the progress of this young Montreal Medical Institution arose from the fact that it was found impossible to obtain a charter for it under which it might be empowered to confer degrees, on the ground that it was not attached to any "Seminary of Learning" nor had it an endowment or foundation. At this time, however, the young University of James McGill which had been established by Royal Charter in 1821 in accordance with the will of the founder, existed only on paper and it had become necessary to institute active educational work in order to retain his

bequest. For both undertakings the psychological moment had arrived, and on June 29, 1829, at the first Governor's Meeting of "Burnside University of McGill College", the memorable step was taken, which gave the Medical Institution its necessary charter and foundation, and McGill an active and highly qualified medical faculty. At this meeting which took place at Burnside House by "Resolution of the Governors of the Corporation" (see figure 6) the members of the Montreal Medical Institution were "engrafted upon the College as its Medical Faculty". The first University degree was conferred in Medicine on Dr W. Logie, May 24, 1833. Throughout its early years this

FIG. 13. The Hôtel Dieu de St Joseph as it is today. The original building as occupied in 1861 is seen in the foreground surmounted by a central dome with massive stone wings on either side. Modern additions shown in the picture are for administration, x-ray department, private wards, and operating rooms (in rear of central dome of old building), pathological laboratory, nurses' home and training school. (An aerial view taken by Cte. Armande Franco-Canadienne.)

Faculty maintained a relatively high standard for that time, but its most brilliant period may be said to have come in the latter third of the nineteenth century when "attracted by the clinical advantages of McGill", William Osler enrolled as a student and graduated from its portals in 1872. In the ten years of his professoriate there he formed one of a productive group of clinical observers among whom the names of Ross, Howard, Shepherd and others will go down to posterity.

The first lectures of the McGill Medical Faculty were given in a small building on Place d'Armes and later on St. Georges Street in the heart of the city. Later, in 1845, this Faculty occupied the newly-erected Arts Building of McGill University (see figure 6) and remained there until 1851 when it removed to a building on Côté Street near the Montreal General Hospital where it remained until 1872, the year of Osler's graduation. In the autumn of that year it returned to the University grounds, for the first time, to a home of its own (see figure 9) a square building which occupied the site of the present Biological Building and which was unfortunately destroyed by fire, with extensive additions made in 1885 and 1901, in the year 1907. In 1910-11, its present handsome Administration Building with accommodation for Libraries and Museum was erected at a cost of \$600,000 (see figure 10). In it is also housed the Osler Library containing the famous collection of early and historical books of medicine and science made by the late Sir William Osler and bequeathed by him to his Alma Mater. A Biological Building was erected in 1922 and a fine Pathological Institute in 1923 at a

combined cost of \$1,000,000. The latest addition is the fine new *Neurological Institute* under the care of Dr. Wilder Penfield which is being erected near the Pathological Institute at a cost for building and endowment of some \$2,000,000.

THE MEDICAL FACULTY OF THE UNIVERSITÉ DE MONTRÉAL

This is the outcome of an earlier school the story of which is so full of stormy vicissitudes that it reads like a romance. It has been well told by the late Dr. L. D. Mignault,⁵ long a member of its staff. The *École de Médecine et de Chirurgie*, its parent institution, originated in 1843 with the double object of meeting the needs of the French-Canadian student body and in protest against the monopoly of teaching privileges at the Montreal General Hospital by the members of the McGill Faculty. It was founded by Francis T. Arnoldi, Francis Badgley, Pierre Monro and others. It labored under the same difficulty as did the Montreal Medical Institution in that it could not confer a university degree without such affiliation, and licenses to practice were only granted by the Province to persons holding such. After repeated efforts at various affiliations it was united with the "*Succursale de Laval*" as the Medical Faculty of the Université de Montréal with the combined clinical facilities of the Hôtel Dieu, Notre Dame, St. Paul, Catholic Maternity, St. Justine and other French hospitals at its disposal. Since then this Faculty has adopted a very progressive course in accordance with modern standards. Its curriculum revised its course of study, approved a pre-medical year multiplied its stu-

atories while placing these in charge of such men of distinction and international reputation as Prof Pierre Masson, of Strasburg, and improved and enlarged its clinical facilities. Nor is the University of Montreal resting there. A great new building is in process of erection on the northwestern slope of Mount Royal with ample accommodation for all its faculties, including those of Medicine and Dentistry and for a large University Hos-

and a well-equipped x-ray department (under the charge of Dr. Léo Pariseau of medical history fame), and additions made in 1916, 1923 and 1925 are utilized for operating rooms, hydrotherapy, laboratories, Nurses' Home and other purposes. The Hospital is still under the charge of the Hospitalières of St Joseph but a Nurses' Training School was inaugurated in 1901 and underwent affiliation with the University of Montreal in 1920.

FIG 15 The Montreal General Hospital on Dorchester Street, as it looks today. The old building with its Richardson and Reid wings is surmounted by a mansard roof and on the left are the important new buildings erected in 1913, with, in front of these the Pathological Institute rebuilt in 1909, and completed with extensions in 1919.

pital at a minimum cost of \$3,000,000. Until this building is occupied its Medical Faculty remains on St Denis Street (see figure 11).

HOSPITALS OF MONTREAL TODAY

The old *Hotel Dieu*, removed from that first site on St Paul Street to its ample property on Pine Avenue carries on now in a huge pile of buildings (see figure 13) which includes the original building with cupola of 1861 modernized and brought up to date by many important extensions. A large wing now houses the private wards

The *Montreal General Hospital* still occupies its historic central block on Dorchester Street erected in 1822 (figure 7) with its early additions, the Richardson and Reid Wings but these have been repeatedly altered and it has been enlarged by new additions to its present capacity. In 1882 two new surgical wings, the Greenhalgh and Campbell Wings, were erected and soon after a new and fully equipped operating room was constructed. In 1894 the old buildings were removed and four new medical wards built. An x-ray department was added in 1901

and a pathological building was erected under the charge of Dr Wyatt Johnston, and completed on a larger scale to house Metabolism in 1919. In 1913 the huge new building which towers above at the rear of the original building (see figure 15) was opened and supplies the additional accommodation needed for what is now an up-to-date 400 bed

and progressive French-Canadian institution of 600 beds, which includes 130 beds at present used for contagious diseases, (replacing the old Hôpital St Paul). It was founded in 1880 to meet the needs of the east end of the city and also to supply clinical facilities for the Laval Medical School, now the University of Montreal. Like the

FIG 16 Hôpital St Justine on St Denis Street. Founded in 1907 for sick children under 14 years of age, showing large recent additions.

hospital 'The Nurses' Training School established by Miss *Nora Livingston* in 1890 soon became famous throughout the continent for its high standard and pioneer work. In 1897 a Jubilee Nurses' Home was built and this was replaced in 1926 by a large separate building erected on land opposite the Hospital at a cost of \$600,000.

In 1914 an amalgamation took place of the General with the Western General Hospital which now bears the title of the *Western Division of the Montreal General Hospital*.

The *Notre Dame Hospital* is a large

Montreal General it has been from its inception a public charity, drawing its financial support from the people. The moving spirit in its organization was the late *Dr E. P. Lachapelle* a man of singular force of character and high scientific standards. Originally situated on Notre Dame Street it was removed in 1924 to its present site on Sherbrooke Street opposite Lafontaine Park and has recently been remodelled to its present capacity (see figure 12). A beautiful and commodious Nurses' Home has been erected and was opened in March, 1932. The report for 1931

for this hospital shows that it had nearly 9,000 admissions and 120,000 consultations in that year

The *Royal Victoria Hospital* received its first patient in January, 1894. This beautiful hospital is erected on a commanding site on the side of Mount Royal on a scale commensurate with the new responsibilities and opportunities for the relief and prevention of disease at the present time, and was made possible by the initial gift of \$1,000,000

356 outdoor consultations in the current year (See figure 14)

Another general hospital that is rapidly assuming a major place in the care and prevention of disease in this city is the *Hôpital St Luc*, situated on St Denis and Dorchester Streets. This started in 1913 as an eye and ear dispensary and developed later as an important industrial and dental clinic. Since receiving Federal aid for the care of sailors, it has now 400 beds and a

FIG 17 The Children's Memorial Hospital on Cedar Avenue, founded by the late Dr A Mackenzie Forbes in 1902 with special reference to orthopedic work showing building erected in 1908, with large new wing on the right opened in 1931

from the late Lord Strathcona and Lord Mount Stephen in Queen Victoria's Jubilee Year, and by generous subscriptions from these and other sources since. In 1916 there was added the *Ross Memorial Pavilion*, a complete private hospital of 120 beds and in 1926 a great new *Women's Pavilion* was erected to house the old *Montreal Maternity Hospital* (removed from St Urbain Street). The total capacity of this hospital with the above additions is now 700 beds, it being the largest in the Province and its last report shows 14,307 indoor patients and 78

new wing is being added which will bring its capacity to 600. In 1933 it will also open a section for contagious diseases containing 300 beds.

Other important hospitals are the *Hôpital St Justine* 340 beds (founded 1907), (see figure 16), the *Children's Memorial Hospital* on Cedar Avenue 200 beds (founded 1902) (see figure 17) and also the *Shriners' Hospital* (founded 1922), for the care of sick or crippled children, the *Alexandria Hospital* for contagious diseases 165 beds (founded in 1900) and the *Hôpital St Louis*

MONTREAL TODAY

After the above somewhat kaleidoscopic retrospect of the evolution of medicine in early Montreal, only a word can be said regarding what this stately city has to offer to the passing traveller at the present time (Figure 18) Vast changes have supervened since that summer, not quite 300 years

Square and the marble slabs placed by the Historical Society on many buildings in the lower city to indicate the sites of stirring past events in the one time little riverside town. Growth and expansion have been very rapid in the past century and especially so in the last thirty years, since when the picturesque river front has been entirely transformed by the gigantic structures of the Montreal Harbor, which stretches from Victoria Bridge (erected

FIG 19 The two remaining towers of the old "Fort des Messieurs", in the grounds of the Seminary on Sherbrooke Street West, built in 1694

ago, when Maisonneuve landed at what is now the harbor front and planted his cross on the western slope of Mount Royal, where later the Sulpicians built their Mountain Fort, the towers of which still stand (see figure 19) Signs of those early days are to be seen in the memorial stone at the corner of McTavish and Sherbrooke Streets that marks the location in Jacques Cartier's day of the Indian village of Hochelaga and in the shining cross on the Mountain top erected by the St. Jean Baptiste Society as also in the Maisonneuve monument on old Place d'Armes

1860) almost to the lower end of the island. Montreal is now said to be the largest grain exporting city anywhere and many enormous grain elevators (one the largest in the world), a huge cold storage plant surrounded by twenty-five steel sheds and by miles of grain-carrying belts extend along the shore, for the loading of shipping to all the earth.

The river is now spanned by three bridges: that of the Canadian Pacific Railway lying with Victoria Bridge to the west while the new St. Lawrence Harbor Bridge connects the city to

part of the city to the outlying farm country, Richelieu and Lake Champlain Districts to the South. This bridge, which is $2\frac{1}{8}$ miles long and the largest in Canada and one of the great bridges of the world, is of modern steel construction, costing over \$12,000,000, and was opened on May 24, 1930. At its farther end is the air-port of St. Hubert from which since 1928 Montreal has had an international air service and regular air connection with the United States, the Lower St. Lawrence and Upper Ottawa.

The commercial section of Montreal has at last entered upon the skyscraper

period in the imposing erections of the Royal Bank of Canada (1928), the Bell Telephone Co. (1930), and the Sun Life Insurance Co. (1931). In its amazing growth and expansion of the last few years the city has come to entirely encircle the Mountain which less than fifty years ago formed only its northern background. So also Sherbrooke Street West, long its residential quarter (on which its beautiful Art Association building with its great collection stands), is rapidly becoming commercialized, and the better class houses are being built today on the western slope of the city's greatest asset, her beautiful Mount Royal.

THE JOHN PHILLIPS MEMORIAL PRIZE

At a meeting of the Board of Regents of the American College of Physicians on November 13, 1932 it was resolved that the John Phillips Memorial Prize for 1933 be awarded to Dr WILLIAM B CASTLE, of Boston, for his series of studies showing the relation of gastric digestion to the pathogenesis of anemia, proving the rôle of extrinsic and intrinsic factors in hematopoiesis, and finally demonstrating that the extrinsic factor palliative in pernicious anemia can be obtained from yeast as well as from meat, thus suggesting that it is closely related to vitamin B. This choice will meet with general approbation. In thus honoring Dr. Castle, the College does honor also to the memory of him for whom this prize is named.

*ECONOMIC ASPECTS OF TREATING SYPHILIS ADEQUATELY**

The major responsibilities of the physician in the effort to control syphilis are those of making an early diagnosis and of then administering adequate treatment. While he cannot ignore the value to public health of educational methods of prophylaxis, and of various other measures in which he may be required to participate actively, upon the physician rests the responsibility of rendering his pa-

tient non-infectious as expeditiously as possible and then preventing or at least mitigating, that long series of disasters which hang, shadow-like, over his subsequent existence. If in the time of prosperity it was difficult to secure for the patient with freshly acquired syphilis that continuity of treatment which he so greatly needs, how much more difficult is it today! In a symposium on "Syphilis as an Economic Problem", appearing in the October number of the *Journal of Social Hygiene* Bromberg¹, Davis,^{1,2} and Snow³ have treated this question in a manner so thought-provoking that it commands the fullest attention. There can be no better argument for the necessity and inestimable value of a long continued intelligent, cooperative physician-patient relationship.

The magnitude of the economic problem involved becomes apparent at once when two facts are brought together. The first of these is that it has been estimated by competent authority upon studies conducted in many parts of the country by the United States Public Health Service,

*BROMBERG, LEON, and DAVIS, M. M.: The cost of treating syphilis. *Am. J. Hyg.* 1932, LXIII, 365-375.

¹DAVIS, MORRIS M.: The cost of syphilis to pay for the treatment of it. *J.* 1932, 378-381.

²SNOW, WILLIAM L.: A comparison of the cost of treating syphilis with the cost of preventing it. *Am. J. Hyg.* 1932, 375-377.

that there are about 500,000 new cases of syphilis in the United States every year. The other is that the average cost of one year of treatment of early syphilis, according to the continuous scheme of therapy recommended by the United States Public Health Service, varies from \$268.00 to \$1,050.00 depending upon whether the fee-bill used is that of a good general practitioner or of the more exclusive type of specialist in this field. Even when the cost is computed according to the schedules of two "pay clinics", set up with salaried physicians and organized on a basis intended to make them no more than self-supporting, it amounts to \$133.50 in one instance, and to \$169.50 in the other. The scheme of therapy referred to was the result of the collaboration of six outstanding syphilologists. While they emphasized that each patient must be treated individually, less than the stated amount of treatment would rarely be considered adequate and changes in the plan of procedure would not materially affect the totals. The recommended medical services for the adequate management of a case of early syphilis during the first year include two physical examinations, twenty-six injections of arsphenamine or neoarsphenamine, twenty-six bismuth or mercury injections, eight serological blood tests and one examination of the spinal fluid. (The reader can readily compute the total cost according to the current charges of his own locality.)

When representative cases were selected from seven different clinics in order to ascertain the precise medical services which had been rendered, it was found that at minimum private office

rates the average cost of treatment for one year would have been \$314; at specialists' rates, \$715. These, again, were early cases; for the treatment of latent syphilis and of neuro-syphilis, the expense is, on the average, considerably higher.

It is recognized that a minimum figure of \$300 does not represent an average of what private patients actually pay for a year's treatment of syphilis. Much of the treatment may be on a charity, or semi-charity basis, the doctor may not administer the recommended courses of medication; or, most frequently, the patient will cease treatment even before the first year is completed. No one can deny that for the treatment outlined, the minimum figures are reasonable. Likewise from the patient's standpoint, the potential benefits that may be derived from adequate treatment make the cost seem trivial. The relation between this cost and the ability of various groups of the population to pay it is another question.

The ability of the patient to pay for adequate treatment of recently acquired syphilis is adversely affected by several special considerations. Since continuity of treatment throughout several years is essential, ability to pay for the initial blood test and for a few intravenous injections is of but little significance. Recently acquired syphilis is most prevalent among young persons between sixteen and thirty years of age when earning power is comparatively low. The feeling of shame and resulting desire for secrecy makes the individual unwilling to inform his family of his difficulty. Thus he is unable to draw upon the resources of

those who would be only too glad to aid him if he had suffered an injury or had acquired a disease unassociated with a social stigmatization. On the other hand the ability of the patient to pay is favorably influenced by the prolonged period of treatment, in that a series of payments may be made rather than a single sum. There is an inherent difficulty here, however. If, after a few weeks of treatment, there are no disturbing signs or symptoms of his disease, the patient is very apt to feel unable, as well as unwilling, to make a further investment in treatment.

Statistical studies by Davis² bring out clearly that for over 80 per cent of the population the minimum cost of treatment of syphilis at minimum private rates would take over ten per cent of their total incomes. While such a proportion may be expended without hardship by those in the higher income groups, from a total income of \$2,000 or less such an amount cannot be withdrawn without cutting into the necessities. For the single man, just starting out as an independent economic unit, with a salary of \$1,200 or less, the difficulty is equally great. From his analysis of the situation, Davis came to the conclusion that at the present time about 80 per cent of the population cannot pay for adequate care of syphilis at private rates and fully one-third of the population, if infected, must re-

ceive treatment for syphilis free or for nominal charges. Thus it must be true that the cost is an important cause of insufficient or inadequate treatment, but practically, it is in all probability a less important cause than is carelessness or indifference on the part of the patient himself.

It is an unthinkable situation that for financial reasons alone the syphilitic cannot receive that treatment which he needs. Not only the welfare of the individual but the health of the community demands that such must not be the case. It is easier to state the problem than to find the solution. That there must be close cooperation between the medical profession and the public health agencies is obvious. Here, as in other problems of medical economics, the medical profession must recognize the need and give understanding aid in arriving at a solution. It seems clear that in different parts of the country, urban and rural and for different economic groups, varying provisions must be made. The medical profession should lead in planning effective action. There can be no doubt that if other solutions are not found, pay clinics and free dispensaries with their attendant evils, must be set up to meet this need, and as previously emphasized a protracted sympathetic co-operative physician-patient relationship, never to be found in the pay clinic or dispensary, is the great need of the patient with syphilis.

Abstracts

The Differential Diagnosis of Primary Neoplasms of the Mediastinum By CUSHMAN D HAAGENSEN, M D (The Am Jr of Cancer, 1932, xvi, 723-782)

The following classification of primary neoplasms of the mediastinum is proposed

A Malignant

1 Lymphosarcoma

- (a) Small round-cell lymphosarcoma (malignant lymphocytoma)
- (b) Large round-cell lymphosarcoma (reticulum-cell lymphosarcoma)

2 Hodgkin's disease

3 Leukemic lymphoma

4 Leukosarcomatosis

5 Thymic carcinoma

B Benign

1 Dermoids

2 Other cysts, including echinococcus cysts and ciliated epithelial cysts

3 Ganglionic neuromas and neurofibromas

4 Benign connective-tissue tumors including fibroleiomyomas, fibromas, chondromas, and lipomas

Since determination of the tumor type by biopsy is rarely possible, although classification is necessary in order to guide therapeutic management and determine prognosis recourse must be had to differential diagnosis upon clinical evidence. As to age, thymic carcinoma usually occurs at a much more advanced age than other malignant neoplasms of the mediastinum. Large round-cell lymphosarcoma and Hodgkin's disease most often occur in patients between 20 and 30. Small round-cell lymphosarcoma (malignant lymphocytoma) usually affects infants. In this age group many dermoid cysts also occur. The duration of symptoms is also a factor in the differential diagnosis. The course of the disease is also a factor. If a process has been long established it is more likely to be benign than if it is of recent onset.

very great that the process is benign. Clinical signs and symptoms, while extremely important in making the diagnosis of mediastinal tumor, frequently are of but little value in differentiation of types. Roentgenographic diagnosis of primary neoplasms of the mediastinum may be rendered difficult by the similar and sometimes identical images produced by aneurysm of the aorta, retrosternal goiter, idiopathic dilation of the esophagus, cold abscess of the vertebrae, tuberculosis of the mediastinal lymph nodes, encapsulated mediastinal pleurisy, mediastinal abscess, lung abscess adjacent to the mediastinum, hydatid cyst, carcinoma primary in a portion of lung adjacent to the mediastinum, and metastatic carcinoma of the mediastinum. Here aneurysm is the chief difficulty. As to roentgenotherapeutic response in differential diagnosis, lymphosarcoma, Hodgkin's disease, leukosarcoma, and leukemic lymphoma are often strikingly radiosensitive, although occasional radioresistant cases are found. Thymic carcinoma and the various benign neoplasms of the mediastinum are radioresistant.

Parotid hypertrophy, an Symptom des Diabetes Mellitus [Hypertrophy of the parotid glands a sign of diabetes mellitus] By ERNST FRAUM (Klin Wochenschr, 1932, xi, 1704-1705)

The investigation forming the basis of this paper had its origin in the observation of symmetrical enlargement of the parotid glands in an elderly woman which was without pain, fever or any other evidence suggesting an inflammatory character. It showed exacerbations between which the glands did not return to normal size. After some years this patient was found to have diabetes mellitus of a moderate grade of severity. Particularly during the periods of more marked enlargement of the parotid glands a characteristic facial configuration

was observable. A similar facial character was found to be common among diabetics, and palpation showed that the fullness in the parotid regions was due to an increase in gland substance and not to pads of fat. Conversely, of 27 patients selected because of enlargement of the parotids, 16 were found to have a definite glycosuria on an unrestricted diet and the fused blood sugar curve of the remaining 11 was of the type considered characteristic for latent diabetes. It is particularly in the sthenic constitutional type, with a tendency to obesity, a strongly developed skeletal system, arterial hypertonicity, enlargement and induration of the liver and arthritic phenomena, that the characteristic change in the parotid glands is observable. The association of this sign with glycosuria was noted by Hess in 1918, and with obesity, by Sprinzels in 1912. Observations of this nature furnish new supporting evidence of an excretory function on the part of the parotid gland, the hypertrophy of which may well be of a compensatory nature. Recognition of this sign should prove of value in the early diagnosis of diabetes in the constitutional type described.

The Occurrence of Sicklemia in the White Race. By SAMUEL ROSENFELD, M.D., and JOSEPH B. PINCUS, M.D. (Am. Jr. Med. Sc., 1932, clxxxiv, 674-682.)

It is generally believed that sickle cells occur only in the blood of the negro or in those with an admixture of negro blood. The incidence of the sickling trait among unselected negroes seems to be about 7 per cent. This trait is hereditary and is transmitted as a Mendelian dominant. The literature alleging the occurrence of sicklemia in white persons has been reviewed, keeping in mind that the chief sources of error lie in mistaking other deformities of the red blood cells for sickling or in failure to exclude the possibility of admixture of negro blood in cases with true sickling. With these possibilities in mind most of the alleged cases of sicklemia in white patients may be eliminated. Only one previous case, that of Cooley and Lee, in a white child of Greek descent, is free from reasonable suspicion. The case reported by Sights and Simon is considered to be supported by data too in-

complete for any conclusion as to its validity. A new group of cases is reported in this paper in which the sickling trait has been definitely shown to be present in three generations of an Italian family, which has been positively without admixture with the colored race for five generations. Moreover this family came from a region in Italy in which negroes are practically unknown. While this evidence would seem to indicate that this anomaly of the blood occurs in other than the negro race, the possibility cannot be absolutely ruled out that in some remotely previous generation there might have been a negro ancestor with sickle cells in the blood. Through dominant inheritance, the sickling trait might have been handed down to white descendants showing no external trace of negro features. Whatever the explanation may be it is obvious that this anomaly will be encountered from time to time in those who are of the white race as far as can be ascertained.

On the Transmission of Huntington's Chorea for 300 Years—the Bures Family Group. By P. R. VESSIE, M.D. (Ir. Nerv. and Ment. Dis., 1932, lxxxi, 553-573.)

Through study of the earliest colonial records the author has ascertained that a group which emigrated from Bures, Suffolk, England in 1630, has contributed very largely to the incidence of hereditary chorea in this country. Approximately 1000 cases of Huntington's chorea have been collected from the direct and collateral lines of this group which consisted of three men and their wives. The social problems of this group and the more immediate descendants show why the choreic affliction was reputed disgraceful and viewed with terror in succeeding generations. The witchcraft literature and records of court procedures indicate the extent to which the violent motions and attitudes of the afflicted played a part in arousing suspicion of witchcraft. In these interlocking conditions there has been a transmission of the chorea, now known as Huntington's, for at least five generations since their arrival in the New World. The family has been isolated, and persistently intermarried with persons without blood relationship to the afflicted group.

Reviews

Special Cytology The Form and Functions of the Cell in Health and Disease A Text-book for Students of Biology By FORTY-SIX CONTRIBUTORS Edited by EDMUND V COWDRY, Washington University, St Louis, Missouri Second edition In three volumes xxiv + 1838 pages, 757 illustrations Paul B Hoeber, Inc., New York 1932 Price, \$30.00 for three volumes

The second edition of *Special Cytology*, edited by E. V. Cowdry, has been strengthened by generous revision, covering the progress of research during the three or four years which have elapsed since the first edition was prepared. Fourteen new contributors have filled in some of the gaps in the list of subjects treated. That such lacunae must exist is inevitable, for the extent to which the structure of the human body may be subdivided for purposes of description and original investigation is all but unlimited. As with all similar compilations, the very item of information which is sought for, may yet be wanting in spite of this expansion. This three volume work has several especially commendable features. One is the excellent mechanical book-making shown, with an unusual freedom from minor errors. (The reviewer cannot refrain, however, from calling attention to the misspelling of 'parathy' on pages 182 and 183.) The contributors, to a remarkable degree have entered into the general spirit of the work in that they have been more concerned in being interpreters of their respective fields of investigation than in presenting individualistic views. Finally, the bringing together, as is seriously attempted in some chapters, of normal and pathological cytology is a new and extremely worthwhile endeavor. More complete utilization of this principle might be made.

Assistant Professor of Gynecology and Obstetrics, Graduate School of Medicine, University of Pennsylvania, Gynecologist to Mt Sinai and to Northern Liberties Hospitals, Philadelphia and LEOPOLD GOLDSREIN, M.D., Demonstrator of Obstetrics, Jefferson Medical College, Assistant Gynecologist to Mt Sinai Hospital, Formerly Fellow in Gynecologic Research, University of Pennsylvania, Philadelphia. 518 pages with 117 illustrations W. B. Saunders Company, Philadelphia and London 1932 Cloth, \$6.00

Clinical Endocrinology of the Female is written by gynecologists and the subject matter is presented chiefly from the point of view of that specialty. Each of the glands of internal secretion, ovary, pituitary, thyroid, adrenal, parathyroid, thymus, pineal gland and pancreas, is thoroughly discussed in regard to its histology and physiology, and just how the hormone or hormones of each is tested for in actual practice. The interrelation of these glands and the effect of this interrelation upon the female is considered from every angle.

There is not the slightest doubt that a knowledge of endocrinology is of tremendous importance and the authors stress the fact that many young women, who previously would have been subjected to needless surgery, are now being successfully treated by gland therapy. This type of therapy is gradually being increased, as more and better standardized extracts become available. Thyroid and pituitary extract have, of course been on the market for some time, as has also suprarenal cortex and insulin. It is to be hoped that Hartman's "cortin" will soon be produced in sufficient quantities to relieve some of the terrific exhaustion of Addison's disease. It is now possible to secure active estrin (lipo-ovarian extract) and active pituitary sex hormone, the latter of which is a cordial to the authors, I

almost specific in the treatment of functional uterine bleeding. They believe that "functional uterine bleeding, regardless of the age of the patient, is due to the continued and unopposed action of oestrin on the endometrium, producing what is commonly called 'endometrial hyperplasia'. The underlying cause is a follicle cytolysis, which results in the prolonged production of oestrin and an absence of the luteal hormone, progesterin." Progesterin, unfortunately, is not yet obtainable for therapeutic use.

Dr Mazer and Dr Goldstein state that "pseudomenstruation", the cyclic uterine bleeding without the presence of a premenstrual endometrium, is due to the failure of ovulation and luteinization, and is a frequent occurrence in regularly menstruating, sterile women, who are free from pelvic disease. They feel certain that many fertilized ova may be expelled, or aborted, because of the lack of a properly prepared endometrium upon which to attach themselves.

The significance and the technique of the Aschheim-Zondek test for pregnancy is given in detail, but the authors prefer the Friedman modification, using one rabbit instead of five mice because of the shorter time required for the test.

The book contains several interesting charts, a number of illustrations and there is also a very full bibliography.

Probably in order to stress the importance of the subject (or perhaps to make a thicker book) there is repetition to the point of making the book a bit tedious in spots. The repetition includes the illustrations, several of which are given twice, with different figure numbers and slightly different captions (Fig 14, p 42 and Fig 51, p 161; Fig 49, p 160 and Fig 97, p 394; Fig 50, p 161 and Fig 98, p 395). It is also rather confusing to read the report of the cure of Frohlich's syndrome, in a boy of seventeen, in a paragraph on low-dosage irradiation of the hypophysis, in the successful treatment of amenorrhoea and about a hundred pages farther on to find the same seventeen year old boy again reported in a paragraph on low-dosage irradiation of the pituitary gland in the treatment of pituitary obesity associ-

ated with menstrual disorders (P 307 and p 450).

This book contains much that is well worth while reading, upon a subject with which the medical profession in general should keep pace in order to treat patients more intelligently. R C W

Clinical Interpretation of Laboratory Reports By ALBERT S. WELCH, A B, M D. Clinical Instructor in Medicine in the University of Kansas School of Medicine in Kansas City, Kansas, Director of the Laboratory of the Alfred Benjamin Dispensary, and Attending Surgeon of St Joseph's Hospital in Kansas City, Missouri, formerly Pathologist to the Kansas City General Hospital, and Chemist to the Coroner of Jackson County. 332 pages, 16 illustrations. P. Blakiston's Son and Co., Inc., Philadelphia. Price, \$4.00, net.

This book is divided into sixteen chapters, one each being devoted to a consideration of the laboratory examination of urine, blood, smears, cultures, cerebro-spinal fluid, gastric and duodenal contents, feces and sputum. The remaining chapters are given over to a consideration of blood chemistry, serology, tissue examination, the basal metabolic rate, the electrocardiogram, forensic and special tests. There is probably a need for a conveniently arranged text dealing with the clinical interpretation of reports based upon complicated (and simple) laboratory procedures. This text however fails to measure up to the criteria the reviewer considers necessary for the consummation of its purpose. In his preface the author quite properly warns clinicians to choose their laboratory with discretion and to discriminate between really large laboratories and the equally reliable ones. And yet throughout the text the reader cannot fail to be impressed by the author's only too evident dependence on laboratory tests and his frequent reference to reports rendered by the pathologist and experienced worker. It seems a pity that a conscientious author, who has taken the red blood cell, the white blood cells, or cells of the cerebro-spinal fluid, for example, as his subject, should

mistake leucocytes or erythrocytes passing in currents, for motile amebae. Nor should confusion be caused by cotton fibers when searching for actinomyces. In the chapter on tissue examination, the implication arises all too frequently of a final pathological diagnosis based solely on the gross appearances. Certainly no competent pathologist would care to append his name to a diagnostic sheet after merely a " cursory examination " of tissue clinically suspicious of actinomycosis (page 279), and carcinoma of the thyroid is not as rare as implied (p. 268), unless the diagnosis is rendered solely on the macroscopic changes. Other statements are equally misleading. Appendiceal carcinoids do not commonly suggest adenocarcinoma. Gelatinous carcinoma of the peritoneum cannot be an entity but must itself be secondary to a mucin-secreting carcinoma elsewhere in the body. Sarcoma in a lymph node can bear only an extremely superficial resemblance to actinomycosis (p. 273) and the two should no more be confused than should absorbing suture material be mistaken for tubercles (p. 276). It is by no means certainly established that a persistently negative Wassermann indicates cured syphilis. It seems doubtful that hair in the urine could often have a dermoid cyst for its source (p. 26) or that "lipoid carcinoma of the prostate may cause the appearance of doubly refractive lipoids in urine". Some passages suggest a distinctly iconoclastic attitude. It is not pleasing to read that "the fragility test is of little clinical value (because) there is as yet little therapeutically that can be done about it", or "it really makes little difference clinically whether the sarcomas of lymph glands without blood changes such as lymphosarcoma, sarcoma of lymph glands, or lymphosarcomatosis are distinguished from each other" (p. 273). Also, attempts to demonstrate spirochetes in tissues are very much worth while especially in primary lesions, despite the author's opinion to the contrary. An experienced observer would not mistake parts of the classical arterioles for the "refractile" material he had already noted in the capillaries. The opportunity is lost to mention a few of the "refractile" material in the

whether the section on forensic tests properly belongs in a book of this kind—the space could with advantage be used in enlarging other sections. Such addition should make the subject matter more readable. Without careful revision, this book cannot be recommended to its intended clientele. H. G.

The Cardiac Output of Man in Health and Disease. By ARTHUR GROLLMAN, Ph.D., M.D., Associate Professor of Physiology in the Medical School of the Johns Hopkins University. xiv+324 pages, 25 figures. Charles C. Thomas, Springfield, Illinois, and Baltimore, Maryland, 1932. Price, \$4.00, postpaid.

In the introduction the author states that this monograph is to deal with the variations of the cardiac output under different physiological and pathological conditions and the relation of these variations to other changes occurring in the circulatory system. In Part I he briefly outlines the methods that have been developed for determining success or failure in these methods and finally gives a comparison of the results obtained by various experimenters using them. Part II is devoted entirely to the Acetylene Method of determining cardiac output which, he says, has been proven accurate and is easily carried out. After deriving the algebraic formula used in calculating the cardiac output from the data obtained and describing the technique, the author gives proofs of the accuracy of the method and ends with a chapter on its applicability in clinical medicine. Part III is a discussion of the variations of cardiac output under many different physiological conditions. Tables and graphs giving data from numerous experiments are included. The application of cardiac output studies to pharmacology and therapeutics is discussed in Part IV. The opportunity offered by these studies for direct observation of the effects of drugs on the heart action in man is emphasized. The next few chapters take up the effects on the cardiac output of a number of drugs and other therapeutic applications which have been studied. Part V pertains to the clinical applications of cardiac output study, with the emphasis placed on the use of the heart and circulation. In

Part VI there is a short discussion of the correlation between cardiac output, metabolic rate, pulse rate, blood pressure and heart size. In the bibliography there are 483 references. This monograph represents an enormous amount of work and in it the author has carried out his purpose admirably in an interesting and understandable style. The subject matter, while of interest to the internist, should be particularly valuable to students of physiology and experimental cardiology. B M H

The Chemistry of Tuberculosis. A Compilation and Critical Review of Existing Knowledge on the Chemistry of the Tubercle Bacillus and Its Products, The Chemical Changes and Processes in the Host, The Chemical Aspects of the Treatment of Tuberculosis. By H GIDEON WELLS, M D, P H D, Director of the Otho S A Sprague Memorial Institute and Professor of Pathology in the University of Chicago, and ESMOND R LONG, M D, P H D, Director of the Laboratory of The Henry Phipps Institute for the Study, Treatment and Prevention of Tuberculosis, and Professor of Pathology, University of Pennsylvania, formerly Professor of Pathology in the University of Chicago. Second edition, thoroughly revised. iv + 481 pages. The Williams & Wilkins Company, Baltimore, 1932. Price, \$7.00.

The purpose and character of this book are set forth in the lengthy subtitle. It is, in fact, a rich storehouse of knowledge of the chemical attributes of tuberculosis in all its phases. This huge material is well organized, and critically analyzed, by the joint authors, who are better qualified than any others to do this task. Ten years have elapsed since the manuscript of the first edition was completed. Slow as progress may seem, the growth of knowledge during that period has necessitated a complete re-writing of the text. The present edition might well be considered a memorial to Dr Lydia M DeWitt co-author of the first edition, whose careful work and conservative interpretations are models of what experimental chemotherapeutic studies should be.

Her death, in 1928, kept her from realizing this revision which was anticipated in the preface of the first edition. Those engaged in striving to solve the problems of tuberculosis will find this book all but indispensable.

A Text-Book of Pathology. An Introduction to Medicine. By WILLIAM BOYD M D, M R C P Ed, F R C P Lond, Dipl Psych, F R S C, Professor of Pathology in the University of Manitoba, Pathologist to the Winnipeg General Hospital, Winnipeg, Canada. 946 pages, 287 figures, one colored plate. Lea & Febiger, Philadelphia, 1932. Price, \$10.00.

On page 723 of this issue an excerpt from the preface of Boyd's Pathology is quoted. It well expresses the aim and spirit of this book—the systematic presentation of pathology in relation to the living patient. The plan of the book does not vary greatly from others of its kind which undertake to present both General and Special Pathology under one cover. It is well-written, with an excellent choice of both textual and illustrative material. The author is forced to be dogmatic for the sake of brevity. A teacher of pathology might well criticize the order of treatment since inflammation is the introductory chapter, while the extrinsic factors in the causation of disease are not considered until the seventh, eighth, ninth, eleventh, and thirteenth chapters are reached. For the practitioner, however, this difficulty will not appear and there is no hesitancy in recommending this as one of the best of the textbooks in Pathology in the English language.

Principles of Chemistry. An Introductory Textbook of Inorganic, Organic, and Physiological Chemistry for Advanced Students of Home Economics and Life Chemistry. With Laboratory Experiments. By JOSEPH H ROE, PH D, Professor of Biochemistry, George Washington University Medical School, Department of Chemistry, Central School of Science, Washington, D C. Captain, Surgeon, Division, U S Medical Reserve. Textbook, 480 pages, 50 illustrations. (C)

Mosby Company, St Louis, 1932 Price, \$2 50

That a third edition of Roe's textbook has been required demonstrates the usefulness of a work of this character. It differs from the elementary texts provided for high schools in the greater emphasis upon physiological chemistry, as indicated by chapters on Milk, The Blood, Digestion, Metabolism, Vitamins, Foods, Dietary Requirements and The Internal Secretions. It is well written and very well printed. The inclusion of considerable theoretical material not found in the earlier editions appears to make the treatment of the subject rather too heavy for the needs of the pupil nurse. Some teachers of nurses will choose to omit certain sections. Where not an assigned text, this book should be included in the training school library for reference.

Medizinische Praxis Band XIII, Blutkrankheiten [System of Medicine Volume XIII, Diseases of the Blood] By PROF. DR. HEINRICH SCHIFFCHT, Medical Direc-

tor of the Ebenhausen Sanatorium near Munich xii + 197 pages, 13 text figures and 2 plates in colors. Theodor Steinkopff, Dresden-Blasewitz, Residenzstrasse 32, Germany. 1932. Price in paper, RM 13 80, bound, RM 15.

This book follows the general plan of practical texts on the blood and diseases of the blood. The first section of 37 pages deals with technical methods, including the numerous newer procedures not in the armamentarium of many whose student days are now well in the past. The second section of about the same size describes systematically the formed constituents of the blood. The remainder is concerned with the diseases of the blood and blood forming organs, and with the changes in the blood associated with various morbid states. This is a clearly and compactly written book, and thoroughly up-to-date. Even ovalocytosis has been included, although the mention is brief. For those reading German readily, this will prove a very useful manual.

College News Notes

NOMINATIONS FOR ELECTIVE OFFICERS 1933-1934

The Nominating Committee herewith transmits the following nominations for elective officers of the American College of Physicians for the year 1933-34:

President-Elect—Jonathan C. Meakins,
Montreal, Canada

1st Vice President—Maurice C. Pincoffs,
Baltimore, Md.

2d Vice President—Charles G. Jennings,
Detroit, Mich.

3rd Vice President—Noble Wiley Jones,
Portland, Ore.

Presented and submitted,

J. H. Myers, Chairman

Leslie B. Pringle

E. J. G. Pennington

W. C. E. Wright

Dr. James M. Anders (Master) read a Memoir on Dr. Hiram Corson before the Section on Medical History of the College of Physicians, Philadelphia, on October 10.

Dr. Anders also read a paper on "The Modern Health Movement" before the Philadelphia County Medical Society on October 26, Pennsylvania Health Day.

On the evening of November 5, Dr. D. Schuyler Pulford (Fellow), of Sacramento, addressed the Placer County Medical Society at its meeting held at the Weimar Sanatorium. Dr. Pulford's address, which was illustrated by lantern slides, was on "The Never Developments: Diagnosis and Treatment of Cancer."

An announcement is made of the following:

gifts to the College Library of publications by members

Dr Carl V Vischer (Fellow), Philadelphia, Pa—1 book, "Pulmonary Tuberculosis".

Dr Jacob M Cahan (Fellow), Philadelphia, Pa—1 reprint,

Dr W W Chrisman (Associate), Macon, Ga—2 reprints,

Dr Nathan Smith Davis, III (Fellow), Chicago, Ill—2 reprints,

Dr Charles F Fisher (Fellow), Brooklyn, N Y—1 reprint,

Dr Alvis E Greer (Fellow), Houston, Texas—2 reprints,

Dr Hyman I Goldstein (Associate), Camden, N J—1 reprint,

Dr Charles C Hinton (Fellow), Macon, Ga—2 reprints,

Dr E W Phillips (Fellow), Phoenix, Ariz—2 reprints,

Dr H L Arnold (Fellow), Honolulu Hawaii—1 reprint,

Dr Ellen C Potter (Fellow), Trenton N J—6 reprints,

Dr Karl Rothschild (Fellow), New Brunswick, N J—1 reprint,

Dr Edward W Schoenherst (Fellow), Asheville, N C—18 reprints

Dr John Dudley Dunham (Fellow), Columbus, Ohio, addressed a joint meeting of physicians and dentists at Hotel Warden, Newark, Ohio, October 27, on "The Interdependence of the Medical and Dental Profession"

At the meeting of The Yorkville Medical Society of the City of New York on November 21, Dr Albert S Hyman (Fellow) New York, spoke on "Recent Advances in the Study of Angina Pectoris" and Dr Joseph B Wolfe (Associate), Philadelphia on "The Use of Heart Hormone (Tissue Extract Substance) in Angina Pectoris". Dr John Homer Cudmore (Fellow), New York, and Dr George I Swetlow (Fellow), Brooklyn, took part in the discussion

Dr Lewis I Moorman (Fellow) Oklahoma City is the author of a new section in Oxford Medicine (Volume 4, Part 2) on 'Industrial and Domestic Gas Hazards Aris-

ing through the Production, Refining and Consumption of Petroleum and Its Products"

Dr Clifford J Barborka (Fellow), for eleven years a consultant physician of the Mayo Clinic, has accepted a position in the Department of Medicine in Northwestern University, and has opened a diagnostic suite for the practice of Internal Medicine at 700 N Michigan Avenue, Chicago

Dr Barborka delivered two lectures, one "Diet in Health and Disease", the other "Dietary Regime in Cardiovascular Renal Disease", at the Oklahoma City Annual Fall Conference. On November 10 he addressed the American Dietetic Association on 'The Present Status of the Ketogenic Diet and Its Use'

Dr Ralph Pemberton (Fellow), Philadelphia, addressed the Academy of Medicine of Des Moines, Iowa, on the subject of 'Arthritis' on November 4, 1932. He addressed the Academy of Medicine of Cincinnati, Ohio, November 14, 1932 on "The Newer Outlook of Arthritis"

Dr Martin H Collier (Fellow), Superintendent of the Lakeland Sanatorium, Gravelock, N J, was elected President of the New Jersey State Tuberculosis League at the Twenty-sixth Annual Meeting of that organization held recently in Newark, N J

Dr John I Marker (Fellow) Davenport Iowa was promoted to Lieutenant Colonel of the Medical Reserve Corps October 4, 1932

Dr Arthur C Morgan (Fellow) Philadelphia addressed meetings in Erie, Pa.,burg, Clearfield and St Mary's Pa. in connection with the observation of Heart Day in October, 1932

Dr William Henry Warr (Fellow) Boston presented a paper at the meeting of the North Side Practitioners' Medical Society recently. Dr Warr was in charge of program for the annual meeting of the American Association

Physical Therapy, held at Philadelphia, October 12-14, 1932

Dr E J G Beardsley (Fellow), Philadelphia, Pa, addressed the Staff of the Lancaster County Hospital Association, Lancaster, Pa, October 20, upon "The Diagnosis of Cardiovascular Disorders" Dr S S Simons (Associate), Lancaster, Pa, presided

Dr Beardsley was also the guest speaker at the Staff Meeting of the Glen Gardner Sanitarium, Glen Gardner, N J, October 21, his subject being, "Conditions that Commonly Simulate Pulmonary Tuberculosis"

Dr Louis F Bishop (Fellow), New York City, has been assigned to the Standing Committee of the New Jersey College of Pharmacy The College is in process of organizing a four-year pre-medical course

Dr Claude E Forkner (Fellow), formerly Assistant Physician to the Thorndike Memorial Laboratory, Boston, is now in Peiping, China, as Associate Professor of Medicine in the Peiping Union Medical College

Dr Howard T Karsner (Fellow), Cleveland Ohio, Professor and Director of the Institute of Pathology of Western Reserve University, has been elected the United States member of the Comité Directeur of the International Society for Geographic Pathology

Dr Huns Reese (Fellow), Madison, Wis, was elected President of the Central Neuropsychiatric Association at their annual meeting at Rochester, Minn, October 6-8, 1932

Dr S A Slater (Fellow), Worthington, Minn Superintendent of the Southwestern Minnesota Sanitarium addressed the Plymouth County Medical Society at LeMars Iowa October 8 on "The Diagnosis of Pulmonary Tuberculosis"

Dr Slater also was the chief speaker at a meeting of the Woodbury County Medical Society at Storm Lake, Iowa October 19

Dr E J G Beardsley (Fellow), Philadelphia,

Ga, was elected President of the Fifth District Medical Society of the State of Georgia on October 12

Dr John G Young (Fellow), Dallas, Texas, addressed the West Texas District Medical Society, October 4, on "Sinus Disease and Its Relation to the Child"

Dr Hyman I Goldstein (Associate), Camden, N J, read a paper entitled, "The Relation of Heart Disease,—Cardiac Murmurs, Angina Pectoris and Coronary Thrombosis,—to Gallbladder Infections and Gallstone Disease", before the Medical Section of the Congrès International de la Lithiase Biliaire at Vichy, France, September 20 Dr Goldstein also attended the annual sessions of the XXII Congrès Français de Médecine, October 10-11, at Paris

Dr Curren Pope (Associate), Louisville, Ky, addressed the staff meeting of Dr Anthony's Hospital at Louisville, Ky, on "Clinical Observations upon Pyretotherapy", on October 11

Dr Marjorie E Reed (Associate), Plymouth, Pa, is the author of a paper entitled, "Sydenham's Chorea, Diagnosis and Treatment", which appeared in the July number of the Medical Woman's Journal

Dr Clyde Brooks (Fellow), New Orleans, La, Professor of Physiology at the Louisiana State University Medical Center, New Orleans, has been selected to head the new department of Pharmacology and Experimental Therapeutics at that institution

The Oklahoma City Clinical Society conducted its annual fall clinical conference October 31 to November 3, under the presidency of Dr Ray M Balyeat (Fellow).

Dr Walter F Donaldson (Fellow), Pittsburgh, Pa, has been re-elected Secretary of the Medical Society of the State of Pennsylvania That organization will hold its 1933 meeting in Philadelphia

Dr Della W Bennett (Associate), San Francisco Calif, has been appointed Director

of the Student Health Service at the University of California

Dr Philip F Barbour (Fellow), Louisville, Ky, was installed as President of the Kentucky State Medical Association at its annual meeting in October

Dr Lawrason Brown (Fellow), Saranac Lake, Dr Ralph Pemberton (Fellow), Philadelphia, and Dr Martin E Reyfuss (Fellow), Philadelphia, appear on the list of lecturers in connection with the 1932-1933 program of the William Harvey Society at Tufts College Medical School, Boston

Dr John T Murphy (Fellow), Toledo, Ohio, was elected President of the American Roentgen Ray Society at its recent annual meeting in Detroit

A program on the History of Physical Diagnosis was offered by the College of Physicians of Philadelphia, Section on Medical History, November 14, 1932, on the occasion of the College's Sixth Annual Students' Night Dr Thomas B Fletcher (Fellow), Baltimore, by invitation, gave an address on "Physical Diagnosis between Laennec and Roentgen", Dr Wm Egbert Robertson (Fellow), Philadelphia, gave an address on "Later Additions to Physical Diagnosis"

OBITUARIES

DOCTOR CHARLES G LUCAS

Dr Charles G Lucas (Fellow), Louisville, Kentucky, died at the St Joseph Infirmary, July 7, 1932, of thrombosis of the cystic artery with peritonitis

Dr Lucas was born in Cincinnati, Ohio, in 1870, his premedical education was obtained in the public schools of Louisville and he graduated from the Medical School, University of Louisville, in 1890. Locating in Louisville, he engaged in general practice for thirteen years as an associate of the late Dr John A Ouchterlony. In 1904 and 1905 he studied Gastro-Enterology in Europe and on returning to Louisville confined his work to that specialty. He held some teaching connection with the Medical School of the University of Louisville until the Department of Gastro-Enterology was established in 1915, when he became the head of that department and held that position until his death. He was a member of the Staff of the Louisville

City Hospital and the St Joseph Infirmary, he was serving as President of the latter hospital staff for the year, 1932. He was a member of the Jefferson County Medical Society, the Kentucky State Medical Association, the American Medical Association, the American Gastro-Enterological Association, (President, 1926, Secretary, 1930-1932) and the American College of Physicians (Regent, 1922-1923, and 1925-1928). He was a communicant of the Catholic Church and a member of the Pendergast and Louisville Country Clubs. He served in the Medical Department of the Army during the Great War, being stationed at Camp McArthur, holding the rank of Major on discharge at its close.

His was both an inquiring and acquisitive mind, while the field of purely scientific medicine was a familiar environment the art of his profession found him a skilled character; his interest in the one did not lure him from the bedside contact of the other.

pleasure in the solitude of intellectual pursuit never deprived him of the joy of the personal contact with the victim of ill health. While the masters in medical literature found a gracious and understanding welcome in his library, the sufferer of one of the ailments considered in these theses learned from him that "Medicine is an art that sometimes cures, often relieves, and always comforts" His manner was pleasing, his nature optimistic, his friendships unusually loyal, and on his going he left a reputation unsullied by selfishness and petty ambition He had an abiding faith in his religion and he lived the Golden Rule as his code of ethics as nearly as humanly possible He will be missed and mourned alike by faculty, friends and patients

(Furnished by VIRGIL E. SIMPSON, M.D., F.A.C.P., Louisville, Kentucky)

DOCTOR CARL VICTOR VISCHER

Dr Carl Victor Vischer (Fellow), one of the younger but much respected and admired physicians of Germantown, Pennsylvania, died, November 15, 1932 His untimely death, after a month of painful, distressing and, from its inception, obviously hopeless illness occurred as the result of a septic process initiated by an osteomyelitis that had been in existence, without manifest symptoms, for a number of years

Dr Vischer's life, judged by the highest ethical standards, was a signal success He was respected, admired and deeply loved by those who knew him best His happy, cheerful and optimistic personality and his professional life of conscientious industry, combined with unrelenting study, caused

him to be regarded by well-informed members of his profession as an admired and trusted colleague Dr Vischer lived an unselfish, admirable and useful life He radiated an atmosphere of cheerfulness, happiness and hope that the world, especially the medical world, needs at all times, but, perhaps, never more than at present

Dr Vischer was born in Philadelphia in 1896, the son of a talented and much admired homeopathic surgeon. The son inherited those traits and characteristics that made his entrance into the medical profession the natural course for him to adopt He graduated from his father's Alma Mater, the Hahnemann Medical College of Philadelphia, in 1919, when twenty-three years of age After serving the Hahnemann Hospital as interne, Dr. Vischer continued to interest himself in the welfare of the Hahnemann Medical College and Hospital, and, as a result of his ability, faithfulness and industry, he was gradually advanced in rank, until at the time of his death, he was Associate Professor of Medicine in the College and Associate Physician to the Hospital Dr Vischer was Chief of the Outpatient Medical Department of the same institution for many years This position afforded him a wealth of experience in clinical medicine As a result of this experience, Dr Vischer published a number of meritorious articles in current journals These well illustrated his desire to share with others the practical knowledge that he had acquired. Dr. Vischer recently published a Handbook on Pulmonary Tuberculosis, which embodied the results of his studies on this disease

He was deeply interested in all phases of medicine, but was best known for his interest in the disorders of the circulatory and respiratory systems. He was greatly interested in the practical phases of the control of pulmonary tuberculosis, and had been Associate Director of Devitt's Camp for tuberculous patients for a number of years.

Dr Carl Vischer's all too brief professional life of thirteen years was well and wisely spent. His temperament and inclinations prevented him from making the all too common error of youthful physicians of magnifying the importance of a knowledge of disease and minimizing the necessity of studying the patient and his reactions.

Dr Vischer was an enthusiastic believer in and a loyal supporter of so-called organized medicine. Early in his medical career, he affiliated himself with the local, state and national homoeopathic societies, and later, with the breadth of view that was as admirable as it is unusual, he also associated himself with the organizations of the so-called regular school. He was elected a Fellow of the American College of Physicians in 1928, and, in his characteristic wholesouled manner, interested himself in the healthy growth and development of the organization. He attended every Clinical Session of the college after his election, and many Fellows throughout the College will be saddened as are his Philadelphia colleagues, by the loss of this vital and charming personality.

M D, F A C P, Governor for eastern
Pennsylvania)

DOCTOR JAMES MANARA RECTOR

Dr James Manara Rector (Fellow), Columbus, Ohio, died September 17 1932, from a cerebral hemorrhage.

Dr Rector was born at Circleville Ohio, June 27, 1877. He was educated in the public schools of Circleville, and in 1903 was graduated from the Medical College of the Ohio State University. He later did postgraduate work at the Chicago Postgraduate College and at the New York Postgraduate Medical School. For many years, Dr Rector had been a member of the staff of Grant Hospital. During the Spanish-American War, he served in Cuba and Porto Rico, and was President of Battery H, Spanish War Veterans. He was a member of the Columbus Society of Internal Medicine, the Columbus Academy of Medicine, the Ohio State Medical Association, the American Medical Association, and had been a Fellow of the American College of Physicians since 1930.

DOCTOR JOSEPH WESLEY MALONE

Again we are called upon to turn our thoughts with respect to one of our associate members, Doctor Joseph Wesley Malone who died September 10, 1932.

Doctor Malone was born in 1866 and was prepared for the College of Physicians and Surgeons of New York at the Elizabeth Normal Academy of Pennsylvania. He graduated in medicine in 1888, and thereafter spent his entire life in the practice of medicine in Brooklyn. There, by industry, ability, and personality he came into the

recognition he deserved. He soon limited his practice to internal medicine and continued to keep abreast with the many advances in that specialty. With this progressive spirit, which kept him delving into the newer fields, he became in later years greatly interested in the allergic diseases. His ability, his fairmindedness, and his friendly understanding are the factors that soon claimed for him the recognition of the hospitals of the city. He was Attending Physician in Kings County Hospital; Attending Physician, Victory Memorial Hospital; and a member of the Courtesy Staffs of the Caledonian and St. John's Hospitals. During the World War he sensed his obligations to his country and gave his time as physician to the Local Board, No. 59, with the rank of Major of the Medical Corps of the United States Army, which work he carried out with his accustomed fidelity.

Doctor Malone was not only interested in scientific medicine but was also an ardent supporter of organized medicine. He was deeply impressed with the idea that the solution of problems arising from the relationship of the public to medicine must be guided by the medical profession if these

problems are to be solved correctly. He spent much time in his local County Society and in the Medical Society of the State of New York in furthering this conviction.

Doctor Malone was a member and ex-President of the Bay Ridge Medical Society, a member of the Flatbush Medical Society, the Medical Society of the County of Kings, and of the Medical Society of the State of New York. He was a Fellow of the American Medical Association, and was ex-President of the Medical Guild of Kings County, and a member of the Association of Military Surgeons of the United States. In 1922 he was made an Associate of the American College of Physicians.

During his years of active participation in medical affairs Doctor Malone made many friends through his sincerity of purpose and the charity of his mind. His standards and ideals of medicine were recognized by all, and in his passing we realize that we have lost a distinguished gentleman from our community as well as a devoted physician and true friend.

(Furnished by LUTHER F. WARREN, M.D., F.A.C.P., Governor for eastern New York.)

The Clinical Significance of Leucopenia with Special Reference to Idiopathic Neutropenia

By STACY R. METTIER, M.D., F.A.C.P., and HARVEY T. OLSAN, M.D.,
San Francisco, California

THE development of leucopenia without apparent cause in a previously healthy individual is a subject about which there has been considerable discussion in recent years. Leucopenia brought on by definite etiologic factors such as certain bacterial and protozoan infections, toxic chemicals, or destruction of the bone marrow by tumor processes is readily understandable. Here the problem is concerned chiefly with diagnosis, and eradication or alleviation of the primary cause. There are instances of leucopenia, however, that are not so readily explained, and in which the cause remains obscure. In the medical literature one may find such conditions designated as "granulopenia", "granulocytopenia" of unknown origin, or "idiopathic" neutropenia. Cases of leucopenia falling in this group warrant further investigation. During the past three years we have had opportunity to observe several cases of leucopenia

of this nature, and certain of these will be discussed in this paper.

Before discussing the clinical aspects of leucopenia, it is necessary to consider the polymorphonuclear leucocyte, its origin and various stages of development from youth to maturity. The progenitor of the granulocyte series is a cell in regard to the exact identity of which there still remain differences of opinion. The concept of Sabin¹ and her associates on leucogenesis, however, has somewhat clarified the situation, and offers a tenable hypothesis on cell development from the primitive form to maturity. Whether or not the erythrocyte and granulocyte arise from a common parent cell, it is generally accepted that leucopoiesis normally takes place outside the blood sinusoids of the bone marrow, and the granulocytes gain entrance to the capillaries through their own motility. According to the concept of Sabin, the primitive progenitor of the granulocyte arises from a reticular cell having the sinusoids of the bone marrow, and from this stage passes through a series of transformations to the adult form. The next cell in order is the myeloblast,

From the Department of Medicine, University of California Medical School, San Francisco.

Presented at the San Francisco Meeting of the American College of Physicians, April 7, 1932.

and from this point on, maturation is a matter of cellular differentiation consisting in nuclear indentation and lobulation. As the cells age, cytoplasmic inclusions appear and their presence and tinctorial differences may be detected through the use of appropriate stains. In the bone marrow the young granular forms are designated as myelocytes a, b, and c, and the metamyelocyte. Normally in the circulation the fully matured form of the granulocyte appears as the motile, polymorphonuclear leucocyte.

When the bone marrow becomes involved by disease, leucopoiesis is interfered with, and under certain conditions leucopenia develops. Improper growth, failure of development, and aplasia of the bone marrow may appear as intrinsic disorders, and the white blood cells, the red blood cells, and the platelets become reduced in number. On the other hand, there are conditions in which the bone marrow shows marked cellular overgrowth of the leucocytic series, but apparently there is retarded maturation and the granulocytes in the blood become reduced.

This brief review is essential to the proper understanding of the pathologic physiology of the cases to be presented.

In an effort to obtain some information concerning the clinical significance of leucopenia, its relation to various clinical conditions, and conditions of occurrence of benign leucopenia, a statistical study of 10,000 hospital records was undertaken. A summary of the observations is presented here in the form of table, and certain deductions are made from the figures observed.

In order to divide properly the 10,000 cases into a leucopenic group, those with normal, and those with elevated leucocyte counts, the figure of 5,000 leucocytes per c mm of blood was accepted as being the low standard for normal. In most text books of medicine it is stated that individuals in whose blood there are found 5,000 leucocytes or less per c mm show a state of leucopenia.

FREQUENCY AND CONDITIONS OF OCCURRENCE OF LEUCOPENIA

There are few data available that concern directly the frequency of leucopenia. Roberts and Kracke², in a statistical study of 8,000 records of patients seen in private practice for the ten-year period between 1920 and 1930, recorded that leucopenia occurred in 1,881 or 23 per cent of their patients. These authors took 6,000 leucocytes per c mm of blood as the lower limit of normal.

The data to be presented have been derived from the records, exclusive of the outpatient department, of the University of California Hospital. Examination of the records was limited to those belonging to the Division of Medicine, and the results obtained, therefore, represent a cross section of the illnesses suffered by the patients entering a general medical service. Patients who were in for "overnight" observation or treatment, and in whose records there does not appear an adequate history, the results of a complete physical examination or the reports of the "routine" laboratory test are excluded from this series.

From January, 1920, until January,

1931, 10,000 case records were made and these form the basis of this study. A high percentage of the patients presented a definite diagnostic problem that required analysis through careful physical examination and laboratory studies. Accordingly, in the records of patients in whose blood there was found an inadequate number of leucocytes, there usually appeared two or more leucocyte counts. An analysis of the blood reports of 1,167 of the total

number of patients showed leucocyte counts of 5,000 cells or less per c mm. Thus, 11.67 per cent of the patients entering the medical wards during the eleven-year period were deficient in white blood cells.

In table I have been summarized the cases of leucopenia occurring in the medical records of the University of California Hospital, together with the percentage frequency of occurrence among the various disorders.

TABLE I

Number of Records Examined		10,000
Number with Leucopenia		1,167
Females with Leucopenia		611—52.4 per cent of cases
Males with Leucopenia		556—47.6 per cent of cases
CONDITION IN WHICH LEUCOPENIA OCCURRED	NUMBER OF CASES WITH LEUCOPENIA	PER CENT INCIDENCE OF LEUCOPENIA IN THE VARIOUS CONDITIONS

V

UNEXPLAINED LEUCOPENIA

No diagnosis	70 cases 6 per cent of all cases of leucopenia
Nervous exhaustion	44 cases 37 per cent of all cases of leucopenia
Neurosis, psychosis, hysteria	

From an examination of the table it will be noted that 52.4 per cent of the total number of cases of leucopenia occurred in females and 47.6 per cent of the cases in males. This indicates a moderately increased incidence of leucopenia in the female sex.

Data relative to the various conditions and different states of ill health in which leucopenia may be found of less frequent occurrence are listed in groups II, III, and IV. It will be observed that leucopenia occurred in very high incidence in a rather limited number of diseases set forth in group I. Of some interest is the appearance of numerous instances of leucopenia in patients with chronic disorders of one sort or another.

Clinically, the division of the idiopathic or obscure leucopenias into well defined groups presents a great difficulty because of lack of knowledge of

the etiologic factors concerned. However, there are cases of severe leucopenia that persist over a period of weeks or months. These are usually associated with other abnormalities of hematopoiesis, and are frequently fatal. These may be differentiated from cases in which the abnormality of leucopoiesis is less severe in degree. With these facts in mind two clinical groups of leucopenia of obscure origin may be defined.

I Malignant leucopenia of obscure origin.

II Benign leucopenia of obscure origin.

MALIGNANT LEUCOPENIA OF OBSCURE ORIGIN

The following cases are illustrative examples of conditions falling into this group.

Case I, Idiopathic Aplastic Anemia* J L T, a white, married, American farmer, aged 27, entered the hospital September 12, 1928, complaining of weakness and pallor. Except for pertussis at 6 years of age, chicken pox at 11, measles at 17, and bilateral mumps at 23 years of age, he had enjoyed good health for four years until the latter part of May, 1928. At that time a localized infection appeared on the back of his right hand, which, with surgical intervention, healed at the end of 3 weeks. About a month later, he began having signs and symptoms of anemia. A week prior to entry, small ecchymoses appeared on his legs following trivial trauma. He lost 10 pounds in weight during the month of June. The patient was undernourished and very pale. There were fading ecchymoses over both tibiae. Physical examination revealed no other abnormality.

Laboratory data. The examination of the blood on September 12 showed erythrocytes 1,216,000 per c mm, hemoglobin, 29 per cent (S), color index, 1.2, hematocrit, 15 per cent of cells, reticulocytes, 0.4 per cent with a comparable number of polychromatic

cells. There were an occasional large and a few small erythrocytes. A few red blood cells were oval in shape and a few showed central pallor. The leucocytes numbered 2,500 per c mm of blood. Differential count: polymorphonuclears, 24 per cent, lymphocytes, 70 per cent, monocytes, 6 per cent. The platelets were greatly reduced. The bleeding time was 15 minutes. The coagulation time by the method of Lee and White was 15 minutes. No clot retraction occurred at the end of 3 hours at 37°C.

The basal metabolic rate was plus 6.5 per cent. The Kahn test on the blood serum was negative. Repeated blood cultures revealed no bacterial growth. Fractional gastric analysis showed the presence of free hydrochloric acid in normal amount.

A biopsy of sternal marrow was performed on September 13. This tissue was made up largely of fat cells. Small focal hematopoietic clusters of cells were scattered between the interstices of those cells, and only in one area was there a focus of apparent cellular activity as shown in figure 1. In these foci there were a moderate

*It is a pleasure to record our thanks to Doctor George R. Minot for the opportunity to study cases I and II at the Thorndike Memorial Laboratory of the Boston City Hospital, and to Doctor Frank B. Mallory of that hospital for the use of the autopsy material.

FIG 1 Specimen of bone marrow removed at biopsy from patient with idiopathic aplastic anemia. Note small focus of hematopoiesis in otherwise cellular bone marrow.

number of neutrophilic myelocytes and an occasional eosinophilic myelocyte, but in the entire specimen no adult granulocytes nor megakaryocytes were observed. The cells comprising the foci were chiefly erythroblasts and myeloblasts, among which an occasional mitotic figure was noted. The endothelial cells lining the sinusoids in the areas of hematopoiesis were of moderate size, but were small in the collapsed sinusoids. A few large phagocytic cells containing pigment were seen. Diagnosis: Aplastic bone marrow.

Course of illness. On September 19, small hemorrhages appeared in the retinae and the following day small petechiae were visible in the skin over different parts of the body. On September 22, 1928, the patient was given his first transfusion of blood. Liver pulp in amounts of 300 grams daily for a period of 10 days and a subsequent course of liver extract 343 N N R, derived from 600 grams of liver daily, failed to affect the bone marrow. Temporary relief was afforded by 6 transfusions of blood, 3 of which were given on 3 successive days prior to splenectomy. During the two and one-half months the patient was in the hospital, examinations of the blood were made at frequent intervals. The erythrocytes fluctuated between 600,000 and 1,000,000 per c. mm., depending chiefly upon transfusions of blood. The reticulocytes varied from 0.4 and 1.0 per cent. The leucocyte count varied from 1,700 to 2,500 per c. mm. The differential count remained essentially the same as at entry. On November 11, 1928, splenectomy was performed notwithstanding the diagnosis of aplastic anemia, there was a forlorn hope that the operation might favorably affect the patient. The spleen weighed 128 grams. Microscopical examination showed it to be normal except for slight enlargement of the malpighian bodies.

A week after splenectomy, petechial hemorrhages reappeared over the body. The patient began to have frequent severe nosebleeds, grew steadily paler and weaker, and died November 28.

The autopsy showed an aplastic fatty bone marrow, the spleen of normal size and weight, and the liver of normal size and weight. The lungs were normal.

DISCUSSION

In this case, idiopathic aplastic anemia occurred in a previously healthy adult male 27 years of age. Neither exposure to overdoses of x-ray, radium, benzol, or arsenicals, nor some hidden focus of infection could be held as an etiological factor. The condition appeared to be an intrinsic abnormality of hematopoiesis, and failure in leucocyte, erythrocyte, and platelet production.

Of some importance, however, is the fact that apparently active but small foci of blood formation could be seen in the specimens of bone marrow removed at biopsy, an example of which is shown in figure 1. Among such clusters of cells a few mitotic figures were noted. Similar observations have been recorded by Mills.³ This evidence of hematopoietic activity holds forth hope of discovery of some substance, the administration of which will permit adequate erythrocyte and leucocyte growth.

Case II, Agranulocytosis, Esophagitis. I. W. S., a Jewish housewife, aged 47 years, was brought to the hospital on May 11, 1929, suffering from weakness, headaches, chills and fever. One of her mother's sisters had died of Hodgkin's disease at 50 years of age. During childhood the patient had "black" measles, mumps, chickenpox, smallpox, and scarlet fever. It was stated that she had had typhoid fever at 14 years of age, and dengue fever at 40. Eleven years before the present illness an abscess developed in the right breast following childbirth. Tonsillectomy was done 10 years before, at which time she lost "much blood." All her upper teeth were removed 9 years before.

The patient said she had been "anemic all her life." About 1916 her blood was reported to show slight anemia. Two years before death she received a series of iron and arsenic injections after which she felt better.

During the winter of 1928 and 1929 she had been as well as usual, but suddenly on the evening of April 14, 1929, she experienced "chills and fever," when she "shook all over." Severe headache accompanied this attack. Her temperature was 101°F. The next day she felt quite well. Similar attacks occurred on April 24, 30, and May 6. The last attack was the most severe, and the headache persisted 4 days. The height of the fever was between 103° and 104°F.

On April 25, 1929, examination of the blood by her physician showed the following: erythrocytes, 3,750,000 per c mm., hemoglobin, 58 per cent, leucocytes, 9,000 per c mm., polymorphonuclear leucocytes, 75 per cent.

On May 1, 1929, the leucocytes were 2,500 per c mm., polymorphonuclear leucocytes, 40 per cent, lymphocytes, 60 per cent.

The patient, on hospital entry, May 11, 1929, appeared well-nourished, and quite comfortable.

Physical examination. There was moderate pallor of the skin and mucous membranes. There was no apparent ulceration of the pharyngeal structures. No enlarged lymph nodes could be felt. The spleen was palpable only on deep inspiration. The liver edge was easily felt.

Laboratory data. Examination of the blood on May 13, 1929, showed: erythrocytes, 3,400,000 per c mm., hemoglobin, 76 per cent (S), hematocrit, 45 per cent of cells, leucocytes, 1,200 per c mm. differential count: polymorphonuclear leucocytes, 6 per cent, monocytes, 32 per cent, large lymphocytes, 28 per cent, small lymphocytes, 32 per cent, young lymphocytes, 2 per cent. Several red blood cells showed polychromatophilia and stippling, and there was slight anisocytosis and poikilocytosis. The platelets appeared in normal numbers. There were 12 per cent of reticulocytes.

X-ray examination of the gall bladder failed to reveal stones or any abnormality in the function of this organ. The Wassermann and Kahn tests were negative.

Between May 16 and 29 daily stool examinations were strongly guaiac-positive for blood, but were negative for parasites or bacteria. Stool cultures were negative for pathogenic bacteria. Several blood cultures showed no bacterial growth.

Examination of the blood on May 20, 1929, showed: erythrocytes, 3,450,000, hemoglobin 76 per cent (S), leucocytes, 1,800 cells per c mm. differential count: supravital stain, polymorphonuclear leucocytes, 0, small lymphocytes, 33 per cent, large lymphocytes, 32 per cent, monocytes 35 per cent. The monocytes were sluggishly motile and contained large multilobulated nuclei. Most of these cells were oxidase negative with the peroxidase stain.

The patient gradually grew worse, became comatose and died on May 20, 1929.

Postmortem examination. Autopsy was performed 2½ hours after death. There was a pale yellow tint to the skin and sclerae. The appendix and a few loops of adjacent small intestine were bound together by fibrous tissue. The liver edge projected 11 cms. below the tip of the xiphoid and 6 cms. below the right costal margin. The mesenteric lymph nodes were not enlarged. Positive findings follow.

Spleen. Weighed 240 grams (about twice normal size). The surface was dark gray-purple and the capsule irregularly thickened. The freshly cut surface was dark red and showed fairly prominent trabeculae. Very little pulp scraped away.

Gastro-intestinal tract. The lower one-third of the esophageal wall and adjacent 2 centimeters of stomach were moderately thickened and the mucosa had a light brown parboiled appearance. It could be rubbed off with ease. Remaining intestinal tract was negative.

Liver. The liver weighed 2200 grams. It was normal in shape and consistency. There were numerous fibrous tracts on the upper surface. The freshly cut surface was red-brown with indistinct markings. The gall bladder was thin-walled and contained a small amount of normal appearing bile.

Bone marrow. The bone marrow of the vertebrae and sternum was red in appearance and of normal consistency. In the femur it was red in the upper end and mostly fat tissue in the lower end.

Microscopic examination. The wall was congested with red cells and lymphocytic infiltration. The cells were mostly small and mature. There were no eosinophils. The cells were mostly small and mature. There were no eosinophils.

and invaded by large numbers of bacteria and fungi. Among the bacteria, cocci and medium-sized bacilli were most numerous. Long, slender, branching forms resembling streptothrix were also present, especially in the deeper portions of the submucosa.

Stomach. A specimen from the cardiac portion of the stomach showed diffuse infiltration with lymphocytes and plasma cells.

Spleen. There was slight increase in connective tissue throughout. A few follicles contained central masses of fibrin. There were several small, round well-encapsulated pink staining masses in which no structure could be made out.

Liver. There was slight lymphocytic infiltration of the portal spaces. There were several small homogeneous pink staining masses similar to those in the spleen.

Bone Marrow. A specimen of bone marrow from the upper third of the right femur showed a slightly increased amount of fat. The cells of the hematopoietic centers were diminished in numbers. No polymorphonuclear leucocytes were to be seen. There were numerous promyelocytes with large single nuclei, and faintly neutrophilic cytoplasm. No definite neutrophilic nor eosinophilic myelocytes could be distinguished. There were normal-appearing foci of erythropoiesis. A fairly good number of megakaryocytes was seen. There was a scattering of lymphocytes and plasma cells.

DISCUSSION

The observation of Schultz¹ in 1922 of a group of patients whose clinical pictures were those of leucopenia associated with sepsis resulted in an attempt at formulation of a new clinical entity. This condition has become known as agranulocytosis, agranulocytic angina, malignant neutropenia, idiopathic neutropenia, and by other descriptive terms. In the past it has been inclined to attribute the leucopenia to the infecting process, sepsis or to the "toxic" nature and most of the cases have been reported from that

point of view. In recent years it has become more and more apparent that the disease may not be an entity as was first supposed but more probably a syndrome. The reason for this change in thought is that the composite clinical picture, which is frequently present, is now known not to be associated with a single or specific type of infectious process, but may be found in the presence of a variety of septic conditions as have been reported by Blumer,⁵ Roberts and Kracke,² Thompson,⁶ Rose and Hauser⁷ and others.

This concept of granulocytopenia occurring as a manifestation of multiple clinical disorders in man is an important one, and has suggested to Rosenthal,⁸ among others, that there may be a leucopenic predisposition or trend in certain individuals. During the life of this patient she was beset with a multiplicity of unrelated types of infection. Terminally there was a profound and persistent idiopathic neutropenia which was found at autopsy to be associated with an esophagitis and gastritis.

The bone marrow in this patient appeared fundamentally different from that in the previous patient. Here there was evidence of adequate platelet and red blood cell production from their precursors in the bone marrow, but it seemed apparent that leucopoiesis was retarded or impaired at the promyelocyte stage.

The recent publication of Jackson⁹ and his associates on the use of a purine nucleotide (nucleotide K-96) for use in cases of malignant neutropenia associated with infection offers some encouragement in the treatment of this disease.

We wish to report a case of neutro-

penia associated with infection in which recovery occurred during the course of administration of nucleotide K-96. No definite conclusions can be drawn as yet with regard to the efficacy of this therapeutic agent until a large number of cases have been studied. The course taken by the leucocytes in the patient reported below is given in figure II.

Case III, Staphylococcus Lymphangitis with Leucopenia, Patient's Subsequent Recovery. S. R. (Hospital No 64,717), a white American housewife, aged 52 years entered the hospital February 29, 1932. She stated that one week prior to hospital entry she had received a slight burn on the antero-radial aspect of the left wrist. This was followed by scab formation, and so far as she knew, the lesion was healing. The day before entry, the patient noticed for the first time "red streaks" extending up the anterior and medial aspects of the left forearm.

Her past history was unimportant except that in childhood she had mumps, pertussis, and measles. Twenty years ago she had an abscess in the left hand that had promptly healed. During the past year she had been under the care of a physician for arterial hypertension.

Physical examination. The patient was well-nourished and developed. There was no apparent ulceration of the pharyngeal structures. No enlarged superficial lymph nodes could be felt. Neither the spleen nor the liver were found enlarged on palpation. The blood pressure was 170 systolic, and 80 diastolic. There was a small, slightly elevated round, hyperemic lesion on the radial aspect of the left wrist. No purulent material was visible. Extending up the forearm were numerous red and enlarged lymphatic vessels. The patient's temperature was 38.4°C, the respiration rate, 24 per minute, and the pulse beat, 120 per minute.

Laboratory data. Examination of the blood on February 29, 1932, showed erythrocytes 4,600,000, hemoglobin, 85 per cent (S), leucocytes, 8,600 cells per c mm, differential count polymorphonuclear leucocytes, 78 per cent, polymorphonuclear basophiles, 1 per cent, lymphocytes, 16 per cent, monocytes,

5 per cent. The platelets appeared slightly increased in number. Several blood cultures showed no bacterial growth. Cultures obtained on two occasions from the inflammatory process on the left wrist were reported to contain *Staphylococcus aureus*. Soon after entry, the patient's left arm was placed in a hot magnesium sulphate bath for two hours. This procedure was carried out twice daily.

Course of illness. On the third day of the patient's stay in the hospital, her leucocytes were found to number 800 per c mm and the following day, 400 per c mm. Nucleotide (K-96) in amounts of 10 cc was administered intramuscularly twice daily for 9 days. Beginning about the fifth day after the initial injection of nucleotide, an increase in the number of polymorphonuclear leucocytes became apparent in the peripheral circulation. On the eleventh day of this treatment, the leucocytes were 10,050 per c mm of blood. Coincident with the increase in the number of leucocytes there was a lessening in the severity of the patient's infection. Fifteen days after the patient entered the hospital there was a complete disappearance of the inflammatory process and the patient's temperature had returned to normal. In figure 2 are recorded the temperature and blood counts of the patient together with the time interval during which nucleotide was administered.

Case II - Acute Myeloblastic Leukemia with Chloroma. E. I. M. (Hospital No 59,836), a four-year old white male was admitted to the Pediatric Service of the University of California Hospital February 18, 1931, because of pallor and weakness of six weeks' duration. In the past she had had pertussis at 2 years of age followed by a severe attack of scarlet fever. This was complicated by otitis media. The patient was a girl recently bedridden since November 1, 1930, when she developed "cold" with severe nasal discharge. The "cold" failed to respond to treatment and about the middle of November the nasal color had become pale. She had become weak and was fed only by mouth. She died in bed. Duration of illness, 10 months.

*We wish to thank Dr. J. H. H. for his assistance in the preparation of this report.

became noticeable upon exertion. About the middle of January, a swelling of the frontal portion of the skull appeared just above the nose, and both eyes began to appear more prominent than previously. Physical examination on admission disclosed an undernourished, pale child who was obviously ill. There was no evidence of rash or petechiae in the skin. All superficial lymph glands were slightly enlarged, discrete and firm. The anterior fontanel was open and the an-

cent (S), the red blood cells were 840,000 per c mm, and the white blood cells, 1,550 per c mm. In the differential count, using the supravital staining technic, there were polymorphonuclear leucocytes, 31 per cent, large lymphocytes, 12 per cent, small lymphocytes, 16 per cent, myelocytes, A, 1 per cent, B, 5 per cent, C, 25 per cent, monocytes, 10 per cent. Tests for bleeding time and clotting time showed these functions to be within normal limits. The blood Wasser-

FIG 2 The occurrence of leucopenia in a female patient with lymphangitis of the arm followed by recovery during the intramuscular administration of nucleotide K-96

terior sutures were separated. The forehead, just above the bridge of the nose, bulged over an area of about 3 by 3 inches, and the veins in this area were slightly more prominent. A loud bruit, synchronous with the pulsation of the temporal artery, was heard over this area. There was bilateral exophthalmos, most marked on the right. Ophthalmoscopic examination showed bilateral choked discs of 1 to 1½ diopters. There were a few scattered retinal hemorrhages of small size. The heart and lungs were normal. The liver edge was felt 2 cms below the right costal margin, and the spleen was felt 3 cms below the left costal margin. The laboratory data showed a hemoglobin of less than 20 per

cent. The mann reaction was one plus. X-ray examinations of the long bones and ribs were negative and there was no evidence of bony destruction in the skull, but there were signs of increased intracranial pressure. Blood cultures failed to produce any bacterial growth.

Course of illness. Following exposure to the x-ray on five different occasions, the mass in the frontal region of the skull diminished in size and the exophthalmos receded. Her strength and appearance were improved by six transfusions of whole blood in amounts of 300 cc. On March 22, 1931, a few days after the last x-ray treatment, a fever of 40°C was noted, and petechial

hemorrhages developed over the forehead, nose and upper chest. From this time on the patient failed to improve following transfusion. A grayish necrotic patch appeared on the right tonsil two weeks before death, and one week later there was evidence of bronchopneumonia. She lost strength rapidly, and on April 16, 1931, death occurred.

The gross findings at the autopsy performed by Doctor Charles L. Connor showed numerous varying-sized hemorrhages in all the serous coverings of the body cavities. The lymph nodes were but slightly enlarged and everywhere were firm and discrete. The liver was firm and slightly enlarged. It weighed 600 grams. The spleen was large and weighed 100 grams. Both kidneys were larger than normal and contained numerous minute pale green areas. The lungs showed no evidence of pneumonia, but there were many small subpleural hemorrhages. In the anterior cranial cavity beneath the dura on both sides lateral to the midline there were deposits of greenish material resembling old hemorrhage, and there were some recent bright hemorrhagic spots also present. The layers of the dura, particularly along the longitudinal sinus and around the lateral and

straight sinuses were infiltrated with a greenish, cellular substance which appeared to be tumor. A small mass of similar material projected through the cribriform plate into the nasopharynx. The bone marrow in the upper third of the right femur appeared light red in color, cellular and seemed to contain very little fat.

On microscopic examination of the bone marrow, it was observed that there was an almost complete absence of fat, and that the normal architecture was in a large measure replaced by masses of cells. These cells contained large, clear, rounded nuclei with the chromatin clustered about the nuclear membrane, as seen in figure 3. The cells appeared immature and many contained an indented bay in the nucleus. None contained granules in the cytoplasm. This cell was considered a myeloblast rather than the so-called lymphoblast. Mitoses were frequently seen. There were very few polymorphonuclear leucocytes, but moderate numbers of myelocytes were discovered. Very small islands of erythroblastic tissue were seen, and rarely a megakaryocyte. Examination of the heart, lungs, liver, spleen, kidneys, adrenals, ovaries, and lymph nodes showed areas of infil-

FIG 3 Specimen of bone marrow removed from sternum of patient in case III. Note marked hyperplasia and presence of large numbers of immature leucocytes.

tration with cells resembling those described above. The tumor tissue removed from the dura was made up largely of this immature cell. It was believed that the concentration of the immature cells, as has been shown by Mallory, accounted for the pale green chloromatous color.

COMMENT

This, then, is another case of idiopathic neutropenia, the pathologic physiology of which apparently is entirely different from the two preceding cases. In contrast to cases I and II, there was in case IV increased cellularity of the bone marrow (figure 3) consisting almost entirely of leukoblastic tissue. Another patient, a female 56 years of age, presented a picture of the bone marrow similar to this in which active maturation of the leucocyte seemed retarded at the myeloblast stage.

Of rather rare occurrence is the development of severe leucopenia in conditions characterized by hemorrhagic tendencies, and in which abnormalities in platelet production appear fundamental. Minot¹⁰ has reported such an instance in association with thrombocytopenic purpura hemorrhagica.

It is of course well known that severe leucopenia may also develop in association with certain abnormalities in red blood cell production. In patients with pernicious anemia, in relapse, leucopenia is more often present than absent. The occurrence of leucopenia in patients with sprue and Banti's disease are other examples. Two instances of leucopenia occurring in patients with severe anemia diagnosed as acquired hemolytic icterus may be briefly cited as follows.

Case I. An Italian male, 58 years of age, had been in good health prior to June, 1930,

when he began to notice the gradual onset of a yellowish tinge in the whites of his eyes. In February, 1931, his skin appeared icteric and his sclerae were yellow in color. His hemoglobin was 40 per cent (S), the red blood cells numbered 2,130,000 per c mm and the white blood cells were 2,900 per c mm. The blood platelets were slightly reduced in number, and 10 per cent of the nucleated cells in the stained blood smear were normoblasts. There was slightly increased hemolysis of the red blood cells to hypotonic salt solution. It is now one year after splenectomy and the patient appears in good health, he has a slight "secondary" anemia, but the leucocytes are present in normal numbers.

The illness from which the second patient suffered is not so clearly defined.

Case VI. This patient was a white male, 72 years of age, who had noticed increasing pallor and weakness of 3½ years' duration. During the past year his family physician had given him several transfusions of blood. When he entered the hospital, slight icterus of the sclerae was noted, and the spleen was moderately enlarged. His hemoglobin was 26 per cent (S), there were 1,160,000 red blood cells per c mm, and the leucocytes were 2,300 per c mm. The platelets were slightly reduced. The icterus index was 15. Reticulocyte counts made daily showed the presence of from 6 to 10 per cent of these cells. Analysis of the gastric content showed the presence of free hydrochloric acid. A biopsy of the sternal marrow was performed and the specimen of tissue removed was extremely cellular and made up almost entirely of normoblasts (figure 4). Because of the foregoing data and the failure to attribute the anemia to blood loss, pernicious anemia or tumor, acquired hemolytic icterus was considered the most likely diagnosis. Splenectomy was resorted to as a therapeutic agent. Two days after the operation the patient died following paralytic ileus. The report from the pathology laboratory was splenomegaly, "type compatible with hemolytic icterus." A postmortem examination revealed the presence of marked erythro-

blastic and normoblastic hyperplasia of the bone marrow, but otherwise was essentially negative

These cases, then, illustrate different types of neutropenia of obscure origin and represent different types of bone marrow reaction leading to alteration in leucopoiesis

BENIGN LEUCOPENIA OF OBSCURE ORIGIN

In group V of table I have been placed the number of patients in whom leucopenia was reported present but in whose records either no diagnosis appears or one that may be considered functional in nature. This group comprised 114 of the cases of leucopenia, or 97 per cent of the total. In this group appear the patients whose complaints were those of chronic fatigue, lassitude, lack of appetite, and vague sorts of distress of one sort or another. Among such cases some of the diag-

noses were listed as neurasthenia, psychosis, hysteria and the various neuroses. Reference to similar cases have been made by Cabot,¹¹ Clough,¹² and Roberts and Kracke² who speak of them as states of "debility" associated with leucopenia. Disturbances in endocrine function¹³ and a constitutional factor¹⁴ have also been pointed out as having some possible relationship to decreased leucocyte formation. In this latter group the cause of the leucopenia must be considered intrinsic in character and decidedly obscure in origin.

SUMMARY AND CONCLUSIONS

1 Five cases of severe leucopenia of obscure origin are presented. Attention is called to the different types of bone marrow reaction occurring in the various cases, namely, aplasia of the bone marrow, depression of leucopoiesis only, hyperplasia of the leuko-

FIG. 4 Specimen of bone marrow removed at biopsy from sternum of patient in case VI. Note marked normoblastic hyperplasia.

poietic tissue, and hyperplasia of the erythropoietic tissue

2 A case of leucopenia associated with lymphangitis of the arm in an adult female is reported in which recovery occurred during the course of administration of nucleotide K-96

3 Among the 10,000 case records of patients cared for in the University of California Hospital between 1920 and 1931, inclusive, examination of the blood revealed leucopenia in 1,167 or 11.67 per cent of the cases

4 611 of the 10,000, or 52.4 per

cent of the cases of leucopenia, occurred in females and 556, or 47.6 per cent, occurred in males. Thus, leucopenia was slightly more prevalent in females than males

5 Leucopenia occurred frequently as a mild manifestation in patients with vague symptoms of one sort or another, such as chronic fatigue, 97 per cent of the cases of leucopenia were classified, therefore, as benign leucopenia of obscure origin

6 A table of the frequency incidence of leucopenia is given

A Clinical Study of the Graves' Constitution and Its Relation to Thyroid Disease

By CARL H. FORTUNE, A.B., M.D., *Lexington, Kentucky*

IT is not the purpose of this paper to discuss the relative merits of existing conceptions of thyroid disease nor to add to such theories, but to present certain data—gathered and interpreted by the clinician—bearing on the constitutional background of hyperthyroidism as expounded by Warthin. From time to time mention has been made of the frequent association between thymic enlargement and thyroid disease, but Warthin's address entitled "The Constitutional Entity of Exophthalmic Goiter and So-Called Toxic Adenoma"¹ is the most comprehensive statement of the significance of this association and has given rise to the phrase "Graves' Constitution (Warthin)" which has been used by other writers to designate this concept. It would be out of place to review that address in this paper, but a brief statement of the essential features is necessary for clarity.

The clinical syndromes, variously spoken of as hyperthyroidism, toxic goiter, toxic adenoma, Graves' disease, and exophthalmic goiter, are well known to physicians generally. Since the time of Parry, Graves and von Basedow, the original triad of goiter,

exophthalmos and tachycardia has been expanded by the addition of symptoms and signs referable to practically every organ in the body. Recent investigations have cast doubt on the assumption that thyroid dysfunction is the primary factor in this condition. The very multiplicity of names which has grown up to designate variations from the typical picture bears testimony to the complexity of the present conception and the difficulty of classifying cases seen. Warthin contends that there is, however, one underlying factor common to all who have this disease syndrome, and that factor is a constitutional abnormality, to which he has applied the term *Graves' constitution*.

The general appearance of the individual with this symptom complex is often so striking that the condition is recognized at a glance by even a relatively inexperienced observer. Quoting from Warthin¹ it is "expressed in *juvenile morphology* and rapid functional reaction." The essential anatomic stigmata, as seen at the autopsy table, are perhaps less widely recognized. Grossly there is found a persistent hyperplastic thymus. The importance and constancy of this finding was emphasized by Potter² in a review of twenty-two autopsies on cases of

¹From the Department of Internal Medicine of the University of Michigan. Received for publication, March 2, 1932.

exophthalmic goiter, and more recently by Moschowitz,³ who, while not finding it in all instances, reports it in ninety-five per cent of his fatal cases. Of equal importance is a generalized hyperplasia of the lymphoid tissue throughout the body, including not only the lymph nodes but also Peyer's patches in the intestine and the minute islands of lymphoid tissue which are found scattered throughout the body. Scarcely less striking is the underdevelopment of the vascular system, particularly the heart and aorta. Likewise the hypoplasia of the adrenals, especially of the medullary portion, is of diagnostic and perhaps also of functional significance.

The lymphoid hyperplasia is the anatomical feature of diagnostic significance in the microscopic examination of the excised thyroid gland. The normal thyroid shows no lymphoid follicles, but there are scattered through it primitive lymph nodes, perhaps represented by only a few lymphoid cells, and so small as to be difficult of recognition. In the Graves' constitution these primitive nodes become hyperplastic, with the development of germinal centers. While this has been recognized by many writers, few have laid stress upon it, but Warthin^{1, 4} has amply demonstrated its diagnostic significance as indicating Graves' constitution. He maintains that every case of exophthalmic goiter, hyperthyroidism, toxic goiter, toxic adenoma, or other variation of the clinical syndrome will show in the excised thyroid gland this evidence of a constitutional abnormality. He does not hold, however, that every person with Graves' constitution will show this clinical syn-

drome. While the individual with this constitutional abnormality is always potentially a subject for so-called thyroid disease, the condition may be dormant throughout his lifetime. We do not know what influences bring out the clinical syndrome. Consequently a simple goiter, a simple adenoma, an otherwise apparently normal thyroid, or even a thyroid of below normal function, may or may not belong to the Graves' constitution. An outline intended to clarify this relationship is given below in table I.

TABLE I

GRAVES' CONSTITUTION

(Lymphoid hyperplasia in thyroid)

Definite thyroid disease

- (a) Exophthalmic goiter
- (b) Toxic goiter, hyperthyroidism and other less well defined abnormalities
- (c) Toxic adenoma

Thyroid function normal or decreased

(Thyroid disease always potentially present, however)

- (a) Normal size and otherwise structurally normal thyroid
- (b) Diffuse colloid goiter
- (c) Adenomatous goiter without toxicity

NO EVIDENCE OF GRAVES' CONSTITUTION

(Thyroid function normal or reduced)

- (a) Normal thyroids
- (b) Diffuse colloid goiter
- (c) Adenomatous goiter

This constitutional relationship to thyroid disease has been discussed at length in three papers appearing since Warthin's address. Simpson,⁵ analyzing the cases at the Miami Valley Hospital corroborates Warthin's findings in their entirety. Hellwig⁶ in a discussion based on fifty-four excised glands and six autopsies disagrees throughout with Warthin's conception. Quite aside from the meager extent of his

material, he has completely misinterpreted Warthin's idea of the Graves' constitution. He implies that since he found lymphocytic hyperplasia in 38.5 per cent of the cases showing no hyperthyroid symptoms there can be nothing diagnostic in this finding. As already pointed out, Warthin contends that Graves' constitution may be present in an otherwise normal thyroid, and that if the stimulus, concerning which we admittedly know little, is not present to set off the metabolic disturbance, the hyperthyroid symptoms may remain latent throughout the individual's lifetime.

A very interesting hypothesis has been advanced by Moschcowitz.³ As already mentioned, he notes an almost uniform association of the thymico-lymphatic constitution with exophthalmic goiter. He maintains, however, that the constitutional background is a neuro-psychiatric instability, which he holds is most often seen in individuals of the thymico-lymphatic habitus, or to use Warthin's nomenclature, the Graves' constitution. He thus believes that there is an indirect relationship between the Graves' constitution and exophthalmic goiter, differing from Warthin, who believes that the neuro-psychiatric instability is merely an attribute of the constitution, and that the constitution is the fundamental requisite for thyroid disease.

In view of the conflicting ideas, I have attempted an evaluation of the importance of the Graves' constitution, approaching the problem as a clinician. In order to limit the amount of material, the period 1927 to 1930 was selected and all the cases were included which, during that period, had been

studied on the medical service of the University of Michigan Hospital and subsequently transferred to the surgical service for thyroidectomy. The excised glands were all examined in the Department of Pathology of the University of Michigan, of which Dr Warthin was at that time the director. The clinical records were thoroughly studied, including laboratory data, such as determinations of basal metabolic rate, and the case was evaluated clinically before any reference was made to the pathologist's report. The clinical and pathological findings were then tabulated and compared. A series of 245 cases was studied and the results are presented in table II. For the sake of clarity, I have avoided fine clinical differentiations, placing together in one group those conditions referred to as hyperthyroidism, exophthalmic goiter without eye signs, toxic goiter, etc.

DISCUSSION

It will be seen at once that 90 per cent of the cases fall into Warthin's classification in just the manner which would be expected. The other 10 per cent in which there is an apparent disagreement between clinical findings and the pathological diagnosis calls for further study. I shall refrain as far as possible from theoretical conclusions, since a presentation of the facts concerning individual cases seems more to the point. For the sake of brevity the cases have been grouped in the above table and numbered with Roman numerals and these numbers will be used to identify them in the following discussion.

The four cases in group I, which clinically were typical exophthalmic

TABLE II

CLINICAL DIAGNOSIS	PATHOLOGICAL DIAGNOSIS			PERCENTAGE AGREEMENT
Group I	Exophthalmic goiter	Exophthalmic goiter with adenomas	No evidence of Graves' constitution	
Exophthalmic goiter with eye signs 67 cases	58 cases	5 cases	4 cases	93.9%
Group II	Exophthalmic goiter, or Graves' constitution			
Exophthalmic goiter without eye signs, hyperthyroidism, etc	53 cases	14 cases	4 cases	94.4%
71 cases				
Group III				
Toxic adenoma	3 cases			100%
3 cases				
Total 141 cases	114 cases	19 cases	8 cases	94.3%
Group IV	Adenomatous goiter with Graves' constitution	No evidence of Graves' constitution		
Toxic adenoma	48 cases	18 cases		72.7%
66 cases				
Group V				
Non-toxic adenoma	12 cases	26 cases		100%
38 cases				
	Percentage of non-toxic adenoma showing no evidence of Graves' constitution 68.4%			
Total cases	Agreement 86 cases	Disagreement 18 cases		82.7%
104				
Grand Total	Agreement 219 cases	Disagreement 26 cases		89.3%
245 cases				

goiter and pathologically showed no evidence of Graves' constitution, are perhaps the most significant. One of these four cases was known to have taken iodine for at least two months previous to operation and another stated that he had taken two or three kinds of goiter medicine before admission. In both these instances the pathologist stated that the microscopic appearance of the thyroid was that usually associated with excess use of iodine. The opinion has frequently

been advanced that overuse of iodine may induce toxicity in an otherwise normal thyroid, an assertion which it is not within the scope of this paper to defend or contest. It was practically impossible to form any opinion concerning the rôle of iodine before admission in the cases reviewed in this study. The prevalence of iodine-containing nostrums posing as "goiter cures" and the frequency with which the patient has no idea of the character of medicine given him by his physi-

cians renders a clinical history of the amount of iodine taken extremely unreliable. While I make no attempt to explain the discrepancy in these two cases by the history of use of iodine the possibility exists that it is a factor.

A third case not showing the histological criteria of Graves' constitution is in some respects not entirely typical of exophthalmic goiter. There was a history of 35 lbs weight loss with a good appetite. Physical examination showed a warm, moist skin and marked exophthalmos. On the other hand, the heart rate was only 65 and the basal metabolism was variable, down to plus 21 per cent at one determination and up to plus 38 per cent four days later. Eight determinations were made showing this type of fluctuation and there was no drop in the basal rate following the use of Lugol's solution. While it seemed that this case must be included in the group of exophthalmic goiters, the diagnosis might be questioned by some. In the fourth case, however, there seems to be no question of the clinical diagnosis, the case being typical throughout of exophthalmic goiter, and the pathological examination of an adequate amount of material showed nothing indicating Graves' constitution.

In group II the diagnosis was open to dispute in one case listed as exophthalmic goiter without exophthalmos because of the presence of diabetes mellitus. The symptoms were those of the diabetes and the diagnosis of hyperthyroidism was based largely on a basal metabolic rate of plus 33 per cent dropping to plus 15 per cent after the use of Lugol's solution. In a second case similarly classified the out-

standing features were 17 pounds weight loss with an appetite described as only fair, a pulse of 100, and a basal metabolic rate of plus 28 per cent dropping to plus 18 per cent on bed rest alone. While the picture suggests a so-called "mild hyperthyroidism" the array of clinical data is not entirely convincing. A third case is similar to this, weight loss of 20 pounds, fatigue, pulse 92, and a basal metabolic rate of plus 23 per cent dropping to 8 per cent without medication. The fourth case of non-agreement between clinical picture and the pathological criteria of Graves' constitution is quite typical of "exophthalmic goiter without exophthalmos", but the patient was 4 to 5 months pregnant. Whether this complicating factor disturbed the general picture is difficult to determine.

From this further study of these eight cases of discrepancy it will be seen that in one instance there is an apparent sharp departure from Warthin's conception of "thyroid disease" and the Graves' constitution. In the other seven cases the degree of divergence from this conception is more or less striking. While there is no attempt in this paper to explain away discrepancies and reconcile conflicting data, one other fact should be presented for the sake of fair consideration of the data. While several blocks were selected from each thyroid for microscopic examination, serial sections were not run. It has been demonstrated that in Graves' constitution the distribution of the lymphoid tissue is not uniform. It is entirely possible that some thyroids reported as not belonging to Graves' constitution may have contained lymphoid tissue which

was not present in the sections examined. Every clinician is familiar with the case of cancer or tuberculosis which is not diagnosed on biopsy because the diagnostic tissue was not present in what was excised for examination, and it is possible that Graves' constitution was not found in some of these cases because of an analogous situation.

In the group of the adenomatous goiters (group IV in table II) there are 18 cases which clinically would be considered "toxic adenoma", but in which the pathologist reported "no evidence of Graves' constitution". In this group evaluation of the data is more difficult, both from the clinical and the pathological points of view. As is well known, the clinical syndromes in this group are less well defined than in the case of "exophthalmic goiter", and it is sometimes difficult to say whether a case should be classified as "simple adenoma" or "toxic adenoma". On the other hand, the pathologist is handicapped because the excised material often consists almost entirely of adenoma, and frequently an adenoma shows no evidence of Graves' constitution whereas the surrounding thyroid tissue shows the stigmata. Thus one of the 18 cases, clinically toxic and pathologically not of Graves' constitution, showed practically nothing in the excised tissue except a very large adenoma. It would be impossible to state what might have been found in the thyroid tissue very properly left behind or in that surrounding the adenoma which had undergone a complete pressure atrophy.

The effect of congestive heart failure

in confusing the clinical appearance of the case of adenomatous goiter is also generally recognized. Five cases were characterized by heart failure which dominated the clinical picture. The basal metabolic rate was definitely elevated in all these instances, but the diagnosis was not as clear-cut as might be desired.

Two other instances are worthy of special mention. One patient had diabetes mellitus. The basal rate was moderately elevated, plus 28 per cent on two occasions falling to plus 15 per cent before operation. The second case record contains a note to the effect that while the basal metabolic rate was definitely elevated, the patient at no time appeared toxic, nor did he have the classic physical signs of "toxic adenoma". None of these cases showed the pathological signs of Graves' constitution.

Regardless of whether the clinical diagnosis is discounted in the seven cases and the pathological opinion in the eighth there still remain ten cases in which it seems that no clinical diagnosis except "toxic adenoma" is possible, in which the excised material was adequate for microscopic examination and in which the pathological diagnosis was "no evidence of Graves' constitution". In group V, the non-toxic adenoma, as already explained, there are no discrepancies to be discussed. Those belonging to Graves' constitution are considered as potentially toxic, but may not have developed any toxic symptoms.

It has become proverbial that statistics can be made to prove or disprove almost any conclusion. Too often the writer approaches his problem with a

preconceived idea of what he wants to prove and naturally he is attracted by facts which appear to substantiate his views. Because of the fact that the very mass of material would make impossible individual consideration of cases, I have made no attempt to gather an imposing array of material. In order that clinical judgment should be uninfluenced by pathological findings, I have utilized the simple device of forming my clinical impression before reading the pathologist's report. I have not disregarded the recorded clinical diagnosis, but because of the fact that it is recorded *after* reading the pathologist's report and accordingly is probably influenced by that report, I have also considered all the other clinical data such as history, physical examination and ward notes. Finally in those instances where the diagnosis seemed open to question, I have given the salient features of the case record. It is my hope that this clinically interpreted data will be of more value than a simple comparison of recorded diagnoses. Using this approach it is apparent that in 245 cases of thyroid disease studied, 89.4 per cent of the clinical diagnoses were in agreement with Warthin's conception of the Graves' constitution as a fundamental factor in these disturbances, the pathological examination of the excised thyroid gland being the criterion of the existence or non-existence of the constitution. In the remaining 10 per cent the clinical diagnosis may be considered open to question in certain instances, but on the basis of the information available it must be said that these cases do not substantiate Warthin's premise.

CONCLUSIONS

It is not within the scope of this paper to explain why the comparison of clinical and pathological findings does not reach 100 per cent of agreement. I have suggested certain possibilities which may explain some instances of discrepancy, but these are impossible of proof with data at hand. I do not wish to be either defendant of, or apologist for, the view presented by Warthin. However, the occurrence of a specific constitutional type in nine out of ten instances of this metabolic disturbance cannot be without significance. I do not feel that my statistics establish beyond question that Graves' constitution is necessary to the development of exophthalmic goiter or the so-called toxic adenoma. They do, however, indicate that these conditions usually develop in the individual with this constitutional anomaly. It has not been my purpose to emphasize a new diagnostic criterion for the pathologist. The conception of the Graves' constitution as presented by Warthin is far more than that. It is, in fact, fundamental in the pathogenesis of thyroid disease and has bearing on the rationale of treatment. My findings, in the main, support Warthin's view, and it is my hope that there may be studies from other sources which will further clarify the situation, either by addition of further support or by refutation of this conception.

SUMMARY

1 Graves' constitution was described by Warthin and others as a congenital body type always present in the clinical syndromes of Graves' dis-

ease, hyperthyroidism, and toxic adenoma

2 A group of cases, from which the thyroid gland was pathologically examined following operation, has been clinically interpreted and studied

3 Of 245 cases thus studied 219, or 89.4 per cent, were in clinical agreement with Warthin's conception. In 141 cases of exophthalmic goiter, the agreement was 94.3 per cent, in 104 cases of adenomatous goiter, the agreement was 82.7 per cent

4 In view of these findings, Warthin's conception of the Graves' constitution appears as an important contribution toward a more complete

understanding of thyroid disease. The initiating factor of the thyrotoxic symptoms is not clear and many phases of the subject are still obscure, but it seems evident that a constitutional anomaly, present from birth, is a factor of great importance.

I wish to acknowledge my great indebtedness to the late Dr A. S. Warthin for stimulation to undertake this problem, and for encouragement to carry it through to the end. I also wish to give recognition to Dr C. V. Weller, Professor of Pathology and Director of the Pathological Laboratories of the University of Michigan, for his assistance in the evaluation of the pathological material in the cases used as a basis for this report.

Photosensitization

By HAROLD F. BLUM, Ph.D., Berkeley, California

THERE are phenomena in a considerable number which are produced in living systems by substances not normally present in these systems which sensitize them to light. These phenomena are described collectively under the term *photodynamic action*, they are of widespread occurrence and manifest themselves in various ways. As examples may be cited the hemolysis of red cells and the destruction of bacteria by light and eosin, and the poisoning of domestic animals by substances ingested from buckwheat. As has been pointed out by Blum (1932), these phenomena are apparently based upon similar chemical reactions, since, so far as they have been studied, all require the presence of molecular oxygen. This separates them at once from a number of similar phenomena produced by ultraviolet light without sensitizers, which take place in either the presence or absence of oxygen. It will be the purpose of the present communication to consider the possible relationship of such mechanisms to clinical medicine.

We will consider first the relation-

From the Division of Physiology, University of California Medical School, Berkeley, California.

Presented at the Sixteenth Annual Clinical Session of the American College of Physicians, Berkeley, California, April 7, 1932.

ship of such mechanisms to certain disease entities, known principally to the dermatologist, which may be classed under the term "light sensitivity." Diseases falling under this head which have been suggested as due to photodynamic sensitization are *Hydroa aestivale seu vacciniiforme*, *Xeroderma pigmentosum*, *Eczema solare*, and others. *Hydroa*, at least, has been widely accepted as a photodynamic phenomenon in which *hematoporphyrin* acts as the sensitizer. I shall not attempt to discuss any of these diseases from a symptomatic standpoint, but only to consider the possibility of abnormal photosensitizers as etiological factors in such conditions.

Before proceeding further, it will be useful to consider a few fundamental principles of photochemistry and of the physiological action of light. Any primary photochemical reaction is assumed to follow the Stark-Einstein equivalence law, according to which a molecule absorbs a quantum of light energy and becomes an activated molecule which persists in the activated state for an extremely short time. This may be represented by the equation

Where S is the light-absorbing molecule, $h\nu$ the light quantum and S' the activated molecule. The molecule S can only absorb light of certain

wave lengths so that only specific wave lengths can activate it. During the short period of activation the molecule may react chemically with other molecules, or undergo other fates which need not concern us here. If a chemical reaction takes place, the type of reaction which occurs will depend not only upon the kind of activated molecule but upon the kind and number of other molecules in the system with which the activated molecule may come in contact. Thus the reaction which takes place depends not only upon the photochemically active molecule and the light which it absorbs, but also upon the other components of the reacting system.

In the human organism there are present certain mechanisms which are stimulated by light. We may assume that the light is absorbed by certain photoactive substances which initiate these reactions, and thus the reactions

are produced only by light of definite wave lengths which are absorbed by this substance. The activating radiations must all lie within the absorption spectrum of the photoactive substance, although all the wave lengths absorbed need not produce the photochemical reaction. The mechanisms of this type which are definitely known in the normal human body are (a) pigmentation of the skin, (b) erythema, and (c) the calcium-phosphorus balance. The wave lengths bringing about these reactions are all in the ultraviolet region, below about $350\text{ m}\mu$ (see figure 1). These reactions may be quite complex in their nature, the calcium-phosphorus balance mechanism is probably due to chemical changes brought about in ergosterol or similar substances circulating in the blood, but the other mechanisms are not so simply explainable. Now it is possible that an upset at any point in one of these

FIG. 1. H = approximate absorption curve of hematoporphyrin, showing position of absorption maxima at $400\text{ m}\mu$ and $560\text{ m}\mu$, only the general regions of absorption are shown (really the curve is much more complex). N = region of wave lengths producing normal skin reactions. G = lower limit of transmission of window glass.

mechanisms might result in a hypersensitivity of the organism to light, expressed in terms of that mechanism. Thus, for example, it may be that *Xeroderma pigmentosum* is due to an upset in some part of the pigment forming mechanism which does not involve the primary photochemical reaction in any way. In such case the light sensitivity would be brought about by the same rays which bring about the normal pigmentation reaction in the organism.

On the other hand, we have the possibility that light sensitivity may be brought about by abnormally present photoactive substances. Sensitization by such substances might be expected to bring about totally different reactions from those due to the photosensitive mechanisms normally extant in the body, although we cannot neglect the possibility that such abnormal photoactive substances might sensitize the normally existing mechanisms and thus exaggerate these reactions. In either case, the wave lengths bringing about these photochemical reactions would be specific for the abnormally present photoactive substance and must lie within the absorption spectrum of that substance. This should provide us with a possible means of distinguishing between the two alternative mechanisms for the light sensitivity mentioned above, on the basis of the wave lengths of light which are active in bringing about these responses, except in the event that the absorption spectrum of the abnormal sensitizer should correspond approximately with that of the photosensitive substances producing the normal light reactions. In other words, if we find

that wave lengths other than those bringing about the normal reactions of the body to light (around 350 m μ), bring about reactions in the skin or elsewhere, we are probably justified in assuming the presence of an abnormal sensitizer.

Hydroa aestivale seu vacciniforme, a condition in which vacciniform lesions of the skin appear, usually occurs during the sunny period of the year, and is considered generally to be a condition of light sensitivity. Furthermore, the condition is quite generally stated to be due to the photosensitizing action of the abnormal blood pigment, *hematoporphyrin*. As a matter of fact, hematoporphyrin is not actually a naturally occurring pigment, but is a substance produced in the laboratory from hemoglobin. The naturally occurring pigments are uroporphyrin and stercoporphyrin (see Garrod, 1923) and possibly others, which, however, are very similar to hematoporphyrin in structure and properties, the term hematoporphyrin has been often used collectively to describe the naturally occurring porphyrins. It is interesting to find in the examination of the literature, that porphyrins are very frequently not demonstrable in the blood or urine of patients showing the lesions definitely associated with the diagnosis of *Hydroa*. This indicates that the porphyrins of this type are not always associated with the condition diagnosed as *Hydroa*, and it also appears doubtful if this particular type of skin lesion always appears as a result of exposure of the skin to the sun's rays. We find actually that some of the *Hydroa* patients in whom the development of the lesions has been quite

definitely associated with exposure to light have shown porphyrins in the blood or urine, while others have not (see Hausmann and Haxthausen, 1929, Barber *et al*, 1926)

Furthermore, an interesting situation appears when we consider the wave lengths active in bringing about skin lesions in Hydroa patients in the few cases in which this has been examined. The results of such examinations are not clearcut but in most cases the sensitivity to light is definitely in the ultraviolet region, with one or two possible exceptions in which there has been some sensitivity to visible radiation (see Hausmann and Haxthausen, 1929, and Barber *et al*, 1926). Now hematoporphyrin and the naturally occurring porphyrins show strong absorption in the visible region around 550 m μ (see figure 1), and animals sensitized by the injection of hematoporphyrin develop very striking symptoms, including skin lesions, when exposed to light of such wave lengths. The experimental animals in this case include man, as Meyer-Betz (1913) performed the experiment upon himself; it should be noted, however, that although Meyer-Betz developed severe edema of the skin and definite localized skin destruction when exposed to strong irradiation, he did not develop any hydroa-like eruption. He was sensitive to radiations which had passed through window glass which would have been extremely weak in ultraviolet radiation. This experimental evidence has often been invoked to establish the relationship between hematoporphyrin and Hydroa, but the lack of correspondence between the radiations active in the two cases ren-

ders this evidence almost valueless. The naturally occurring porphyrins, uroporphyrin and stercoporphylin, are very similar to hematoporphyrin in chemical structure and show practically the same absorption spectrum. Hausmann and Krumpel (1927) have shown that all these porphyrins show absorption in the violet and ultraviolet with a maximum at about 400 m μ (see figure 1), and moreover, Hausmann and Sonne (1927) and Lassen (1927) have demonstrated that photodynamic sensitization occurs in this region. Thus it is possible that hematoporphyrin may sensitize Hydroa patients in this region, but no explanation is offered by this assumption for the failure of these substances to sensitize the Hydroa patients to light of 550 m μ .

Fischer has suggested that the porphyrins themselves may not be the photosensitizers, but the porphyrinogens or leucobases of the porphyrins. The porphyrinogens absorb principally in the ultraviolet and thus their sensitizing action would be in this region, the absorption of these substances in the ultraviolet has been demonstrated by Hausmann and Krumpel (1929). Unfortunately, these wave lengths are in the same general region to which the normal skin mechanisms react, so that we cannot easily prove or refute this hypothesis by studying the wave lengths which produce Hydroa. The porphyrinogens are supposedly changed to porphyrins by the action of light, according to this hypothesis, so that we are still presented with the question as to why the porphyrins found in the blood stream do not produce sensitization in the visible region.

Another argument against the con-

cept that this disease is produced by a photoactive substance circulating in the blood is that in certain of the cases studied it was found that only those skin areas which had previously shown the Hydroa lesions could be sensitized by ultraviolet radiation. This would indicate that the reaction produced by this means represents a hyperactivity of the normal erythema reaction brought about by the ultraviolet wave lengths and is not due to an abnormal sensitizer circulating in the blood stream, since in the latter case all skin areas should be light sensitive to approximately the same extent. Furthermore, porphyrins are frequently found in the blood stream and in the urine in conditions not associated with light sensitivity. We may cite as examples the condition following veronal or lead poisoning, often referred to as *hematoporphyrina toxica*, and the idiopathic condition *hematoporphyrina acuta* (see Rothman, 1926, and Mason and Farnham 1931). In these conditions considerable quantities of porphyrin may be demonstrable in the blood and urine, but only rarely are these cases light sensitive (see Hausmann and Haxthausen, 1929).

The problem is obviously much more complicated than we are led to expect, and the exact relationship between porphyrins and Hydroa is certainly not clearly understood. It is quite possible that the porphyrins play no part whatsoever in the light sensitivity or, again, that they represent products of skin injury. The relation of abnormal sensitizers to other light sensitive diseases is still more obscure. Further well-controlled observations on light sensitive cases should prove of great

value in settling this question. It would be of considerable value if observations could be made to determine whether or not individuals showing porphyrins in the blood or urine were actually light sensitive, and if so, whether to visible light as well as to ultraviolet. The latter fact should be determinable by exposing the subject to sunlight with a part of the skin exposed directly, and a part protected by window glass which cuts out practically all ultraviolet radiation active in bringing about the normal skin reactions (see figure 1).

Photosensitization by ingested substances which enter the blood stream occurs in domestic animals. At least two well established instances are the conditions of *fagopirismus* and *hypericismus* which develop when animals are fed upon buckwheat or St. Johnswort respectively. No examples of such sensitization by foods are known in man although the possibility exists. Buckwheat poisoning has been described (Smith, 1909) but this was undoubtedly allergy and not photosensitization*.

Various instances of photosensitization as the result of the therapeutic use of photoactive substances in the clinic have occurred. The substances have sometimes been given by mouth, sometimes by intravenous or subcutaneous injection and sometimes applied to the skin. The earliest example is that of Prime (Hausmann, 1923, p

*The well-established opinions of the laity that "buckwheat rash" develops in the spring, and that buckwheat should not be eaten during the summer months are explainable with difficulty unless buckwheat has a photodynamic effect in man as well as in the lower animals. EDITOR

156) who attempted to treat twenty-six epileptic patients with the bromine containing compound *eosin*. His patients developed a dermatitis and showed damage to the nails, particularly the thumbnail, which was most exposed to light. Jausion and Marceron (1925) observed sunstroke ("coup de soleil") in nine of twenty soldiers treated with *trypaflavine* for gonorrhea, dermatitis and excessive pigmentation were described by other observers using various *acridine* preparations (Hausmann and Haxthausen, 1929, p 79-80). Numerous instances of sensitization by acridine compounds have been described for workers using this substance, or substances containing it, in technical procedures. The writer has recently been informed of a case in which *rose-bengale* had been used in liver function test, in which obstruction was present so that the dye was retained and the patient was photosensitive for a short time.

Dermatitis produced by substances applied to the skin have been described as photosensitizations (see Hausmann and Haxthausen, 1929), some of which may fall under this group. The toilet water or "Berlock" dermatitis which has been frequently described within the last few years is probably not a photodynamic effect.

It is probably safe to predict that more cases of photosensitization will soon be described, as the use of sensitizing substances in light therapy is being taken up to a certain extent. The use of photosensitizers (*erythrosin*) in light therapy was tried out in Finsen's Institute shortly after 1900 and subsequently abandoned. It was also tried out by Jausionck and Tappener (1905)

in the treatment of superficial carcinoma with no definite results. Recently the use of sensitizers as a therapeutic measure has again been taken up. Gyorgi and Gottlieb (1923) claimed to have obtained good results in the treatment of rickets, and Macht and Anderson (1928) for the treatment of pernicious anemia using eosin as a sensitizer. Others have apparently applied the treatment to any condition which had at any time been treated by ultraviolet light, the sensitizers used include *trypaflavine*, and *methylene blue* as well as the fluorescein dyes such as eosin and erythrosin.

I do not wish to deny the results claimed by these workers, but only to point out certain dangers which present themselves from a more or less theoretical viewpoint. Sensitizers of the type used are all known to produce damage to living cells by oxidative processes involving molecular oxygen. Other photochemical reactions of the sensitizers may be produced in organic or inorganic systems, e.g., the sensitization of the photographic plate, but such have never been demonstrated in living tissues (see Blum, 1932). It seems, for instance, highly improbable, though not impossible, that such substances should sensitize the particular process involved in the treatment of rickets, viz., the transformation of ergosterol to vitamin D, and much more probable that the destructive oxidative effects would predominate. The former was apparently the thesis assumed by Strauch (1930) who injected hematoporphyrin into two farmer boys having rickets. Strauch observed an erythema in these children upon exposure to light and came to the con-

clusion that the treatment might be effective in curing rickets, he does not state, however, whether the patients recovered from rickets or not. I do not wish to deny that photochemotherapy may have some application, but such methods should not be applied to patients without more animal experimentation, where possible, to establish the results.

The assumption that visible light and a sensitizer will accomplish the same reactions as ultraviolet light is without theoretical or experimental support at the present time. Both accomplish the same gross effect, erythema. The histological effects on the skin are described as being the same

by Levy (1929), but Videbech (1931) states that there is much more injury to connective tissue in the case of the photosensitized erythema, this may be a question of the extent of the irradiation, etc.

The dangers arising from the use of photosensitizers in therapeutics cannot be too strongly emphasized. If such methods are applied, they should at least be used with great caution. It should be remembered that Meyer-Betz (1913) remained sensitive to light for several months after a single injection of hematoporphyrin and that lasting damage can be done by the incautious use of such methods.

The Contributions of Medicine

"IT HAS been inevitable that medical services should be influenced by the various economic and social changes which have developed in this country in recent years. While changes in industrial and community life are having an influence on the health of the people, the enormous growth of knowledge of disease and methods of control and prevention have revolutionized conditions of living during the last fifty years. The death rate at present is only about three-fifths of what it was a half century ago. The virtual elimination of smallpox, typhoid fever, yellow fever, typhus, bubonic plague, and cholera from large areas of the world, the rapid reduction in the incidence of tuberculosis and diphtheria, and the control of hookworm, malaria, and other parasitic diseases suggest a few of the striking contributions which science is making to the safety and comfort of modern life, contributions which in some instances have transformed living and working conditions in large sections of the country. Special attention to nutrition and the influence of foods, minerals, and vitamins on the health of the individual, and efforts to secure a better understanding of the mental processes which is fundamental for a sound program of dealing with human behavior, are likely to result in further contributions.

"No difficulty is experienced in demonstrating that physical and mental health is the greatest asset of a nation as well as of an individual. It is one of the necessities of everyday life. The prosperity and happiness of a people are largely dependent upon mental and physical vigor. Ill health and its effects are recognized widely as one of the major causes of dependency and unemployment. The most pressing health problem is to devise a permanent and comprehensive program of conserving health and treating illness and disability which will become an essential part of the cooperative endeavor known as civilization."

The Cardiac Complications of Trichterbrust

By JAMES G. CARR, M.D., F.A.C.P., *Chicago, Illinois*

TO an unusual thoracic deformity characterized by an oval or circular, almost funnel-shaped depression of the middle of the anterior thoracic wall, the deepest part of which lies in the sternum itself, the name *Trichterbrust*, the German for funnel-breast, has come into common use in many languages. Von Fruhwald's definition includes a clause making specific mention of the diminution of the capacity of the thorax and Dächter included in his criteria, "Increasing depression of the sternum with the age of the patient and a progressive enlargement of the transverse diameter as the depression is deepened." In one of the earliest contributions to the subject, Eggel had pointed out this last-mentioned feature of the deformity, when he described "a compensation of the spatial defects, produced by the depression of the anterior chest-wall, which is accomplished in three ways (1) the enlargement of the antero-posterior diameter in the mammillary lines, (2) the very significant enlargement of the transverse, and (3) the enlargement of the vertical diameter of the thorax, the latter fact must be concluded from the low position of the upper limit of hepatic dulness and the

displacement of the cardiac apex to a deep position."

It is obvious that such a deformity may cause displacement of various organs and interference with their function. Here our attention will be confined chiefly to the anatomical and physiological effects of *Trichterbrust* upon the heart.

Historically, the credit for presenting the condition to the profession as a clinical entity and for the first use of the name now so generally employed, goes to Wilhelm Ebstein, who in 1882 summarized the reports of five cases in the literature, coordinated them as a single disease-picture and used the word "*Trichterbrust*" to describe the clinical entity. Prior to his publication another case had been reported to which Ebstein did not refer. This was the case of Williams, recorded in the "*Transactions of the Pathological Society of London*" for 1872. The patient in this instance was a "lad of 17" who "was born with this hollow in his chest."

In discussing the history of the subject practically all authors refer to the anonymous communication which appeared in the *Gaz des Hôp* in 1860 as the first description of funnel-breast. In the same year Woillez reported a case with a careful study. It seems likely that Woillez reported

Presented at the San Francisco meeting of the American College of Physicians, April 7, 1932

a patient who had been seen and discussed by Rokitsky in 1857, a medical student from a German University who was making the rounds of the medical schools of Europe about that time (E von Ebstein) W von Ebstein mentioned that the local Pathological Institute at Gottingen contained a plaster cast designated as demonstrating "congenital collapse of the sternum" which completely conforms to the deformity described Prof Orth was authority for the statement that the plaster model dated from 1850. An even more interesting note on the historical aspects of this subject was contributed by Erich von Ebstein in 1921, the author of an extensive article on Trichterbrust in 1909. In this brief reference the statement is made that attention had already been paid to these conditions by the end of the sixteenth century. A short, excellent observation occurs in the principal work of the Freiburg physician, Johann Schenck, of Graefenberg (1531-1598). He set for himself the difficult but very useful task of collecting the literature on a large scale. In order to make this possible he was not satisfied to take from works at hand and to add cases from his own large practice but he was in communication with the foremost correspondents of his time. He quotes Johann Bauhinus who described the principal clinical symptoms—"dyspnea, associated with cough increasing to paroxysms of suffocation". From this same Bauhinus is quoted a description of a case in which "The sternum with the ribs was turned inward from birth, causing difficulty of breathing. The patient was a boy of seven in whom

the ensiform cartilage was turned toward the interior of the body so that a great cavity appeared" Doubtless the funnel-shaped breast described by Eggel in 1871 as "A Rare Deformity of the Thorax" has not actually been so uncommon as early writers presumed.

As to the anatomical characteristics of Trichterbrust, Wolostnich says there is practical agreement as to the following picture "The upper limit of the Trichterbrust is formed by the connecting line between the manubrium and corpus sterni, from this situation the funnel-shaped depression runs downward and backward, in most instances the greatest depth is reached at the scrobiculus cordis. The rounded base has a very slight extension, the diameter of which is variable. From the base of this depression its wall runs forward in such a manner, corresponding to its funnel-shape, that on the anterior wall of the body the maximum breadth varies between 9 and 17.2 cm. The center of the depression is not always in the middle of the sternum and the line of depth of the furrow is not always straight." This circular or oval depression at the lower end of the sternum may reach a depth of several centimeters, as much as 6 or 7. Picqué and Colombani measured the capacity of the depression in cubic centimeters of water. In the less pronounced cases this amounted to about 50 cc but in the more severe to 170 cc or more.

As one result of this depression various degrees of cardiac displacement have been reported. Versé studied the thorax of a female subject who died at the age of 48 years. The

thorax was removed *in toto* and hardened for two days. The lower end of the corpus sterni included the deepest part of the depression and almost touched the spine at the level of the cartilage between the tenth and eleventh thoracic vertebrae. Here the distance from bone to bone measured only about 1 cm. This could be increased to $1\frac{1}{2}$ cm by lifting the sternum. The thin cartilaginous process xiphoides was 4 cm long and directed obliquely forward, its tip was distant from the spine 37 cm. The chief mass of the heart was found to the left of the midline. Almost the entire left ventricle and a small part of the left auricle with the greatest section of the mitral valve were found lateral to the left parasternal line. Von Bien reported an autopsy at which the heart was found to lie "entirely in the left half of the thorax, while the right half was filled by the lungs, behind the heart a thin half-moon-shaped section of the lung was seen. The heart in its entirety was displaced to the left. If one drew the median line of the body in such a way that the line of the ensiform process was connected with the most ventrally situated points of the vertebrae it so happened that not a single section of the heart lay in the right half of the body. But corresponding to the displacement of the sternum to the left a part of the heart was in contact with the inner surface of the sternum, a small portion of the anterior wall of the right ventricle and a small part of the right auricle attached thereto. If, at the place of deepest depression, one lifted the anterior wall from the heart a deep depression of the auricle was seen

which extended to a portion of the right ventricle." In this case the displacement involved the roots of the vessels at the base of the heart. At the time of his report in 1920, Stadtmüller stated that he could find in the literature only eight reports of autopsies, in four of these the subjects were adults. He added the report of an autopsy upon the body of a man of 60 and stated that the heart showed (1) total displacement to the left and (2) the appearance of being turned about its sagittal axis. Von Hoffmeister quotes Henschen and Nageli as having observed a significant pressure point on the right ventricle. Rudolph von Pohl has described another type of cardiac involvement in those cases of Trichterbrust in which the median position of the heart is retained. "The thoracic deformity produces an indentation of the heart in front, corresponding to the in-bowing of the anterior thoracic wall, and the anteroposterior cardiac diameter is diminished."

Clinically, displacement has frequently been noted. In recent years roentgenological examination has confirmed this finding. Sauerbruch stated that "by physical examination and the roentgen-ray one may determine displacement of the heart to the left with or without simultaneous rotation about its axis." L. Meyer, von Hoffmeister and Alexander all wrote of the demonstration of displacement to the left by means of the roentgenological examination. Von Rosler, discussing the results of examination by the X-ray in cases of thoracic deformity, remarked regarding Trichterbrust "It is plausible that in high-grade cases,

through the flattening of the heart the cardiac work is unfavorably influenced, the normal systolic-diastolic change of form and rotation must be made difficult, the circulatory relations of the blood in the heart itself, probably also the position and form of the venous openings, may be changed."

In spite of the marked deformity, the changes in the dimensions of the space normally occupied by the heart and the anatomical evidence of change in the position and even of the shape of the heart, those who have contributed to our knowledge of the subject are not agreed as to the effect of the deformity upon cardiac function. Von Eggel's patient, in whom the distance from the deepest part of the sternum to the corresponding vertebral spine was only 11 cm (according to Vierordt the normal distance from the ensiform to the thoracic spine is 15 to 19 cm), "could not lift such heavy burdens nor run as fast as others of like occupation, but without distress he carried on his work as an efficient farmer, walked with firm tread and showed no trace of dyspnea, to say nothing of cyanosis. When he was six years old his physician had predicted that he would not outlive his twentieth year. Within four weeks of his birth the breast was so sunken that an egg could have been laid in the furrow." In von Flesch's case, although the depression was extreme, "respiratory pains had never been present, even hard work can be done without dyspnea." Graeffner made a similar observation. In 1911, Groedel reviewed his records for cases of Trichterbrust and reported three well-marked instances. It was his opinion that satisfactory

evidence was not at hand to warrant the assertion that this deformity is responsible for cardiac failure. He contends that while Trichterbrust does change the form and shape of the thorax, it does not change the content. The lung accommodates itself to displacement as does the heart, without necessarily involving these organs in functional damage. Groedel raised a question of interest and importance in the determination of the relationship of symptoms to the deformity. He emphasized the frequent association of Trichterbrust with the habitus asthenicus, in which condition are often found symptoms of circulatory embarrassment similar to those described as resulting from the displacement or pressure produced by Trichterbrust. In the latter condition surgical procedures to relieve dyspnea or other disturbances attributable to impairment of cardiac function must be based upon a conviction of the relationship between the deformity and the symptoms. The frequency of associated stigmata of the habitus asthenicus calls for careful consideration as to the amount of permanent relief which may be expected by surgical treatment of the deformity. In this connection we may quote again from Wolostnich who reviewed the literature thirty years after the first publication of von Ebstein. "The function of the heart and the pulmonary capacity commonly remain normal. The affected individuals have no pains from their Trichterbrust and very often—as is definitely stated in many works—the whole deformity presents an accidental and incidental finding upon the examination of a patient who has sought the

physician for other reasons" Kuhns has recently expressed this conservative statement "With careful pathological studies and fuller understanding of the physiological disturbances which such displacement of thoracic and abdominal viscera produces, has come an appreciation of the rôle of this condition in inducing fatigue, subnormal health and disease"

While in general these views of the lack of demonstrable connection between the deformity and cardiac or respiratory symptoms have been dominant since the condition was first described, attempts have been made, first by orthopedic procedures and later by surgery, to correct the deformity and thereby relieve associated symptoms attributed by the operators to the deformity In 1911, Ludwig Meyer performed the first operation for such relief He prefaces the description of the technic with a discussion of the case and remarks that "The literature tells us little or nothing of the symptoms which result from the deformity

For a patient of this sort, when he suffers from dyspnea, therapy can only be effective when it changes the anatomical conditions fundamentally and provides conditions compatible with respiration" The operation consisted in the removal of the second and third costal cartilages of the right side, each about $2\frac{1}{2}$ cm in length Von Hoffmeister, reporting a case from Lexer's clinic in 1927, implied that the result in Meyer's case was not satisfactory After describing resection of a considerable portion of the sternum in a young man whose symptoms were dyspnea upon exertion, sticking pain in the region of the heart and palpi-

tion, he makes this remark "That only an extensive removal of the diseased portion gives a result, the unsuccessful attempt of L. Meyer has shown" Sauerbruch reported a successful operation upon a young man of 18 years with congenital Trichterbrust, whose symptoms were cardiac irregularity and dyspnea upon exertion The operation was undertaken because "the patient was not able to do his work in his father's watch factory, since the least effort caused palpitation and a feeling of oppression" After some two or three weeks in the hospital, prior to operation, a short walk on a street with a moderate rise produced "marked cardiac irregularity and dyspnea" which were attributed to a mechanical interference with cardiac function It was the surgeon's idea that "removal of the rigid funnel would give more room to the heart and free it from the constricting pressure of the thoracic wall" On the left side the costal cartilages with portions of the sixth to the ninth ribs (the length of each resected portion was about 3 cm) and about one-half of the sternum corresponding, were removed The post-operative course was smooth Three years later the patient had gained weight, felt well and was working twelve to fourteen hours a day Von Hoffmeister reported from Lexer's clinic the case of a young man of 19, who had complained for two years of cardiac pain, dyspnea upon exertion and palpitation Below the attachment of the fifth rib the sternum with the costal cartilages was removed Twelve weeks after operation the general condition was essentially improved, there was a gain in weight and dyspnea

was present in only slight degree. The pains in the heart were definitely less in comparison to those earlier observed. Zahradnicek reported the case of a boy of 16 with a high degree of funnel-shaped chest. The sagittal diameter at the point of depression was about 10 cm. The patient was dyspneic and had palpitation. The operation consisted in perforation of the sternum and the introduction of two wires which were used for traction. The result was quite satisfactory. Two cases of "traumatic pectus excavatum" were reported by Alexander in 1931. A boy of 16, whose depression had followed an injury while wrestling, complained of dyspnea and occasional dysphagia. Ten months after operation the patient wrote that he had no pain nor dyspnea even upon exertion, and that the correction of the deformity was maintained. The second patient was a woman of 20 whose deformity followed an automobile accident. She complained of severe pain in the region of the heart, of dyspnea and palpitation. The pain was usually referred to the left shoulder. The cardiac pain was disabling and unrelieved by long rest. She had no cardiac, shoulder or left axillary pain after the operation.

These few cases serve to confirm Sauerbruch's opinion that "high-grade disturbance of cardiac and pulmonary function with signs of congestion in the peripheral vessels may occur." Proper selection of cases justifies surgical interference in certain cases of Trichterbrust. Two important principles should govern the decision as to operation in any given case. (1) Trichterbrust is not in itself an indi-

cation for operation, (2) there should be a high probability of relationship between the symptoms and the deformity before operation is justifiable. An interesting sidelight on the conditions proposed is derived from Gerstenberg's monograph published in 1904. He compiled a list of twenty-one published cases in which the measurements of the deformity had been given. The oldest patient in this group was 39 years of age. One may conclude that the condition is sufficiently disabling to bring its victims to the attention of the physician in early life. This fact alone should stimulate us to continued effort in our search for a means of relieving the deformity which forebodes only increasing disability and shortening of life. To experienced and careful surgeons, especially to those skillful in thoracic work, the indications for surgery just mentioned may reasonably be liberalized in the presence of individual problems.

CASE REPORTS

In the past year two cases of Trichterbrust with cardiac symptoms have come under our observation. The *first* patient was a young woman of 19, unmarried. She complained of rapidity of the cardiac action and a feeling of faintness and dyspnea upon exertion. She had never been strong. She had had measles, chickenpox, pertussis and pneumonia in childhood. During her twelfth year she had several attacks of fainting and was unable to attend school. During the last two years she has had fainting spells which were responsible for several falls, in one of which her left arm was broken. Three times within two years she has attempted to take training for the nursing profession, only to be sent home after a few weeks, because of her health. From the last hospital training school which she attended she was

discharged with a diagnosis of mitral disease. She has consulted many physicians. Several specimens of sputum have been examined without the discovery of tubercle bacilli. Once a diagnosis of pulmonary tuberculosis was made roentgenologically. Epilepsy has been diagnosed. Tonsillectomy has been done. Strychnine has been taken over long periods of time, under this therapy she became sick and restless.

The patient was a thin sickly young woman with moderate cyanosis of the lips. There was no evidence of disease of the lungs. The left border of the heart was $7\frac{1}{2}$ cm to the left of the midsternal line, the right $1\frac{1}{2}$ cm to the right. A systolic murmur was heard over the precordium, most distinctly at the base and over the left side of the back to the inside of the scapula and

below it. Except that the lower pole of the right kidney was palpable the abdomen was negative. Normal reflexes were present and pathological reflexes were not elicited. The cardiac rhythm was regular, the rate 112 (after entering the hospital the rate varied between 90 and 100), the blood pressure was 130/90. The blood count was essentially normal. The urine was negative. The basal metabolic rate was -4.6 per cent. The electrocardiogram showed normal mechanism with a diphasic T in Lead 2, a negative T in Lead 3, slurring near the apex of the R-spike in Lead 2 and deep splitting of R in Lead 3. Roentgenological examination of the chest showed a heart of normal size slightly displaced to the left, the right border showed indistinctly, which was attributed by the roentgenologist to pleuro-

FIG 1 Lateral roentgenogram of the chest of the first patient, who was operated upon

pericardial adhesions, although fluoroscopically free movement of the heart was demonstrated. The lateral plate showed marked depression of the sternum. The distance from the eleventh dorsal spine to the point of maximum depression of the Trichterbrust measured 13 cm.

the lower end and behind the xyphoid." Following the operation the cardiac rate fell to 70 to 80 and remained so for a day, then slowly went up over two or three days to 120 and receded within a few days to 80 to 90.

Four weeks after her discharge the pa-

FIG. 2 Photograph of the second patient

After ten days of observation this patient was operated upon by Dr. Jerome Head. "On the left side the 3rd, 4th, 5th, 6th and 7th costal cartilages were removed and on the right side the 4th, 5th, 6th and 7th. The lower one-half of the sternum together with the xyphoid was resected. The pectoral muscles were drawn together in the midline over the upper half of the defect. The fascia and subcutaneous tissues were closed similarly over the lower part of the defect. At the beginning of the operation the pulse rate was 100, coincident with the removal of the cartilages on the left the pulse dropped to 65. When a finger was inserted beneath the sternum the heart pressed against the finger, especially at

the lower end and behind the xyphoid." Following the operation the cardiac rate fell to 70 to 80 and remained so for a day, then slowly went up over two or three days to 120 and receded within a few days to 80 to 90. Four weeks after her discharge the patient reported that she had lost her cardiac consciousness and was walking a mile or more daily. After another three months continued improvement was reported. At this time the murmur noted prior to operation was confined to a small area about the second and third interspaces to the left of the sternum. Nine months after the operation she was seen again. At this time she was not doing so well. The original cardiac symptoms were not present but the patient was nervous and had lost some weight, (following the operation she had gained). An unhappy domestic situation was probably responsible for the nervous symptoms then present.

The second case was that of a boy of 13

years, who was referred to us from the Children's Memorial Hospital, where he had been under treatment for hemorrhage from a duodenal ulcer. The patient when first seen was cyanotic and moderately short of breath. He weighed 78½ pounds. The temperature was 97.8, pulse, 84, respirations, 20. The blood count was normal. The distance from the second thoracic vertebra to

yet sure enough of our ground to urge surgical interference without such symptoms as may be regarded as making an operation mandatory if the patient is to live without actual distress.

SUMMARY

1 Trichterbrust is the term applied to a characteristic deformity of

FIG 3 Autero-posterior roentgenogram of the chest of the second patient

the sternum was 10 cm, the anteroposterior diameter at the point of deepest depression was 8 cm. The width of the depression was 11 cm, the depth, 4 cm, and the vertical diameter, 14 cm. The apex was in the fifth interspace, 10½ cm to the left of the mid-sternal line, the apex rate was 84, the blood pressure, 104/82. The X-ray plate showed displacement of the heart to the left and a widening of the transverse diameter. Three months after the first examination the cyanosis was rather less marked, the dyspnea definitely less. Operation has been discussed with the father but not urged, we are not

the sternum, with depression thereof, resulting in pressure upon the heart, usually with displacement. Definite cardiac symptoms are not the rule in these cases, but such do occur. Dyspnea and palpitation are the most common symptoms.

2 Operative procedures have been reported, especially in recent years, with good results. Another case is here reported in which operation was followed by prompt amelioration of

the symptoms. A smooth post-operative course, such as this patient presented, is not always to be expected. Since the operation reported, Dr Head has operated upon another patient, not mine to report, who died within forty-eight hours following the operation.

3 In anticipation of operation, care should be taken to differentiate the cardiac effects of the deformity from the cardiac symptoms of the habitus asthenicus. Only in case the symptoms may reasonably be attributed to the former is surgical treatment justifiable.

An Unusual Speech Disorder following Encephalitis Lethargica: Its Interpretation and Therapeutic Management

By ALFRED GORDON, A M, M D, F A C P, *Philadelphia, Pennsylvania*

IN reviewing the various sequelae of encephalitis lethargica reported by observers one is surprised at the multiplicity of phenomena in the different spheres of human organization. The sensory system in general, the special sensorium, the motor-system at its various levels, the vegetative sphere, the sympathetic nervous system, finally the psychic functions in general, including the affective status, may all isolatedly or conjointly become involved. Data are continuously accumulating. Many varieties of tic-like movements and analogous hyperkinetic manifestations have been observed and described. Some of them are relatively frequent, such as oculogyric crises, other manifestations are more or less rare, such as speech disturbances. Since 1922 there have appeared occasionally in the literature cases in which the tongue would be involved, namely propulsion followed by retreat, frequently or continuously repeated.¹ Smacking of the lips or continuously moistening the lips,² contraction of the muscles of the tongue between

the teeth,³ and vibratory or myoclonic contractions of the tongue have also been reported. In W. Sterling's case,⁴ there was a linguo-salivary symptom perpetually vibrating tremor alternating at times with paroxysmal trepidation of the myoclonic type so violent that saliva would run out of the mouth. The manifestations presented by the two patients described below are exceptional, and perhaps have not been observed before. They concern the buccal cavity, lips, chin, and especially the tongue which renders the speech unusual. This condition presents an additional postencephalitic phenomenon among the large number already observed. The cases here described are excellent examples for a somewhat different interpretation of affective manifestations in a condition which, generally speaking, has an organic basis, with the result of favorable therapeutic management.

CASE REPORTS

Case I S. S., female, age 17. Four years ago, following a slight febrile condition, she began to observe a mild impediment of speech. This condition progressed and became more and more pronounced for a time, but for the last two years the condition has been stationary.

Her present condition is as follows. In

Read, and patients exhibited, at the January meeting of the Philadelphia Neurological Society, 1932.

Received for publication, January 18, 1932.

speaking her tongue has a tendency to protrude between the teeth. In the beginning of her speech, the tongue rolls, curls, and places itself mostly on the right side. The muscles near the angles of the mouth and those of the chin contract more than the other muscles of the cheeks so that two deep furrows appear on both sides of her mouth. It seems that all the other muscles of her face remain immobile while the lip muscles function. This is observed in the beginning of her attempts to speak. The speech itself becomes indistinct, the tongue is always in the way. It may give the impression of stammering, but it is not. There is no evidence of aphasia, or paraphasia, of anarthria or dysarthria.

There is also noticeable, while speaking, a peculiar state of the lower jaw, namely a tendency to droop so that she frequently puts her hand under her chin to hold it up. While there is no paralysis of the tongue, as it can move in all directions, nevertheless the food remains in the mouth a long while and at times there is some difficulty in swallowing. The patient also complains of pronounced salivation. Examination of the buccal cavity fails to reveal any motor or sensory involvement of the muscles of palate and pharynx.

About six months ago the patient says she began to observe a gradually oncoming weakness of the right upper extremity. Examination reveals a certain amount of weakness of every segment of that limb and a fine tremor of the hand. She claims to have difficulty in threading a needle or doing other fine work.

Further examination shows increased kneejerks but no other pathological reflex. In respect to serology, blood, eyes, sphincters, and sensations there are no abnormalities.

Case II J. B., female, age 19, had five years ago an attack of a depressive psychosis from which she made a complete recovery. Two years ago following a slight febrile state, she developed a speech disorder from which she is suffering now. One year later she developed a tic of the face.

The course of development, pro-

gressive course and the present state of the speech difficulty, are all identical with those of the first case, except that they are more pronounced. The position of the tongue, the condition of the muscles of the angle of the mouth and of those of the chin are also the same as in the first case. In addition to this, the patient also complains of food and liquids running out of her mouth during mastication.

It is interesting to note that this patient like the first one also presents a weakness of the right upper extremity in every segment of it. Her grip of the right hand is 50 and in the left 60 on the dynamometer, although like the first patient she is right handed. A detailed examination shows that in every other respect this patient is normal somatically.

If the two cases are postencephalitic it is to be presumed that the speech disorder like all the other sequelae reported in the literature is due to a lesion in the striatum with the usual structural damage. A question arises as to the possibility or impossibility of explaining the distorted speech on this purely organic basis. It is indeed difficult to admit that a direct injury to the striate body would be the sole cause of so many somatic, vegetative, and psychical manifestations as constitute the various groups of postencephalitic manifestations. A close examination of the mode of speaking of these patients leads to the conception of a purposeful pattern which originated four and two years ago respectively and remained as such up to the present. Both patients had difficulties of an affective character at the onset of the disorder and as an outlet from the states of anxiety in which they found themselves they developed a substitution or a compensation phenomenon in the form of a compulsion neurosis.

DISCUSSION

An analysis of the identical peculiarity of speech in both patients does not permit one to classify it as a manifestation of aphasia or paraphasia, anarthria or dysarthria. The typical symptoms of the latter are not existing. Besides, the mode of onset, the lack of an acute insult to the parts of the central pathways of speech, the absence of phenomena which usually accompany organic speech disorders,—all these data are absent in the histories of our patients. A close examination of all the peripheral elements which enter into the formation of syllables and words in speech shows that the disorder lies in the improper and abnormal use of the many small muscles which are at work in the enunciation of words. The irregular display of the muscles of the tongue, lips, of the angles of the mouth, and of the chin described above, are sufficiently striking to exclude the possibility of organic dysarthria or aphasia.

Hypertonia or dystonia and hyperkinesia are very frequently met with in encephalitis lethargica and are quite characteristic of postencephalitic parkinsonism, these muscular phenomena may be generalized or limited to circumscribed areas. In our cases there was a history strongly suggestive of a brief attack of encephalitis and as a sequela there remains an irregular muscular function confined to the peripheral agencies used in the formation of letters, syllables, and words.

When an attempt is made to find an explanation of this speech disorder, one naturally turns first of all to the pathological substratum commonly found in the parkinsonian syndrome. Although

lesions have been found at many levels of the brain, cerebellum, medulla and even spinal cord, nevertheless the striatal region occupies the center of attention. In fact almost all the varieties of postencephalitic phenomena have been explained on the basis of damage to the striatum. If motor or sensory disorders, hypertonic or dyskinetic disturbances may be due to an interruption in the structural connection of the striatum with various important segments of the central nervous system, thus explaining directly the anatomophysiological morbid manifestations, it leaves us in total ignorance with regard to the complex psychical phenomena which are so frequently observed in postencephalitic states. Alterations of character, disposition, behavior, radical changes in the affective state have been so frequently recorded¹. Are we in a position to speak of the striatum as a center for affective-psychic functions? Even if we could indulge in such a speculation, would this cover the ground? Could it explain why the postencephalitic individual blinks his eyes, and turns his eyes only in a certain definite direction in cases of oculogyric crises? Can it explain why in our two patients the speech is particularly disturbed when they meet strangers or when they are called upon to answer questions or when they have to participate in games, plays, etc.? The second patient relates that the speech disorder developed first, blinking of the eyes followed when the former began to improve. Presently both phenomena appear simultaneously, one reinforces the other when the patient attempts voluntarily to improve one of them. To content oneself with the

statement that the striatal system alone is the causal factor in all the varieties of affective or psychical abnormalities following an attack of encephalitis, would not be scientific

In our two cases the speech disturbance and in one of them also the association of the eye blinking with the speech are closely connected with certain affective situations in the past as well as in the present

Patient S S was obliged to leave the regular school unfinished to prepare herself for a salaried job in order to help out her relatives. She was in a state of great anxiety about the uncertainty of her heroic efforts. She deprived herself of necessities in order to accomplish her purpose. She is still working in this direction. In the midst of such an anxiety state and evidently because of it, she developed a tendency to walk, act and talk rapidly. She would become irritated, would make extreme efforts to refrain from giving sharp answers, from insulting the people who helped her financially during her preparation period. In addition to this there is another anxiety element in the life of this patient. Because of her home situation she is unable to participate in the pleasures of life: she is obliged to deny herself attending parties, dances, excursions to which she has been frequently invited. When occasionally she visits her friends and finds herself in a crowd she is seized with fear of not being able to keep up with the rest. Her speech becomes then particularly indistinct.

In patient J B, there is also a history of a state of anxiety but of a different origin. About the time of her first attack of encephalitis, she led a

life of extreme comfort, without even being forced to apply herself in acquiring knowledge. At the early age of 15 she received considerable attention on the part of her friends. One of her boy friends became unusually friendly and began to court her. She showed great fondness for him. At the time of her encephalitis her parents forbade him to call. The boy never returned. Having found out the cause of his abrupt abandonment of her, she had a number of violent altercations with her father. She became depressed, isolated herself, and could not sleep. In order to help her out the parents gradually induced her former friends to resume their friendship and to show her the same attention as before her illness. She then noticed a gradually oncoming difficulty of speech. At first it would occur only in the presence of male friends but later also in the presence of females. When therapeutic attempts were made to improve her speech, the blinking of the eyes would appear. Gradually both conditions became fixed and presently both phenomena are simultaneous. She is greatly depressed, refuses to appear in public and the unintelligent comments of her parents on this disorder contribute to its deeper fixation.

We observe a state of anxiety in both patients. In the first case, the fear of being unable to accomplish what she set out to do, also the long isolation and the shut-in existence which made her exceedingly shy and fearful of not being able to entertain and converse with people who made friendly advances to her finally led to the development of a compulsion neurosis in the form of a distorted speech.

In the second patient, the sudden abandonment of a male friend rendered her much depressed. She remained in this state a long time, refused new associations and finally when an effort was made by the parents to correct the situation, the patient began to hesitate in addressing others and thus developed the compulsion neurosis in the form of a distorted speech and later on of blinking as if she felt embarrassed in the presence of people and could not look straight in their eyes.

Both phenomena, the distorted speech and the blinking movements, are of the same order, they are defence reactions against an unconscious command. It is therefore evident that the compulsive phenomenon in both cases is a purposeful pattern and it originated from sources of an affective nature. The serious subjective state of both patients is their great anxiety which stands out as a conspicuous exteriorization of their inner life in the form of psychomotor phenomena of a compulsive character. The purpose behind the tongue or eye movements is self-evident. The latter merely represent a physical maladaptation phenomenon or a compulsive behavior reaction in the lives of two organisms. To understand fully an organism in its activities it is absolutely necessary to view it not merely as a structure but also, and especially, to see its background at all levels of its adaptive ability. A functional purposive level will always be revealed. If such a conception of compulsive situations is admitted by the therapist, some favorable results may be expected from a judicial application of the principles discussed above. In the two cases described

above the fact of an organic insult to the midbrain and particularly to the striatum could not be altogether denied. It was also evident that the exclusive acceptance of an organic structural substratum disarms one from any attempt to remedy the morbid situation. On the other hand, granting the existence of a pathological lesion, if an effort is made also to consider the inner life of these patients and what lies at the main nucleus of their anxiety state, thereby directing attention more to the positive side of the situation, therapeutic results may be expected. Such a procedure brought fruit in our two patients, when we succeeded in demonstrating to them the logical connection of their anxiety with the affective experiences in their life. Progressive improvement is noticeable in spite of the possible existence of an organic lesion.

SUMMARY

An unusual postencephalitic sequela is described as observed in two patients. Attention is called to the fact that in addition to an organic lesion ordinarily found in encephalitis there are other factors of a functional character which may elucidate the nature of the multiple postencephalitic disorders observed so frequently. An organic lesion *per se* will not explain its *modus operandi* in creating all these disorders, especially those of an affective character. Recognition of this principle is of high value in therapeutic endeavors. The two cases described present an excellent illustration of this contention. The occurrence of the speech disorder described adds another though rare phenomenon to the large number of postencephalitic sequelae already known.

Introduction to Clinical Medicine

"HISTORY taking, one of the most important disciplines of medical training, should familiarize the student with the life history and distinctive features of the onset, symptoms, and course of at least the common diseases and those with which they are most likely to be confused. It is very important that this early period of preliminary clinical training should be under the direction and supervision of the older and experienced members of the faculty, in order to secure the most satisfactory results and to establish a sound basis for the subsequent work of the student. With an experience in history taking, physical examination, laboratory diagnosis, and the use of instruments of examination, the student should be prepared to begin the study of clinical medicine.

"Teachers of clinical medicine should make it clear to students that many of the special examinations made in teaching hospitals are to show the student how knowledge is acquired and to supply complete data on a given patient for the purposes of instruction, not as an illustration of the actual requirements of practice. The specialized examinations and instruments can only supplement, they cannot supplant or substitute for, the direct clinical study of patients. Probably the overemphasis on special examinations by recent graduates and the tendency for them to seek practice in a specialty is partly due to the wrong emphasis in their clinical teaching.

"Students should be made to realize from the beginning of their clinical studies that the diagnosis in a large majority of illnesses can be made on the basis of a searching history, a thorough physical examination, relatively simple laboratory determinations, and the thoughtful consideration of the problem presented. The needs of a majority of patients can be solved by well recognized, relatively simple clinical methods. Some patients present functional disturbances which require considerable patience, time, sympathy, and an insight into the factors responsible. Only a small proportion need the services of specialists for a diagnosis. The physician and the student should be aware, however, of the importance of these special examinations as supplementary aids to established methods of clinical study in certain instances. An important feature of practice is the discrimination and judgment the physician should use in the selection of the time and type of such supplementary aids."

Oral Administration of Metaphen in the Treatment of Gastric and Duodenal Ulcers

By CLARENCE MORTON TRIPPE, A M, M D, F A C P,
Asbury Park, New Jersey

THE opinion is at present generally held that many patients with ulcer belong to the spasmophilic-vasoneurotic type, and therefore antispasmodic drugs, such as atropine and belladonna, in conjunction with the Sippy diet, are used in the treatment of ulcers and nervous dyspepsia. However, it is the opinion of the author (and also that of many other neurologists) that more attention must be paid to direct treatment of the stomach and the intestines, and that one should not rely exclusively on the above and on general methods of psychotherapy and physiotherapy, as, for instance, drug sedatives and stimulants. In the direct treatment of ulcers, the drugs commonly used are sodium bicarbonate in large quantities, chalk of magnesia, bismuth preparations and silver nitrate. Tincture of iodine in five drop doses in a wine glass of water has also been recommended.¹

Early in 1928, the author began administering to psychoneurotic patients who present symptoms of chronic abdominal distress, 3 cc of the 1:500 solution of metaphen, with most gratifying results. In fact, the author feels that a more rapid cure of the psychoneurotic state has been thus obtained

in almost every case, than he has been able to accomplish by any other method. His opinion is based entirely on personal experience, as no literature concerning the use of metaphen in the treatment of gastro-intestinal disturbances, is as yet available.

Metaphen, an organic mercurial, was elaborated by Dr George W Raiziss^{2,3} after an extensive study of chemical compounds involving the nitro-benzene-mercury complex. Metaphen, which is 4-nitro-anhydro-hydroxy-mercury-ortho-cresol, possesses, according to Dr Raiziss, greater germicidal properties than mercuric chloride and many other antiseptics, being especially destructive for staphylococci and other bacteria of the same group, its bactericidal effect on other microorganisms is also very high. This is especially true of spore-bearing bacilli, such as *bacillus subtilis* and anthrax.

Recently, Konrad E Birkhaug⁴ also studied the bactericidal and bacteriostatic properties of metaphen, which was found by him to possess unusual disinfecting and antiseptic powers far in excess of mercuric chloride and other commonly used antiseptics. When *staphylococcus aureus* was used as the test organism, metaphen had a phenol coefficient of 1,500. Metaphen

was 400 times more efficient than mercurochrome against *staphylococcus aureus* when dissolved in equal parts of human serum and broth. It inhibits the growth of *staphylococcus aureus* after 48 hours incubation in a dilution of 1:16,400,000 while mercuric chloride accomplishes the same in a dilution of 1:32,000. The action of most antiseptics is greatly diminished in the presence of proteins. Hirschfelder and Wright⁷ made an excellent study of the colloid chemistry of antiseptics and chemotherapy, and the effect of certain antiseptics upon proteins. In this study, the authors state

"Metaphen did not produce any noticeable changes in the ultramicroscopic appearance either of egg albumin or plasma, presumably because it has but little affinity for the plasma proteins."

The following table indicates that the toxicity of metaphen is comparatively low when given per os. The rabbit has tolerated from 15 to 30 cc of a 1:1,000 solution, so that the average maximum tolerated dose is about 24 cc per kilo of body weight.

The aqueous solution of metaphen, owing to its high bactericidal and bacteriostatic power and the fact that it does not precipitate proteins, has a wide range of application in many branches of medicine, surgery^{6,7,8,9,10,11}, obstetrics, dentistry^{12,13}, otolaryngology^{14,15,16,17}, ophthalmology, urology¹⁸, and blood stream infections¹⁹.

The author's experience of four years in the oral use of metaphen in gastro-intestinal cases, is summarized in the accompanying table, which gives an analysis of 82 cases taken from his records. These comprise 26 examples of gastric, and 56 of duodenal ulcers. Twenty-seven of these have had thorough x-ray studies, many have had test meal and microscopic study of gastric contents to confirm diagnosis.

The table lists each case by initials, giving age, sex, diagnosis, dosage, and comments regarding x-rays, laboratory tests, diets, and the length of time during which gastro-intestinal symptoms were observed, and present condition, January, 1932.

ORAL ADMINISTRATION OF METAPHEN SOLUTION
1:1,000 TO RABBITS

DATE	DOSE PER KILO OF BODY WEIGHT	TOTAL AMOUNT GIVEN**	RESULTS OBTAINED

1-25-31	25 cc	78 cc	Survived

*1 cc of 1:1,000 solution is equal to 1 mgm. of metaphen

**Figures in the column indicate amount actually given according to weight of rabbit
2.5 lbs. and 2.5 lbs. given

The percentage of complete recoveries suggests a possible specific cure for peptic and duodenal ulcers. This will be proved by more extensive studies as other physicians report their observations.

*I=Improved

In searching for the fate of the metaphen taken orally, the laboratory has found large traces of mercury in the stool, but none whatsoever in the urine or blood

Toxicity of any type has in no case been demonstrated, and the author has had many patients who have continued metaphen at the dosage of 16 c c daily for months without reporting to him—patients who felt so well that they were afraid to discontinue treatment for fear of recurrence of gastro-intestinal disorders

In 1929, the author increased the dose to 4 c c three times a day, and since then no further increase has been necessary to obtain relief from either pain, pressure or other distress in the abdomen due to gastric ulcer, duodenal ulcer, chronic ulcerative colitis, or other types of colitis. About half of his patients have taken the prescribed dose of the 1:500 solution of metaphen diluted with equal parts of either glycerin or cinnamon water in half a glass of water directly before or after meals in cases of gastric ulcer, or one hour before or two hours after meals in cases of duodenal ulcer. In colitis, metaphen has been given directly after each meal and at bedtime in order that the drug might be carried throughout the intestines along with the food.

In practically all his cases there has been relief from pain in three days' time on the average, regardless of the fact that most of the patients have suffered for years. Many have come to him with the diagnosis of nervous dyspepsia vomiting everything taken by mouth even water. The metaphen solution, however, was never vomited,

and in one to three days the patients were able to eat large meals.

Usually when all pain or distress is relieved in the three day period, the author continues with three or four doses daily for one week, two doses daily the second week, one dose daily the third week, and then a dose every other day the fourth week, stopping the drug thereafter. It is interesting to note the large proportion of these cases, which have had no recurrence of their chronic gastro-intestinal symptoms since their treatment. Their nervous and mental symptoms have disappeared entirely and they have become readjusted to their environment.

X-rays taken before and after the oral administration of metaphen, have shown complete disappearance of the ulcers of the gastric and duodenal types. Chronic ulcerative colitis cases have become symptom-free in a very short time. Diarrheal stools, containing pus and blood, have ceased after the first day.

Most of these cases of ulcers had been on a strict Sippy diet or modified forms of it, and, in every case, the patients have been placed upon a varied diet, nevertheless, there has been no complaint or resulting pain or pressure.

It must be continually borne in mind that all of these cases involved psychoneurosis, either plainly hysterical in type or they were suffering from anxiety or compulsion forms of neurosis. The psychoneurosis has apparently subsided as a result of the direct attack of metaphen upon the gastro-intestinal lesions.

A few of the more striking cases are now described.

CASE REPORTS

Case No I Miss E C, age 45, a clerk in a very responsible position. Chief complaint distress in the entire abdomen.

Appetite poor. Bowels constipated. No sleep without sedatives. Suffering from a complete nervous breakdown since March, 1930, when her mother died suddenly in her arms. Came under the author's care after three months' treatment in a private clinic in a neurological institution. In 1905 both ovaries were operated upon for cysts. In 1914 she had four operations; the first was a gastro-enterostomy on account of gastric ulcers, the other three eventually resulted in a gastrectomy removing four-fifths of the stomach. At age 38 she experienced her menopause.

On July 7, 1930, a gastro-intestinal x-ray series showed another ulcer on the small remaining portion of the stomach. She was still suffering from psychoneurosis. She was given metaphen solution 1 500, 4 cc one hour before meals and at bedtime, diluted in an equal amount of glycerin. In three days the distress in the epigastrium had entirely disappeared, and in nine days she had gained seven pounds in weight.

X-rays of the stomach, April 6, 1931, showed no sign of peptic ulcer. She returned to work September 2, 1931, and has not lost any more time. She has never had any return of the epigastric pain. Her nervous condition has entirely disappeared.

Case No II E B W, male, age 53, occupation, proprietor of laundry. Chief complaint, distress in epigastrium two hours after each meal.

He was a case of profound psychoneurosis. On April 24, 1930 he was given 4 cc of the solution of metaphen, 1 500, with an equal amount of glycerin two hours after meals. In three days there was no more distress, and he felt like a new man. April 29, 1930, the dose of metaphen was reduced to 2 cc. X-rays of his gastro-intestinal tract taken in 1928 in October, 1929, and March 1930, all showed ulcer of the bulb of the duodenum. X-rays taken June 27, 1930, showed the ulcer greatly improved. The x-ray report dated June 27, 1930, was as follows:

"Duodenum. First portion is fairly large and at times filled completely, with a normal outline, at other times there was a tendency to trefoil deformity. Comparing these with previous radiographs made in March, this year, elsewhere, we find that the duodenal cap at this time fills decidedly better and that the deformity noted on the mesial aspect has practically entirely disappeared. The deformity noted in prepyloric ulcer is generally organic. The deformity noted in postpyloric or duodenal ulcer is generally due to spasm unless a niche or accessory pocket is found. We note that at the previous examination in March, the doctor reports that the duodenal cap was not unduly tender on pressure. At this time we do not find any marked tenderness, but there is definite tenderness noted over the duodenal cap that is not found elsewhere. However, we feel that so far as the deformity of the cap, which is the result of spasticity, is concerned there is definite improvement between March and the present time."

X-rays made in April, 1931, showed no lesion of the stomach or duodenum, and his psychoneurosis had been cured.

Case No III P E A, male, age 39, occupation, certified public accountant. Chief complaint, complete nervous breakdown. This patient has not worked for three years, and complains of distress two to four hours after each meal. X-rays, July 19, 1929, showed ulcer of the duodenal bulb. He was given 4 cc of metaphen solution, 1 500, with equal amounts of glycerin two hours after meals and in three days the epigastric distress was entirely gone. He returned to work immediately and has continued to be employed without interruption to date. X-rays taken in July 1930, showed no evidence of duodenal ulcer. His psychoneurosis disappeared with the cessation of epigastric distress.

Case No IV Mrs W C, age 56, occupation, advertising manager of a department store. Chief complaint vomiting after meals and nine hemorrhages from the bowels shown by profuse coal tar stools since October, 1927. January 31, 1929, she was in a state of profound psychoneurosis. X-rays of the gastro-intestinal tract in March 1928 dem-

onstrated an ulcer of the lesser curvature of the stomach. February 11, 1929, she began to take metaphen solution, 1.500, 3 cc in cinnamon water immediately after meals and at bedtime. In three days the gastric distress, vomiting, and symptoms of psychoneurosis disappeared. On March 11, 1929, she was able to stop metaphen and has had no need of any medication whatever to date.

Case No V W S H, male, age 55, occupation, sales manager, constantly travelling throughout the United States. Chief complaint, constant pain in epigastrium aggravated by food. This patient was profoundly neurasthenic, introspective and apprehensive. X-rays, December 18, 1928, demonstrated an ulcer the size of a twenty-five cent piece on the lesser curvature of the stomach. Gastric analysis showed red blood cells in all tests, normal otherwise. He was placed upon metaphen solution, 1.500, 3 cc in cinnamon water one-half hour after meals and at bedtime, and his report on the third day was that he was entirely relieved of distress after eating. His psychoneurosis has disappeared and he has never had any return of the gastric distress to date.

Case No VI S F M, male, age 62, occupation, retired. Chief complaint, vomiting attacks two hours after eating, loss of weight, and great nervousness. X-rays, March 22, 1928, showed a large penetrating ulcer in the duodenal bulb. He was given 3 cc of metaphen solution, 1.500, diluted in water two hours after meals, and his report on the third day was that he had not vomited since he began taking the metaphen. His nervousness was rapidly improving.

Frequent reports to date (October 1, 1931) are of no recurrence of any signs of ulcer, and he has been absolutely well with no need of any medication whatsoever after the first month.

It now becomes of interest to consider the possible explanation of the beneficent action of metaphen, primarily a bactericidal agent on gastro-intestinal ulcers. In this connection, it may be pointed out that recently the

thesis has been sustained by several authors, that infection plays an important rôle in the evolution of many such ulcers. Extensive investigations in this direction have been carried out by Rosenow^{20,21,22,23}, who was able to demonstrate the presence of streptococci in several cases of duodenal and gastric ulcer. By injection of these organisms into dogs and rabbits he obtained ulcers resembling those in man in respect to location, gross microscopic appearance and in the tendency to become chronic, to perforate, and to cause severe and fatal hemorrhages. The same organism was isolated by him from ulcers in the hog, calf, cow, sheep and dog. These experiments were repeated by Celler and Thalhimer²⁴ who found that non-hemolytic streptococci are present in practically all gastric ulcers; these authors, however, do not regard this as proof that this organism is the factor which either initiates the ulceration or prevents healing; but the constant presence of streptococci in such lesions must have some significance which requires further elucidation.

A similar opinion is expressed by Duval and his co-workers^{25,26}, who ascribe to infection a secondary if not a primary rôle in the development of gastric ulcers. This view is supported by the following facts. While ulcers are usually regarded as evolving without fever, actually a subfebrile state or even an acute elevation of temperature will often appear during a gastric attack; the development of ulcers appears to be influenced by some epidemics and ulcers are frequently aggravated as a consequence of intercurrent infectious diseases. Hyper-

leucocytosis is often observed in patients afflicted with ulcer, thus, Girault²⁶ has found the number of leucocytes above normal in 23 out of 28 patients with ulcer confirmed by operation. Duval has found the intradermoinjection with streptococcus positive in 60 per cent of cases, while the number of leucocytes was above normal in 33 per cent of cases. Furthermore, inflammatory exacerbations in chronic ulcers, and the presence of bacteria in the wall of the ulcer, support Duval's thesis. Of interest is the fact that mortality following large excisions is less than that following small excisions. This apparently paradoxical fact seems to indicate the possibility that the small excision is within an infected zone.

Askanazy²⁷ has found the organism of thrush (*Oidium albicans*) in the tissues of operated gastric ulcers in 25 out of 30 cases. He has also succeeded in creating ulcers experimentally by the inoculation of animals with impaired mucous membrane of the stomach with this organism.

Smithies²⁸ in a study of the etiological factors associated with chronic gastric ulcer, has found that 137 out of 522 histologically proved ulcers, or 33.7 per cent, were associated with an infection.

It thus seems very probable that infection plays an important part in gastro-intestinal ulcer, and it is there-

fore not entirely irrational to expect that a strong bactericidal agent, which is at the same time non-injurious to the tissues in the solutions used should exercise a healing effect on ulcers. The patients' histories, here presented, show that such is the case.

CONCLUSIONS

1 Metaphen, in 1:500 solution, was given orally to patients with symptoms of chronic abdominal distress in the dose of 4 c.c. three times a day with very gratifying results.

2 The material presented includes an analysis of 82 cases, 26 of gastric and 56 of duodenal ulcers. Complete x-ray studies were made of 27 of these cases, diagnosis was also confirmed in many cases by test meal and microscopic study of gastric contents.

3 Relief from pain was obtained in practically all cases in an average of three days' time.

4 No toxic effects were ever observed.

5 Complete disappearance of gastric and duodenal ulcers consequent upon treatment with metaphen has been demonstrated by means of x-ray studies, made before and after treatment.

6 A possible explanation of the action of metaphen, primarily a bactericidal agent, may lie in the part played by infection in the evolution of ulcers of the type considered, as has been recently emphasized by several authors.

The Rôle of the Bowel in Chronic Arthritis

By E. F. TRAUT, M.D., *Chicago, Illinois*

THE bowel is usually mentioned as a possible origin of the varied nerve, muscle, and joint syndromes characterizing chronic infectious or atrophic (American Committee for the Control of Rheumatism) arthritis. The colon has been taken to be a focus of infection, the source of bacterial toxins or the seat of auto-intoxication. Free action of the bowels has always been advocated in the treatment of arthritis. Numerous medicinal and mechanical measures have been elaborated to secure this. The adnexa of the bowel, the appendix and gall-bladder, have played prominent rôles as possible foci of infection. Fletcher and Graham¹ found the colon in chronic arthritis characteristically atonic.

The varied and varying flora of the bowel has been repeatedly studied in its relation to arthritis. Burbank,² Keating³ and Crowe⁴ have reported success in using vaccines of fecal organisms in the treatment of chronic arthritis.

Traut and Herrold⁵ found streptococci much more commonly on the rectal mucosa of arthritic patients than in the rectums of controls. Since then the rectal flora of many more patients has been studied. The later results

tally with those already reported. Streptococci, usually green, less commonly hemolytic, are found far more commonly in the rectums of arthritic patients than in normal controls and often are the predominating organisms in cultures made by our method (Table I). This method has been a great improvement over previous means of isolating bacteria not included in the bacterial population of normal individuals, the bacteria peculiar to the arthritic. The usual stool culture selects material from the bowel lumen or stool center, a medium unfavorable to the growth of a delicate streptococcus because of competitive bacteria, presence of bacteriostatic substances and lack of water.

Repeated cultures of the rectal wall have usually shown similar floras. To some extent the kinds of bacteria and their relative proportions have fluctuated with exacerbations and remissions of the patient's joint or gastrointestinal symptoms. Frequently I was able to confirm the opinion that with looser stools there was a higher percentage of streptococci. In some rectums staphylococci have been especially numerous. They are usually white staphylococci. Checks of our method have failed to demonstrate skin contaminations. As will be shown later many of these staphylococci are agglutinated strongly by serum from

arthritic patients Vaccines made from them have acted as powerful antigens aiding the patients in recovery Crowe has also isolated his "*micrococcus deformans*", a white staphylococcus, from the stool

The percentage of streptococci in the rectum bore no relation to the severity of the disease Neither was the type of streptococci related to the variety or severity of joint disease except in one instance In one case of rheumatic fever indifferent streptococci were repeatedly isolated from the rectum The rectum of a patient with rheumatic purpura yielded five per

cent to ten per cent of green streptococci on two examinations Streptococci were rarely found in the rectums of patients with osteo-arthritis

Other workers, as well as I, have found the streptococci of the mouth and teeth very similar, if not indistinguishable from the streptococci of the bowel It is presumable that pathogenic bacteria resident in the mouth or ingested in food passing the more or less efficient and variable barrier of the bactericidal stomach secretions should enter the bowel unscathed The bowel stasis described as characteristic of the entire gastro-intestinal tract by

Fletcher and Pemberton, would favor their absorption or the absorption of their toxic products. Arnold⁶ has found *B. prodigiosus* in the blood after feeding it to guinea pigs. The subsequent involvement of joint or other tissues is a direct consequence. Redewill, Potter and Garrison⁷ mention the migration of streptococci from the bowel to teeth and tonsils.

The remarkable frequency of gastro-intestinal symptoms and findings in patients with atrophic arthritis stimulated me to investigate the relation of the gastro-intestinal disorders to joint disease. Care was taken to separate such localized diseases as cholecystitis or appendicitis. In most of the patients, abdominal symptoms were those commonly ascribed to irritable bowel, mucous or spastic colitis. Almost all had some intolerance to starch. Their digestive disturbances were much improved by reducing the gross starch of their diets. Fermentative colitis and its possible relation to Pemberton's disturbed carbohydrate utilization in these patients has recently been described by Monro and Hall.⁸ Under the fluoroscope the colons of most of these patients were dilated and atonic.

In my patients the gastro-intestinal complaints were so prominent as to demand dietary instruction as one of the very first measures in our broad attack upon the rheumatic disease. The relation between the gastro-intestinal dysfunction and the joint disease was obvious. Exacerbations of joint symptoms were coincident with relapses of the gastro-intestinal disease. The most common complaint was increase in the flatulence and swelling of the abdomen. The other articular symptoms

abdominal pain, flatulence and loose stools. Constipation has been prominent in the complaints of most of my patients. Relief of constipation has always meant substitution of vegetables and fruits for foods of high carbohydrate and caloric value. Improvement has been much more marked by relieving constipation through dietary measures rather than by cathartics.

Seven of the sixty patients cultured showed no streptococci in the rectum. Nos. 28 and 47 had chronic prostatitis. Obvious foci had been removed from the other five patients previous to the rectal cultures. Patients 1, 18, 25, and 28 showed no streptococci on one culture. Patient 33 showed none on two examinations. Possibly further cultures in these cases would have shown streptococci. Patient 25 was a healed case in perfect health except for ankylosis of a hip and the vertebrae. Her active arthritis had terminated more than 15 years before.

The history of patient 13 is interesting. She first consulted me because of purpura. On this occasion no streptococci were obtained from the rectum. Thirteen months later she complained of stiffness of the neck associated with grating in the cervical vertebrae. These vertebrae were definitely tender. Coincidentally streptococci were easily isolated from the rectum.

Hemolytic streptococci were first obtained from the rectum of Mrs. B. She was given five subcutaneous injections of a vaccine of these organisms. After 18 days no hemolytic bacteria were detected. Coincidentally her arthritis had disappeared.

The colon bacilli would have usually been of the non-hemolytic group.

type In six instances hemolytic colon bacilli were isolated

I have arbitrarily graded chronic arthritis into grades I to IV Grade I comprises those with pain and little deformity or those with deformity of slight degree, not interfering with their occupation Grade II includes those with more marked disability Grade III embraces those with deformity in many joints but still allowing the patient to be about with much discomfort Grade IV includes those completely disabled, the bedridden, and those able to be about only on crutches or in wheel chairs

We have cultured the rectum in fifteen patients free from arthritis Streptococci were found only in a patient with purpura of the rheumatic type, a syndrome allied to arthritis and in two patients with chronic ulcerative colitis Streicher and Kaplan⁹ have called attention to the frequency of streptococci in the colons of patients with ulcerative colitis Cultures were repeatedly made of the nonarthritic patients Those without streptococci in the first examination did not have streptococci in subsequent examinations

Relief of the arthritic symptoms and findings was usually coincident with a reduction of the number of streptococci in the rectum In my opinion the improvement indicated a change in the "soil", a lessened susceptibility to its parasitic flora, as well as a reduction of invading pathogens

Eighty-one per cent of my patients were women and of these seventy-one per cent were between 40 and 60 years of age

In a few instances we encountered

the difficulties in classification of chronic arthritis patients mentioned by Jordan and Boland¹⁰ Whether a patient had a recurrence of rheumatic fever or a flare-up of atrophic (rheumatoid) arthritis was occasionally difficult to ascertain

The streptococci isolated were usually of the viridans type They were usually in short chains All retained the Gram stain They were ovoid to round Usually the individual bacteria were large They frequently appeared in pairs, like an individual coccus or a diplococcus Their broth cultures were diffusely clouded Only rarely was it difficult to grow them in broth Their colonies were originally all "smooth", with evenly round borders Prolonged cultivation brought out dissociation Colonies might not grow so distinctly green, approaching the indifferent or gamma group of Brown

It is impossible to classify my strains of rectal origin according to the plan of Andrews and Horder¹¹ According to them *streptococcus fecalis* ferments the same sugars as does *streptococcus salivarius*, namely, it ferments mannite but does not ferment raffinose or inulin I have found no green streptococci in the bowel fulfilling these requirements The green streptococci found fermenting mannite but not raffinose have also been resistant to bile and heat, placing them in the class of enterococci The *enterococcus* and *streptococcus mitis* (Holman) predominate

The green streptococci isolated from the bowel have usually been of low virulence for animals One cubic centimeter of a 24-hour broth culture injected intraperitoneally does not kill

mice; and even in doses as large as 5 c.c., has failed to produce arthritis in rabbits. I discovered that arthritis could occasionally be produced by inoculating the streptococci into the colon. The same strains were without effect on intravenous injection.

Hemolytic streptococci were isolated from the rectums of four patients with atrophic arthritis. According to their fermentative ability they were *Streptococcus hemolyticus II* (Holman), *Streptococcus infrequens*, and *Streptococcus subacidus*. These streptococci have retained their extreme hemolyzing ability over one year of subculturing. Of any of these hemolytic strains, 0.5 c.c. of a broth culture is fatal to mice in 12 hours. The heart's blood of the dead mice was subcultured on blood agar plates. The washings of one of these plates proved fatal to rabbits in 5 to 14 days. Both purulent and non-purulent arthritis were manifested by these rabbits.

Some strains are conspicuously agglutinated by high dilutions of patient's blood. Extensive agglutination experiments suggest the inter-relationship of these various strains as well as their relation to the disease of their hosts. The isolated streptococci were usually agglutinated by their homologous sera. Certain strains were agglutinated by the sera of other patients in such high dilutions as to suggest an immunological relationship of the rectal streptococci found in arthritis.

TREATMENT

The serum of patients was routinely used in agglutination experiments against significant bacteria isolated from the rectum, from the interior and

exterior of extracted teeth, from prostatic secretions or from the centers of excised tonsils. I included in these agglutinations long-studied strains agglutinated by the sera of other arthritics. I selected such as had proven effective antigens in the vaccine treatment of other patients as judged by the relief of the arthritic symptoms and the disappearance of the arthritic findings. The vaccines used were made of the organisms agglutinated by the patient's serum in high titer. For the most part these were streptococci of rectal origin.

Fifty-eight patients with chronic arthritis were observed sufficiently long to justify an appraisal of their treatment. These patients were followed for three years. Twenty-seven of these patients received no vaccine from me. Thirteen of these non-vaccine patients, or 48 per cent, recovered entirely or were greatly relieved. All of the patients, when first seen, are placed in the non-vaccine group. It is only after their failure to improve upon graded exercise, regulated rest, diet, massage and removal of foci, and after a careful bacteriological and immunological assay that they are subjected to vaccine treatment. Consequently the second group, the vaccine cases, really represent the more difficult patients, those remaining after non-specific measures have failed. Thirty-one patients were treated with vaccine. Twenty-one (68 per cent) of these were markedly improved or recovered. Four had almost no relief. One of these has osteo-arthritis. Osteo-arthritis is not recognized as an infection and is not accessible to treatment by bacterial antigens. Another was a

stenographer, badly crippled and terribly fatigued, managing to stay at work. She seemed "burned out", depleted of the elements necessary to recovery. She is now in remission, after cessation of vaccines, upon the institution of rest periods and the postural exercises of Goldthwaite and Osgood. A man, although badly crippled, sold goods from house to house. Like the stenographer, he was continually exhausted, unable to marshal sufficient energy or resistance to fight the disease. Four of the 31 vaccine patients made substantial improvements on subcutaneous administration of a suspension of the *Micrococcus deformans* of Crowe, and casein. Since the sera of these patients did not agglutinate the *Micrococcus deformans*, and no staphylococci were isolated from their foci of infection, improvement of these four patients must be credited to foreign protein.

A solution of casein was often combined with the streptococcus vaccine. Given alone it did not benefit any patient with arthritis. The combination was much more effective than either the streptococcus emulsion or the casein used in much larger amounts separately. Possibly the casein prepared the tissues, increasing their susceptibility to the bacterial antigen. As noted

by Crowe the addition of a staphylococcus to the streptococcus vaccine enhanced its benefits. Crowe ascribes specificity to this staphylococcus effect. Again, a polyvalent vaccine of all the bacteria agglutinated by the patient's serum was successful where an autogenous vaccine failed.

Whether vaccine raises the resistance of the patient or desensitizes him to bacterial allergens, it has an important position in the treatment of chronic arthritis.

SUMMARY

1 Rectal cultures in arthritic patients yielded streptococci more frequently and in larger numbers than did similar cultures in non-arthritics.

2 Streptococci isolated have for the most part belonged to the enterococcus group.

3 Agglutination by the serum of the host and cross-agglutination of other rectal strains are present.

4 Forty-eight per cent of a group of patients with chronic arthritis were markedly improved or recovered with the help of non-specific treatment.

5 Sixty-eight per cent of the patients treated with vaccines of the streptococci from rectal and other foci were markedly improved.

Hygiene of the Soul by Maimonides 1135 to 1204 A.D.

"IT IS known to my lord, may God lengthen his days, that the emotions of the soul bring about great, general, obvious, definite changes in the body. One sees how a person of robust build, sonorous voice, and blooming complexion, when he suddenly receives news that troubles him exceedingly, at once his color becomes pale, his look softens, his posture stoops, his voice becomes weak, and if he should want with all his might to raise his voice, he is unable to do so, his strength weakens. He often trembles on account of weakness, his pulse beat becomes smaller, his eyes sink into their orbits. His eyelids become so heavy that they cannot move, the body surface becomes cold, and his appetite vanishes. The cause of all these phenomena is the withdrawal of the natural heat and blood into the body. The reverse of this is seen in an individual of weak physique, changeable color, and tender voice, as soon as he is met with something that rejoices him a great deal, how his physical strength is increased, his voice raised, the face lit up, his movements become lighter. His pulse beat becomes stronger, his body surface warmer, joy and delight appear so evident that he no longer can conceal it and keep it to himself. All these happenings, the movements of the natural heat and the blood to the periphery of the body, the condition of the body, and the condition of the coward and hopeful as well as that of the indifferent and phlegmatic person are well known, and likewise the conditions of the one in despair as well as of the one conscious of success are clear."

A Sporadic Benign Rickettsial Fever With Occasional Exanthem

By NOXON TOOMEY, M D, F A C P, *Palmyra, Missouri*

IN the north temperate latitude, fevers of abrupt onset and intense, short course, but without rash or contagiousness are among the commoner ailments of the summer months. Food or water borne infections cause a goodly proportion of such cases. The respiratory tract infections, exacerbations of chronic intestinal, nasopharyngeal or other focal infections, and the acute pyogenic processes of cryptic location all contribute such a share of cases that by coincidence and concatenation of circumstances they may even give rise at times to the false appearance of a sporadic or epidemic disease being present in a locality. Acute non-exanthematic infections of transmissible nature, such as mild anterior poliomyelitis in sporadic or epidemic form, influenza and other known diseases, such as scarlatina in a very mild form, may also cause a sporadic outbreak the nature of which is not recognized at first, or even throughout its course, provided necessary diagnostic procedures are not carried out.

That the food and water borne infections, endogenous and contact diseases do not, however, account for all sporadic outbreaks in the summer

months of the north temperate latitude may be suspected from our knowledge of the insect borne diseases, such as malaria, typhus fever and dengue of the less temperate climates. It is possible, therefore, that insects are the vectors of some of the acute, prostrating, non-exanthematous fevers of short duration and unknown nature, as observed in the north during the summer months, and called "summer flu" or summer influenza. Whether this sporadic summer disease of the north is in reality influenza or an influenza-like disease, or some quite distinct sort of disease has not been investigated at all, it having been taken too generally for granted that it is "influenza for all practical purposes". While one cannot deny that influenza may occur epidemically, or even sporadically, in the summer months, yet it actually appears that most of the cases of so-called "summer flu" have characteristics by which a careful observer can distinguish them from influenza as it is known in the winter and spring, and in reality throughout the whole year.

The main clinical differences between influenza and the so-called "summer flu" consist in the absence in the latter of lachrymation, corvza (or rhinorrhea) and more or less bron-

chitis, whereas in "summer flu" the fever is higher and steadier, the pulse more rapid and wiry, and in "summer flu" there is greater likelihood of nausea, vomiting and constipation, but less hebetude and drowsiness, the initially keyed-up sensorium of "summer flu" giving place at times to a light delirium. While headache, backache and aches generally are equally common in both diseases, the weariness and malaise of influenza are comparatively more vaguely localized, whereas in "summer flu" they are more apt to be described as neuralgic or rheumatoid pains in definite places, chiefly the neck, back and extremities. One curious minor difference is that the neuralgia of the scalp so commonly encountered in influenza is absent in "summer flu". Finally it may be said, but with less assurance, that the convalescence from "summer flu" is more rapid than from influenza, at least it does not have a sequential nasopharyngeal suppuration as influenza may have.

Surmising from the above facts that "summer flu" may consist in part, at least, of some disease of unknown nature, it has been our object to determine the nature of the disease, its mode of spread, and in whatwise it may be a form of, or else related to, well known diseases that occur elsewhere, particularly in less temperate climates.

The data and conclusions presented herewith are the result of observations extending over a period of six years, and are a development of certain early observations that suggested but did not at once prove that certain spotted and eruptive fevers might follow the

bites of certain blood sucking bugs (hemiptera). A discussion of the cases with exanthem conforming to the spotted fever type or the endemic typhus type, with particular reference to the vectors involved, will be reserved for a subsequent paper. This article will be limited, therefore, to a description of the non-exanthematic, or very usually non-exanthematic fever, that has, in the northern states, added its cases to the medley popularly known as "summer flu". For the sake of preciseness and clarity, the basis for our characterization of this definite entity will be the following presentation of our findings in a definite group of cases studied recently. We were led to investigate this sporadic outbreak on account of our interest in, and in conformity with, conclusions that we had previously deduced from a study of cases in which the element of sporadic outbreak was not so well marked. In general it may be said, however, that our previously recognized isolated cases conformed in clinical course to the disease here described as a typhus-like disease, and that a consideration of them would not alter or add to the characterization of the disease as made out from a study of the sporadic group upon which we base our report, except insofar as to indicate that the non-exanthematic typhus-like disease of the summer months in a temperate climate may occur as isolated cases and may run a somewhat milder course than encountered for the most part in the sporadic outbreak reported in this article.

A systematic description of the disease will be followed by epidemiologic

cal notes on the sporadic outbreak that was the source of this material, by case histories of ten of the eleven cases in this group, and by protocols of blood studies on eight of the above mentioned eleven cases. A comparison with the related diseases of the typhus-spotted group will conclude the article.

DESCRIPTION OF THE BENIGN TYPHUS-LIKE DISEASE

Initial bites by insects have been noted in about 80% of the cases. The lesions at the sites of the bites have been small erythematous papules about three millimeters in diameter. The papules have never ulcerated nor commonly shown vesiculation at their apices.

The incubation period varies from ten to fourteen days, being mostly twelve days in duration. Well characterized prodromes do not occur, although a fourth or a third part of those about to take ill notice an unusual sense of fatigue, and a vague malaise for some hours before onset.

Without a preceding subnormal temperature, the onset comes on suddenly (or occasionally subabruptly) with nausea, malaise and a rapid accession of fever. With the rise of the latter there may be a feeling of chilliness, but this is not an outstanding feature of the onset. Rigors occur only very exceptionally. Dull headache, chiefly of a diffuse or vertex type, is complained of by patients during or a little after the onset. Abdominal discomfort, rarely severe, and usually of upper abdominal or diffuse type, develops *pari passu* with nausea and vomiting. The latter usually occurs one or more times, and often

repeatedly, protractedly, and with bilious ejecta.

Neuralgic or rheumatoid pains are not a prominent feature of the disease at onset or latterly, but occur to some extent, being noticed in the cervical and dorsolumbar muscles chiefly, and as cramp-like pains of the extremities, chiefly the lower.

The fever reaches a fastigium (or prefastigium) of 104°F to 105°F within twelve hours, usually rising during the next twenty-four hours (with or without a slight preceding remission) to a perfastigium of 105.5°F to 106°F. The latter temperature, or more usually a degree lower is held with very slight remissions for the next sixty to seventy-two hours thereupon declining by very rapid lysis to normal or near normal, or even subnormal. Sometimes the lysis is not so rapid, the temperature declining consistently at the rate of about two degrees a day for two or three days. A secondary rise will be noticed later.

Both pulse rate and respirations are accelerated, the latter in proportion to the fever, but the pulse, up to 140 or 145 per minute, being for the most part slightly accelerated out of proportion to the temperature, although well sustained, tense and wiry, except in elderly persons.

Toward the end of the first twelve or eighteen hours of fever the face becomes flushed and the conjunctivæ become intensely congested, but lachrymation, rhinorrhea, coryza, or turbinal or pharyngeal congestion do not occur at any time. Faucial or tonsillar engorgement is invariably absent, and a subjective sensation of sore throat is

almost never noticed. Cough is infrequent and invariably dry, but most patients cough a little toward the end of the disease.

Constipation is troublesome from the outstart, and throughout the whole course of the disease, often falling but little short of a serious obstipation. The tongue becomes coated with a universal, thin, dry, white fur, but is neither swollen nor shrunken, nor protrudable with difficulty. There is no difficulty in micturition.

The sensorium is clear throughout the first two or three days, sleep being usually troubled, and occasionally somewhat wanting. Delirium, even the mildest, is a quite exceptional occurrence, but has been noticed for brief periods in a few cases. Micropsia was reported in one case. Drowsiness supervenes after the first two or three days (occasionally earlier) but stupor does not occur. Increase of mental and muscular fatigability are noticed toward the end of the disease, but with onset of convalescence the mental and muscular tone improve rapidly, even at a rate greater than the impaired circulatory tone would seem to justify. The moderately impaired circulatory tone and the considerable secondary anemia are the chief features of the latter course of the disease. The appetite returns readily.

A rash is not a frequent phenomenon of the sporadic benign rickettsial disease. It occurred once only in the eleven cases of this epidemic. Preliminary phenomena such as maculorecous mottling, erythema of the skin, etc., do not occur except that the face becomes habitually flushed after the fever reaches the height or is receding.

The rash as observed consisted of a lentil sized, non-confluent, erythematous-macular (deep rose colored) exanthem that appeared three and a half days after onset and was at no time either hemorrhagic or pruritic. It appeared first around the ankles and thence spread up the lower limbs to reach the groins by the end of the first day. The arms broke out not quite a day after the first appearance of the rash, the abdomen, flanks and chest, in order named, being the last parts to become involved. The rash faded quickly with the subsidence of the fever, but came out again less intensely during the secondary rise of the temperature.

A secondary rise of temperature was observed as an unmistakable phenomenon in one-half of the cases, but could be noticed to a slight degree in most of the other cases. In most instances the remission fell to below normal and lasted only a day or a little less, but in one case the remission lasted two days. The secondary rise lasted only one day, and seldom exceeded 101°F . Subsequent remissions of very slight degree were noticed in one or two cases.

In four cases, a blanching of the papules at the site of insect bites was noticed two to four days following the lysis of the fever. It was quite probable that this phenomenon occurred in other cases but failed to be observed. The white spots of the anemic areas lasted two to several days.

EPIDEMIOGRAPHY

In early August of 1932, there occurred in Pittsfield, Illinois, the almost simultaneous appearance of eleven cases of an acute febrile non-specific

thematous, hyperpyrexial fever of short duration. The known cases of clinically distinguishable character occurred chiefly among a party of boys who visited a natural swimming pool. The latter had long been a resort known favorably for its sanitary character.

On the day of exposure, July 26, the pool was visited by two groups, the boys above mentioned, and a smaller group that did not partake of the same food as the boys, and kept well apart, although not strictly isolated from them. Nine cases developed among twenty-three persons (three adults and twenty children) comprising the boys' group, and one (possibly two) cases developed among five adults and four children comprising the other group. The following day the pool was visited by a small group in nowise in contact with either of the first two groups. In this third group one case developed.

Food could be positively excluded as the source of the infection inasmuch as all twenty-three persons of the first group partook of the same food, but only nine were taken ill. The food consisted of peanut butter and pimento sandwiches, homemade cookies, deviled eggs, and ice cream cones. No water was drunk at the pool or at a farmstead as the meal was eaten in town.

Water of the pool swallowed by the boys while in swimming could not so clearly be excluded as the source of the infection. This possible source was considered the more likely on account of the pool being more turbid than usual due to a preceding rain that had washed the surrounding

drainage area, mostly orchard lands. However, of the thirty odd persons who were in swimming, only ten became ill. On the other hand, one adult (case C C) who became infected was known not to have been in or close to the pool. The boys changed clothes at various places behind a thicket of small trees and bushes. It was not possible to correlate the cases with any particular place in the brush. No one encountered a living or dead rodent in or near the pool. Insect bites were experienced by many who visited the pool, and by all who took ill, but only one patient (case C C) was able to identify at least one species of insect, these she identified as hymenoptera of the genus, *Halictus*, popularly known as "sweat bees". The latter fact was corroborated by another adult who was stung by sweat bees and possibly had a mild attack of the disease, but whose case was not investigated serologically, and was not included in this series. Whether fleas also were present or absent was not determined, but they were known to be a common pest elsewhere about the countryside at that time. With a high degree of probability it was possible to exclude ticks, blood-sucking bugs (hemiptera) and mites (chiggers) as the actual vector.

That the disease was not caused by a typhoid or paratyphoid organism was evident from the negative findings (by agglutination and culture) made on blood and stool specimens sent from several of the cases to the Illinois State Board of Health Laboratory, Springfield, Illinois.

CASE HISTORIES

Case I H U (Case of Dr. Frank N. Wells). A tall, spare built lad of 14 years

of age. He had been quite well for the preceding several years. Without prodromes, he became suddenly ill on the evening of Friday, August 5, the onset being characterized by headache, lassitude, malaise, broken slumber, and coldness such as led him to keep under heavy bed covers on a hot day, but chill and rigors were absent. His temperature at noon the next day was 102.5°F , rising steadily to 105°F by that evening. Thereafter, for forty-eight hours the fever continued constantly at 104° to 104.4°F , except for brief periods following spontaneous hyperhidrosis, when it fell to 102.5° or 103°F . Drenching sweats, occurring every three or four hours, were a feature of this case from shortly after onset until after defervescence. Sleep occurred only for brief periods following the sweats, and was troubled with frightful dreams. Between naps there was no drowsiness or delirium, the sensorium being clear but without ability to concentrate.

By the end of the first 24 hours the face was flushed and the eyes became "terribly blood shot"—shot with red—and sore in their sockets, but the eyes did not run, there was no sore throat at any time. Headache persisted from onset, but nausea did not develop at once, the patient vomiting for the first time about 48 hours after onset. Vomiting persisted for three days, possibly due partly to exhibition of calomel. The temperature was kept to 104°F the third (Monday) night by constant all-over cool sponging, the pulse then being 110 to 116, but cyanosis such as could be recognized by a layman was not present.

Three and one-half days after onset the boy broke out with a nonpruritic, macular, nonhemorrhagic rash of splotchy appearance and deep rose color, that first appeared around his ankles and spread upwards throughout the day. His arms broke out Wednesday morning and the abdomen and chest during the afternoon of the same day. Twelve hours later the rash faded quickly, with abatement of the fever, but returned later, the evening with a return of the fever. For the next three days the temperature was between 102° and 103°F , the fever being more pronounced during the first two days.

moved the dejecta had an unbearable odor. Dysuria was never present.

Case II R N (Case of Dr Wells) A nine year old boy, previously healthy. He experienced no prodromes. The onset was sudden and violent Saturday morning, August 6. The onset was characterized by nausea and terrible headache, with rise of temperature to 102°F (at 8 A M), and a slight feeling of chilliness but no chill. Nausea and headache persisted throughout the day, a stiff neck, without local tenderness or cervical adenopathy supervening. The temperature rose to 103.6°F (6 P M) the face becoming flushed, and the conjunctivae intensely congested, but sneezing or rhinorrhea were at no time in evidence. That night the boy did not sleep, the fever rose to 104.5°F , he vomited the next morning. For two and one-half days the patient was "bordering on delirium", with a constant temperature of 105°F , reaching 106.4° (axillary) at 4 P M Wednesday, but falling by the early part of next day. Hyperhidrosis was not a pronounced feature. A right inguinal adenopathy was noticed during the early course of the disease. After the fifth day a dry hacking cough, "but nothing of pronounced degree" occurred for three days.

The pulse was slow, weak and intermittent throughout Friday and Saturday, the seventh and eighth days of the disease. A stubborn constipation, noticed shortly after onset, persisted throughout the disease. A secondary rise of temperature, to 102.1° occurred on the seventh day. No rash had appeared at any time, but on the eleventh day it was observed that the previously noticed "bites" had become minute flat papules and totally anemic (intensely white) in color.

Case III R McR (Case of Dr McRaven) A 10 year old boy with a history of having had two or three prior attacks of abdominal distress, but none for the preceding eight months. He became suddenly ill Sunday evening, August 7, with chilliness (but no chill), tongue, and a rapid rise of temperature. He had no delirium or depression or vomiting at onset. His temperature varied between 105.1° and 105.6°F for three days and then fell to 102.1°F on the fourth day.

normal While the fever was high his face was flushed, his conjunctivae were congested and his bowels were constipated, but he was without lacrymation, coryza, sore throat or bronchitis He had no rash, and his sensorium remained clear

Abdominal tenderness and vomiting supervened after the second day of fever, and again during the secondary rise of his fever, but as the latter attack appeared to be a recrudescence of his previous appendiceal trouble, he was hospitalized and no longer considered an uncomplicated medical case

Case IV L G (Case of Dr Peacock)
An 11 year old boy, not previously ill He had a prodromal malaise for some ten hours before onset Onset was Saturday evening, August 6, with headache, stomachache and rise of temperature to 102.5°F He did not vomit at onset or at any time afterwards, although his head ached almost constantly throughout the course of disease, and stomach ached from time to time After the first twelve hours the temperature rose to 104.5°F and continued thereabouts constantly for three days, reaching 105°F in the evening of the fourth day, and thence twelve hours later declined by a rapid lysis Shortly after onset his eyes became blood shot and his condition progressed to what was called a dry granulation of his lids, with photophobia but without a mucoid or purulent exudate His throat at no time became injected or sore although he had a slight cough towards the end of the fever His doctor thought he heard some fine râles in the upper part of chest Constipation was not a marked feature, diarrhea did not develop There was no lymphadenopathy Following the lysis there were two or three remittances of the fever, but accurate records were not kept No rash developed Insect bites, believed to be mosquito bites, had been noticed

Case V D L (Case of Dr McRaven)
An anemic boy of small stature for his age of 13 years Some two to three weeks prior to his illness, his father had a short, prostrating fever with violent rigors and nausea but no sore throat, coryza, bronchitis or exanthem His mother and sister were likewise ill shortly afterwards, but only moderately to slightly so

The boy became ill suddenly, Saturday night, August 6, with headache, prostration and a sudden rise of temperature to 103°F He did not vomit until the next morning "His eyes became terribly blood shot and his nose ran although his throat was clear and not sore at any time For three days and three nights his fever was 103°F and did not vary the least at any time He developed a pain behind his ears and aches down his legs His bowels scarcely moved at all and never got loose About the fourth day his nose began to run, his eyes watered, and he developed a dry cough, after which he spat up a lot for a day or two His headache, which had gone away, came back terribly with the return of the fever" This patient had an abrupt lysis on the fourth day with intermittence of one day, and a secondary rise on the sixth His sensorium remained clear, and no rash developed Ten or eleven days after onset, his mother found noticeable for the first time, white macules about 3.5 mm in diameter These were scattered at random over the upper part of his chest, shoulders and neck On at least one, and probably two occasions, a week or so after defervescence, and following moderate exertion, he had a sharp rise of temperature lasting several hours

Case VI W K (Case of Dr McRaven)
A robust boy 12 years of age, not previously ill Onset was abrupt Saturday night, August 6, with slight malaise and chilliness, but without rigor or headache He did not vomit until the next morning (temperature then 103.4°F) The temperature taken Monday morning, when he again vomited, was 102°F , it was 103° that afternoon, and 104.8° that evening He had considerable injection of the conjunctivae (second and third days only) but had no lacrymation, coryza or sore throat This patient had no headache or pains at any time, and no cough at any time He was constipated throughout the whole course of the disease There was a lysis to subnormal (98.2°) about the middle of the fifth day, and thence a slight rise (to 99.6°) twelve hours later, the temperature remaining normal after the sixth day

Case VII L N (Case of Dr Wells) A boy thirteen years of age who had not previously been ill, was taken ill suddenly

on Sunday morning, August 7, the onset being characterized by dizziness, headache, nausea, and a rise of temperature to 102°F . He vomited shortly after onset and retched frequently and severely until the end of the third day, his temperature during the time rising to 104.4°F at 12 hours after onset, and thereafter remaining practically constant until the end of the fourth day. After a rapid lysis, and an intermission of one day (at 99.6°F), there was a rise to 103°F by the end of the following day, the temperature declining to subnormal (97°F) at the end of seventh day, but after the eighth day remaining nearly normal.

Towards the end of the fever this patient noticed some stiffness of his lower limbs. A nonproductive conjunctivitis was present, and the tongue was heavily coated, but there was no coryza, sorethroat, or cough. Constipation was troublesome throughout the whole course of the disease. The pulse (mostly 136 to 142) was unusually rapid for the temperature according to his mother, a trained nurse. Continuous drowsiness was a feature of this case.

On the ninth or tenth day after onset, the temperature then being normal, numerous anemic macules (white spots) were noticed for the first time on the upper part of his trunk. They were where small erythematous papules, 'insect bites', had been.

Case VIII E. A. (Case of Dr. McRaven). An active lad, $12\frac{1}{2}$ years of age, not previously ill. He became ill sometime Monday, August 8, there having been for some hours what might have been a prodromal period. The illness was characterized by an extreme sense of fatigue and weariness. Onset was with headache, flushed face, conjunctival engorgement, increased malaise, and a rise of temperature to 103°F . Chilliness and vomiting did not occur and nausea was at no time in evidence. Herpes labialis was noticed on the third day, but never was his throat sore. He never coughed, nor had any coryza or coryza. The fever reached 104.1°F at 36 hours after onset and continued with decline to 102°F on the fourth day, then on the next day, reaching to 101°F and then down to 100°F on the sixth day. It was then normal.

fifth and sixth days. There was a secondary rise (to 100.2°F) throughout the seventh day. Constipation occurred, with diarrhea at no time. The patient's sensorium remained clear. No rash developed. There was no remembrance of bone, joint or muscle pains, except for general "tiredness".

Case IX J. C. (Case of Dr. McRaven). A somewhat nervous lad of 11 years of age, not previously ill. He became ill rather suddenly on Monday evening, August 8. Onset was characterized chiefly by vertigo, sleeplessness and rise of temperature to 101°F , there being but slight chilliness. The next morning his "face and eyes looked real red and feverish, but his eyes did not water". During the day his temperature rose constantly, reaching 104.2°F , about 24 hours after onset. Twinges of sharp pain were noticed about that time and afterwards. He did not vomit at onset or during the first few days. He was constipated, the forced dejecta being dark green and black, and very offensive, a coated tongue was noted.

His temperature continued about constant at 103.6°F , during the second, third and fourth days, the general sweat, 48 hours after onset, and several slighter ones somewhat reducing it transitorily. There was no sore throat, coryza or chest symptoms at any time. A drop of his temperature to normal through the fifth day was followed by a rise to 100°F throughout the sixth day, exacerbation being accompanied by headache and vomiting. No rash appeared.

Case X was in a boy who visited the swimming pool about twenty-four hours after the day most of the boys were infected, and who at no time had been in contact with any one else who contracted the disease, or had partaken of food in common with them. The disease in this case was reported to have consisted of high continued fever with marked prostration, vomiting, and absence of respiratory tract symptoms and intestinal looseness. Although the disease was of the more severe sort, no rash developed. The incubation period was eleven days. Further information was not obtainable.

Case XI Mrs. C. C. This patient is a woman 48 years of age, who had had a fever for a few days, but no abdominal symptoms.

was done two years previously. She was not robust but had been free from abdominal discomfort and febrile reaction during the preceding twelve months. She was seized Tuesday morning, Aug 9, with sudden profound weakness, chilliness, and general malaise, but without headache, rigor or definite nausea. Bites by insects (to a considerable extent) were sustained July 26. No conjunctivitis, coryza, sore throat, or chest symptoms developed at any time. Constipation was natural to her and was not replaced by any looseness. Diffuse abdominal soreness, without nausea, but with pains in the sides and the back, was a prominent feature of this case. Frequent heavy sweats at irregular intervals and profound drowsiness, both of which lasted five or six days, were outstanding features. A temperature record was not preserved, but it was clear that after an illness of eight days she quite suddenly improved, and for the following weeks remained free from symptoms suggesting a focal infection. Although a definite retrospective diagnosis was not possible in this case, the apparent occurrence of an incubation period, the sudden onset of a se-

verely prostrating illness with numerous irregular sweats, the absence of symptoms suggesting one of the commoner focal ailments, and the sudden convalescence after eight days suggested that she may have had the benign typhus-like disease (a fact later confirmed serologically).

BLOOD MORPHOLOGY

No blood counts were made by the attending physicians during the early course and fastigium of the disease. While the blood picture as found by the author at the end of lysis, and recorded below, is not conclusive evidence of a particular type of reaction, nevertheless it is evident that the disease produced a secondary anemia of moderate degree, and a slight leucocytosis, the latter being due chiefly to an absolute and relative increase in the lymphocytes and mononuclears, a change almost invariably noted in the rickettsial group of diseases.

SEROLOGY

Specimens of six sera were titrated against two local strains of *Proteus* of unknown type, but for the purpose of this article known as M₁ and M₂. While our titrations against these strains gave fairly significant results it was thought best to ask that titrations be made against a large number of strains of *Proteus* X organisms. Accordingly, six samples of the sera were sent to the National Institute of Health, Washington, D C, and six samples to the Rocky Mountain Spot-

"These serums have been run against *B proteus* X₁₀—No 504, which our experience has shown to be the most sensitive of our stock cultures of *B proteus*. The result as shown on the enclosed sheet are suggestive that the cases are either typhus or mild spotted fever, and we would suggest since these samples were taken about the 8th or 9th day of fever, second samples be withdrawn sometime after the end of the second week. They may show a much higher titer."

Titration at the National Institute of Health were made against only *B proteus* OX₁₀—No 504. The protocol of these titrations is as follows

TABLE III
TITRATIONS AGAINST *PROTEUS* OX₁₀—No 504

CASE			DAYS AFTER ONSET	N H I NO	1/20	1/40	1/80	1/160	1/320	1/640
I	H	U	9.5	3248	4	4	2	0	0	0

VII.	L	N	8		4	4	4	4	2	0
VIII	F	A	8	3250	4	4	4	4	0	0

ted Fever Laboratory, Hamilton, Montana. In each instance it was asked that the sera be titrated against the following strains of *Proteus* X: ONK, HXK, OX₂, OX₁₀, HX₁₀, W (N H I No 533), 271, 560, and 568.

In reply to our request, Dr R E

To determine whether there was an increase in the titer during convalescence, the following specimens of blood drawn 18 to 20.5 days after onset (or about 9 to 10 days after defervescence) were titrated against strain No 504 with the following results:

CASE			DAYS AFTER ONSET	1/20	1/40	1/80	1/160	1/320	1/640
II	R	N	20.5	4	4	4	2	2	0

*National Institute of Health

Eight to nine days after onset, none of the cases agglutinated the X₂ strains. However, blood drawn eleven days later, from cases II, V, VII, VIII, and XI, showed a very low and incomplete titer for both HX₂ and OX₂.

Comments of Dr R. R. Parker, Special Expert in charge of the Rocky Mountain Spotted Fever Laboratory, under date of August 26, 1932, were as follows:

"As a result of our experience with this agglutination test in Rocky Mountain spotted fever, I would be inclined to feel that these results mean little, either in a negative or positive way. Identical results with those listed could be secured with perfectly good clinical cases of Rocky Mountain spotted fever. We could also secure as high agglutinin titer as the highest shown in your series with the sera of occasional persons whom there is no reason to suspect have ever had a typhus-like infection. I offer these comments for whatever you may think them worth.

"The result of possible significance in connection with these tests is that the sera

of Underwood, Kern, Logsdon, and Niebur all show some agglutination of the Kingsbury strains, either OXK, HXX, or both. The agglutinin titer is, of course, very low, but in our experience it is very seldom that either a normal or a spotted fever serum causes agglutination of this strain even at 1:10. As possibly you may know from the literature, there are certain of the typhus-like infections that agglutinate Kingsbury strains more consistently than any other *Proteus X* organism.

"Certainly one has to admit that the possibilities of transmission of typhus-like diseases by biting insects have only been touched."

Concerning an increase in titer of sera drawn from four cases (cases II, V, VII, VIII) on the eighteenth to nineteenth day after onset, Dr Parker, under date of Sept 22, 1932, wrote as follows:

"I am forwarding the results of the agglutination tests with the second group of six sera. It appears difficult to draw any definite conclusions from these results. Possibly the most suggestive data are those for the Richard Niebur case, in which all three

protus strains used for the first test and found negative showed low agglutination for the sample of Sept 7. The two samples for Logsdon show no essential difference. The second sample for Louis Niebur shows a slightly increased titer against two strains. These are the same two strains that showed increased titer in the second sample from Richard Niebur. This may be of some significance."

ANIMAL INOCULATIONS

Seven healthy guinea pigs weighing from 236 to 810 grams were inoculated, each with one blood specimen from one of the cases indicated in the accompanying protocol. The blood was injected intraperitoneally after the abdomen had been shaved and wiped with merthiolate 1-1000. In several instances a minute amount of the blood specimen was injected into the cornea of one eye.

Concerning what may be regarded as a febrile reaction in guinea pigs it has been our experience that a normal *average* temperature for pigs of the ages used in our experiments, and kept under optimum housing and nutritional conditions at a room temperature of 80° F (26.7° C), may be determined as being approximately 102.4° F (39.1° C) with maximum *average* variations from 101.5° F (38.6° C) before morning feeding, to 102.6° F (39.2° C)

after afternoon feeding, younger pigs usually having a slightly higher temperature than older pigs. In individual cases the range of normal is from 100.8° F (38.2° C) to 103.6° F (39.8° C). Hence in testing out individual pigs a temperature up to 103.6° F should be considered within the range of normal. When, however, the temperatures of a number of guinea pigs submitted to a group experiment are taken at the same time and averaged together for the purpose of constructing a histogram of the average temperature, it seems proper to compare the ascertained average with the known normal average under the prevailing housing and nutritional conditions. It is on that basis, therefore, that the following graph (see chart II) has been prepared. For the daily temperature readings of the individual guinea pigs see table IX.

Towards determining whether the virus causative of these cases was that of typhus fever or spotted fever, or possibly a yet unidentified typhus-like virus, it became necessary to determine whether the disease produced in the guinea pigs by the unknown virus left them susceptible to or wholly or partially immune to test viruses of known character: those of spotted fever and of typhus fever. Accordingly, blood virus of known character was inoculated as indicated in table VII. This table is a consolidation of observation

TABLE V

made independently by the author, and by Dr R R Parker at the Rocky Mountain Spotted Fever Laboratory. Dr Parker kindly furnished us with Rocky Mountain spotted fever blood virus to make our tests, but as there was the possibility of the spotted fever losing potency in transit, we shipped four of our guinea pigs to Dr Parker, who kindly carried out cross-inoculation tests on them. Similarly, five of our pigs infected with the unknown virus, after we tested them against spotted fever virus, were shipped to Dr R E Dyer, Acting Director, National Institute of Health, Washington, D C, where they were cross-inoculated with typhus. The protocols of the cross-immunity tests are set forth in tables VII and VIII.

To determine whether persons con-

valescent from the benign rickettsial fever still carried the live virus in their blood, six guinea pigs were inoculated, each with the fresh whole, non-citrated blood of one case drawn on the eighteenth to twentieth day after onset. The results are set forth in table IX.

COMPARATIVE PATHOLOGY

Numerous typhus,^{2,17,22} typhus-like,^{4,15,23,28} and spotted fevers,^{12,19,20,26} of diverse types have been described in recent years. Lately these fevers have been arranged systematically according to their serologic reactions, their clinical manifestations, and the biologic positions of the vectors involved in their transmission.³¹ On that account it is now inadequate to give a clinical description of a typhus-like disease without accompanying the report with

Guinea pig numbers indicate weight in grams of respective animals when first taken for experimental purposes. All guinea pigs lost from 24 per cent to 30 per cent (average 26 per cent) of their weight as a result of the typhus-like infection.

CHART II

TEMPERATURE CURVES OF THE DISEASE IN GUINEA PIG

The upper curve represents typical temperature curve of individual guinea pig charted by the U. S. Public Health Service (recognizing as typhus-like infection). The lower curve represents average temperature of four guinea pigs (No. 595, 705, 732, and 810) inoculated with a blood culture from one of four cases (Case II, H. U.). The shaded area indicates normal range of average normal temperature of guinea pigs.

* Letter report by Dr G W McCoy, Director, National Institute of Health, October 8, 1932, as follows: 'The five guinea pigs received from you on September 22 have been tested for immunity to endemic typhus as you requested. Three of them gave the usual reaction of fever and redness and swelling of the scrotum and hence were considered non-immune to endemic typhus, while two of them died during the course of the test, presumably from secondary infection, and it could not be determined whether they were immune.'

pertinent serologic and immunologic data.

As to what criteria will prove to be the ultimate means for classifying the fevers of the typhus-spotted fever group can not be predicted with assurance, but those tests that establish the natural relationships of these fevers will naturally be accepted as the basis for classification. If any of these tests, or any combination of them, can be shown to be a differentiating criterion of fundamental value...

properties of the blood with respect to the different strains of the Proteus X... Whether the diverse agglutination characteristics of these diseases can be dependably correlated with their immunological differences can not at present be accepted with finality, although it does appear that the power to agglutinate either or both of the X... or the Kingbury strain is a differentiating criterion of fundamental value...

While the behavior of these viruses when inoculated into guinea pigs has been studied by several observers,^{1,5,6,7,8,11,20} it appears that the febrile, peritoneal, scrotal, and perhaps cerebral reactions are conditioned as much or more by the degree (state) of virulency of the virus employed, than by its individual character. Thus scrotal lesions are common in the malignant form of Rocky Mountain spotted fever but may be absent in the mild forms of the disease. They are not common in the epidemic typhus of Europe but are common in certain of the American and Mexican strains of typhus fever,^{1,6,30} although occasionally absent in those infections, and occasionally observed in the epidemic typhus of Europe.^{7,30}

In comparison with the other diseases of the typhus-spotted fever group, the disease described in this report has a unique place. We remark it having a rash somewhat similar to the spotted fever of the Rocky Mountains, at least with respect to its upward progression from the ankles. Also, the disease appeared to give a partial, but apparently incomplete immunity to spotted fever. On the other hand it caused agglutination of the Kingsbury strains of *Proteus* HK and OK, something that Rocky Mountain spotted fever seldom does. Also there was a longer incubation period in the guinea pig and not as great a degree of scrotal reaction as one might expect in spotted fever, although in the eastern-southeastern states' strain of spotted fever, the scrotal reaction is not commonly observed. Ticks, the so-far-as-known only vectors of Rocky Mountain spotted fever could be ex-

cluded as the vectors of this disease. This fact raises the question whether the virus concerned was that of spotted fever somewhat altered by being adapted to a vector of a different biologic order.

In comparison with the diseases known to agglutinate the Kingsbury strains, the scrub typhus of Malasia, pseudotyphus of Sumatra, tsutsugamushi disease, and tick-bite fever of South Africa, we note them as usually having a primary sore, as invariably (?) having a rash, a more prolonged febrile course, and more pronounced nervous symptoms. In fact our benign sporadic disease is clinically less similar to the Kingsbury group of diseases than to endemic typhus, especially a mild endemic typhus *sine exanthem*. As to one other fever in which the Weil-Felix test has been found positive, the Port Elizabeth fever,²⁴ we note the latter's prevalently low, irregular fever, the nervous symptoms and the rash, a syndrome quite distinct from that found in our disease.

When compared with the tick-borne *fièvre boutonneuse* (exanthematic fever) and the tick typhus of India, diseases somewhat resembling Rocky Mountain spotted fever, we find no resemblance to them greater than our disease has to spotted fever of the Rocky Mountains. On the other hand, of the tick-borne group we find the greatest similarity between our present disease and the (non-exanthematic) American mountain tick-fever described by us as a distinct entity about a year ago.^{21,25} So close is this resemblance that it would at times be impossible to distinguish between these

diseases by clinical means alone, the main differences at most being that the American mountain tick-fever has a shorter incubation period, is usually accompanied by more aches and pains of muscles and bones and runs a slightly longer course with two or three remissions instead of one, but these clinical differences could be due to our present disease being caused by a less virulent strain of the same virus.

As to our present disease being a mild typhus *sine exanthem*, we can say that the low *Proteus* X_{10} titer, the mononuclear rather than a lymphocytic leucocytosis, the absence of scrotal lesions in guinea pigs, and the less accentuated disturbance of the nervous, circulatory and bronchial systems are against such a supposition.

SUMMARY AND CONCLUSIONS

An intensely febrile typhus-like disease of short duration was observed to cause a sharply localized group of cases in the west-central part of Illinois during early August, 1932. Of the eleven known cases, ten were without exanthem. One case developed on the fourth day a lenticular, ascending, non-hemorrhagic erythematous macular rash somewhat resembling the rash of mild Rocky Mountain spotted fever except that it disappeared suddenly with the lysis of the fever.

The disease was characterized by an incubation period of about twelve days, by sudden onset, abrupt rise of temperature usually with headache, chills, a cold, sore throat and by a high continued fever that fell abruptly 3 to 5 days after the onset. A remission occurred in 2 of 11 cases, frequently

followed by a secondary rise of temperature lasting one day. Constipation and an intense non-productive conjunctivitis (not accompanied by lacrymation) were characteristic symptoms. Coryza, pharyngeal engorgement and chest symptoms were wholly absent, except for an occasional slight dry cough towards the end of the disease. Neuralgic and rheumatoid pains were almost wholly absent, and the sensorium remained clear. Hyperhidrosis and a regional lymphadenopathy were occasionally observed, but were not constant features of the disease. There was no mortality.

The disease caused a slight leucocytosis due to a relative and absolute increase in the lymphocytes and large mononuclears, particularly the latter. Considerable secondary anemia developed, but convalescence was rapid.

Although the disease was undoubtedly insect borne, a primary sore at site of inoculation could not be made out in any case. Small erythematous papules, the sites of insect bites, were commonly observed to become anemic (white macules) following the termination of the fever. The vector was not identified but there was evidence suggesting that the virus was transmitted by a hymenopteron of the genus *Halictus* (family Halictidae).

Agglutination tests against strains of *Proteus* X organisms showed no affinity for the non-indologenic or Kingsbury strains in addition to a moderate affinity for the X_{10} strain. The X_2 strains were not significantly agglutinated. There was an accentuated and at most very slight increase in the agglutination titer during convalescence.

Guinea pigs were found moderately susceptible to the virus. The disease in guinea pigs was without a noticeable scrotal lesion and was principally neurotropic, thus resembling epidemic typhus more than certain strains of endemic typhus or Rocky Mountain spotted fever. Inoculation of convalescent guinea pigs with the virus of Rocky Mountain spotted fever showed that the guinea pigs were susceptible to the spotted fever virus but appeared to have a partial or group immunity to spotted fever.

Preliminary studies, not developed in this report, indicate that the disease occurs not uncommonly in a very mild form, and that it is the cause of some of the cases hitherto loosely called "summer flu" or influenza.

Clinically and immunologically it is necessary to recognize this disease as a separate entity. Serologically it is related to the diseases having an affinity

for the non-indologenic (Kingsbury) strains of the *Proteus X* organisms. An approximate clinical similarity to the American mountain tick-fever is noted.

ACKNOWLEDGEMENTS

For carrying out the agglutination reactions and some of the cross immunity tests, as elsewhere noted, the author is greatly indebted to Dr R R Parker, Special Expert in charge of the Rocky Mountain Spotted Fever Laboratory, Hamilton, Montana, and to Dr R E Dyer, Acting Director of the National Institute of Health, Washington, D C.

In connection with his field studies, the author is particularly indebted to Frank N Wells, M D, of Pittsfield, Illinois, for his interest in this disease and for his efforts to assist the author's field studies. Assistance was furnished also by Drs Peacock, Berry, and McRaven of Pittsfield. For helpful observations as well as for blood specimens the author is particularly indebted to Mrs Edith McCarty Niebur, R N, and to Mr and Mrs Harry Underwood, Evans Kern, Dean Logsdon, Bentley Caughlan, and Ray Atwood.

An Obstinate Case of Intestinal Myiasis

By W B HERMS, M A , *Berkeley, California*, and Q O GILBERT, M D ,
F A C P , *Oakland, California*

BY the term *myiasis* is usually meant the invasion of organs or tissues of animals including man by the larvae of flies belonging to the order Diptera. Although there are a number of species of flies, notably the Oestridae (bots, warbles, etc.), in which this invasion is an obligatory form of parasitism there are many more species in which this is an accidental relationship, i.e., the normal existence is free-living and invasion of the internal organs of higher animals is through ingestion of infested food or drink, or ingress through wounds or the natural openings (nasal and anal).

Among the more obviously free-living Diptera which have been definitely incriminated in intestinal myiasis is the cheese fly, *Piophilula casei*, which deposits its eggs in old cheeses, ham, bacon, and similar fatty products. It is easy to understand how larvae of this species might be ingested but it is not so easy to understand how the larvae could continue to live for any length of time in the intestine. Yet

Thebault¹ (1901) according to Riley and Johannsen² (1932) recovered living larvae of this species of fly from bloody excrement voided by a child. It has been shown experimentally that a dog fed on cheese containing these larvae suffered marked intestinal injury, the papillae of the small intestine having been destroyed in spots and the walls almost perforated, presumably the result of larval attack.

However, among the Diptera more commonly reported as causing intestinal myiasis are the lesser housefly, *Fannia canicularis* L., and the latrine fly, *Fannia scalaris*, F., neither of which breeds in materials which might normally be ingested in or with food, i.e., their larval food is principally fecal material. Both species invade the house and, of course, might deposit eggs under stress of circumstances in decomposing vegetable matter or meat. Riley and Johannsen (*loc cit*) describe the symptoms caused by the invasion of these flies as vaguely resembling helminthiasis, or more specifically, "as causing vertigo, severe headache, nausea and vomiting, severe abdominal pains, and in some instances, bloody diarrhea." Living larvae have been recovered in stools.

Our concern in the case we are about to describe is with a group of flies which have a much wider range

From the Medical Entomology Laboratory of the Division of Entomology and Parasitology, University of California.

Presented at the Sixteenth Annual Clinical Session of the American College of Physicians, Berkeley, California, April 5, 1932.

of larval feeding habits, namely, the Muscoidea, including such genera as *Lucilia*, *Phormia*, and *Calliphora*, commonly known as the green bottle and blue bottle or blow flies, all of which deposit eggs on a wide range of materials including human food, particularly cold meat. Flies belonging to the family Sarcophagidae are especially partial to meat and are larviparous, i.e., deposit living larvae. The larvae of this entire group of flies develop very rapidly under normal conditions reaching full growth usually in four or five days after which they leave the food in search of drier and protected conditions for pupation. The pupal stage is also quite brief. The entire life history from egg to winged insect requires but from 15 to 18 days under favorable conditions. All stages may be considerably prolonged under stress

CASE REPORT (Q O G)

The patient, Z. W., a female, age 38 years, was first seen on April 26, 1930. Her chief complaints were attacks of nausea, vomiting and diarrhea, nervousness and joint aches. She had lived in Texas for a number of years. For years she had had recurring attacks of diarrhea which would last for a short time. In 1928, there was a more severe attack. She was able to work from January, 1929, to October, 1929, when she quit because of nausea, vomiting and bowel distress. She was in bed about a month, then she went to southern California where a clinical diagnosis of tuberculosis of the lungs was made. She came to Oakland in the early spring of 1930, where we saw her first on April. Her past history included the following children's diseases, pneumonia, measles, mumps, and a mother died of questionable tuberculosis. The patient was a social drinker, but not a heavy one. She had been married for 12 years. Her husband was a physician and was also a social drinker. She had been married for 12 years. Her husband was a physician and was also a social drinker. She had been married for 12 years. Her husband was a physician and was also a social drinker.

ing and diarrhea. She was operated on again for some adhesions and two small tumors of the uterus. But the major sickness has been definitely worse the past two years. Recently finger joints have become sore, also knees and ankles, and she has had rather frequent colds.

The examination showed a slender woman, with the appearance of moderate anemia. General physical examination was negative except for abdominal tenderness. Gastro-intestinal x-ray examination was negative except for hypermotility and evidence of colitis. Urine was negative. Examination of the blood showed hemoglobin, 68 per cent, red blood cells, 3,776,000, white blood cells, 5,000, polymorphonuclear leucocytes, 75 per cent, small lymphocytes, 17 per cent, large lymphocytes, 6 per cent, eosinophiles, 2 per cent. Repeated stool examinations showed giardia and yeast cells, mucus, pus, a few cysts of *Endamoeba dysenteriae*, *Coccidia*, *Coccidia tenuis*, gram negative bacteria predominating. Repeated examination of stools showed no evidence of tubercle bacilli. The rectum showed congestion of the mucosa with rather marked internal hemorrhoids which bled easily. Five months later cysts of *Endamoeba dysenteriae* were still found. The patient had a prolonged treatment of emetine intravenously, quinine, and autogenous vaccine from stool cultures. There was general improvement in the patient's condition during the summer and fall. However, there were recurring attacks of nervousness, vomiting and diarrhea and apparently rather frequent hemorrhages from the bowel. The patient was considerably depressed at times and treatment was difficult because of lack of cooperation except after she had had a bad spell. Because of the difficulty of obtaining stool specimens, especially during the acute attacks, and in view of the fact that we had felt that there might be other reasons for her condition, early in the spring of 1931 during an attack of nausea with vomiting and diarrhea we kept the patient for one entire day in the office for observation and obtainment of stool specimens. Both of us were present and the patient was kept in the office for one entire day. The patient was kept in the office for one entire day. The patient was kept in the office for one entire day. The patient was kept in the office for one entire day.

observation she was given santonin by mouth and colonic irrigations containing thymol. Many larvae were recovered after this, all of which were dead. Following the attacks of diarrhea the patient had a number of severe hemorrhages. Tetrachlorethylene capsules were given by mouth but they caused gastric distress. In the hospital a duodenal tube was passed and tetrachlorethylene was injected beyond the stomach. For a few weeks there was apparent improvement, but the same attacks recurred, with the passage of larvae by vomiting and bowel discharge. In addition to the severe hemorrhages from the bowel, the patient vomited blood. There were bleeding hemorrhoids. It was necessary to give two blood transfusions in September, 1931, and again after another hemorrhage in November, 1931.

Once during the summer after tetrachlorethylene was given through a duodenal tube, 1,000 cc of a solution containing Epsom salts was administered at a temperature of 110°F. This gave no permanent result. At Christmas time, 1931, the patient found it necessary to go to the southern part of the state where her condition has remained unchanged.

THE LARVAE

Specimens of fly larvae as stated above were brought to the Medical Entomology Laboratory of the University of California on March 31, 1931. Two full grown larvae placed in a receptacle with dry sand, pupated, one during the following night, and the other April 1. The first winged fly emerged April 10, and the second, April 11. These were both blue bottle flies, *Calliphora* sp.

The second lot of larvae was received May 12. These were contained in very liquid feces and were less than half grown. Fifteen of these larvae were carefully transferred to a small piece of fresh fish in a jar with dry sand and the cover of the jar sealed with vaseline. The larvae grew rapidly and pupated May 22. Seven adult

flies emerged on June 4 and 5. These were green bottle flies, *Lucilia* sp. Three days later seven other flies emerged which belonged to still another genus, namely *Sarcophaga*, a species of larviparous grey flesh fly. The carefully sealed jar fully excluded any possibility of contamination on the part of flies from the outside, and the facts of the life history of these two species pointed positively to their origin as already explained.

On July 28, 1931, another lot of larvae was brought to our laboratories. These were in a specimen of stool, also very liquid. Three fully grown larvae were transferred to a jar with dry sand as before and on July 30 one pupated, the others died, and on August 11 an adult fly emerged which proved to be another blue bottle, *Calliphora* sp., like those of the first lot received, except that this specimen was decidedly undersized.

DISCUSSION

The food habits of the three genera of flies involved in this case of intestinal myiasis would seem to indicate that the original infection was due to the ingestion of cold meat, possibly pork in some form. The genus *Sarcophaga* is a strongly carnivorous group of flies which supports this theory, although the two other genera, *Lucilia* and *Calliphora*, are more omnivorous. The recurrence of violent symptoms with egestion of larvae in vomit and stools would ordinarily point to repeated infections like the original infection, but the fact remains that the patient lived in a way that would seem to preclude repeated infestations.

The other alternative explanation of the long period of maggot infestation and the periodic recurrence of violent symptoms is that of pedogenesis, *i.e.*, the production of other larvae on the part of fully grown larvae already in the digestive tract. Normal reproduction following the usual sequence of events, pupation, emergence of adult flies, fertilization, and egg laying (or viviparous larval production) all within the intestine of a human being, is extremely difficult to believe. Certainly there were broods of very young larvae at intervals, at which time also full grown larvae were present. No examination was made of these mature larvae for evidences of pedogenesis.

At least one instance of pedogenetic reproduction has been reported for *Calliphora*, that by Parker³ (1922), who states, "The increases led me to believe that *Calliphora erythrocephala* occasionally multiplies in an unusual way, and that this way is not polyembryony but pedogenesis"

In retrospect the patient must have had the condition of myiasis for a number of years because of the similarity of the many attacks. The condition complicated the protozoan infestation. There are at least three outstanding facts: (1) The condition was demonstrably present for at least a year, historically present for many years. (2) The attacks came at quite regular intervals, associated with great abdominal distress with the passage of feces by mouth and bowel. Following the attacks there would be a period of very quietness, even to be followed by the same sequence with the next attack. (3) During the past

year the patient lived in a clean modern home where the food was handled in a sanitary manner, and during the many times we were in the home no flies were seen. In view of these facts it seems impossible to explain the situation except on a basis of constant reproduction of the larvae within the gastro-intestinal tract, reaching a stage of maturity at intervals when the attacks would occur.*

Unfortunately the several species of flies involved in this case have a rather wide distribution, otherwise if one or more of these species were localized particularly in relation to Texas where the patient lived prior to coming to California, evidence would be at hand confirming our belief that this was a case of intestinal myiasis of long standing,—a very remarkable instance.

Our effort is now being directed toward a study of pedogenesis in the flesh flies. If we can produce artificial conditions simulating the digestive tract and can induce pedogenesis then, at least, a forward step has been made in the solution of our problem, but there would still remain to be had

*Note by the Editor. In response to inquiry as to the completeness with which extra-corporal contamination had been excluded, Dr. Gilbert replied as follows:

The specimens of feces sent to Dr. Herms were obtained either here at my home or while the patient was in Perdue Hospital. There was absolutely no chance of error in obtaining the specimens. They were obtained from defecation, from vomitus, from the rectum through a proctoscope. The material was kept and the specimens were obtained more than a dozen times before the case closed, usually in the form of very careful bottles or sterile containers.

reason for the incomplete response to treatment, made difficult because of severe complications

Withal, the possibility of repeated

ingestion of larva- or egg-infested food, though hard to believe under the circumstances, is still not completely

ruled out

Familial Congenital Clubbing of Fingers and Toes

Report of a Case

By OSCAR B RAGINS, M D , and E B FREILICH, M D , *Chicago, Illinois*

CONGENITAL familial clubbing of fingers and toes is apparently a rare condition. A review of literature revealed no report of such conditions. We therefore thought the present example worthwhile reporting.

Mr. B , 34 years old, presented himself for examination with minor complaints of gastro-intestinal origin. Dur-

ing the course of examination, the peculiar clubbing of his fingers and toes was noted. There were no abnormal findings in his heart or lungs. Except for a slight tic of the palpebral muscles of his left eye, the physical examination was essentially negative.

The patient related that his sister, father, and paternal uncle have identical clubbing of their fingers and toes. He had no information as to the presence of this condition in any of his grandparents.

Received for publication April 20, 1932
From the Out Patient Department, Mount Sinai Hospital, Chicago

X-ray study of various parts of his skeleton and cranium revealed that the distal phalanges of the upper and lower extremities show slight enlargement, but proportionate to the other bony structures. The middle phalanx of the toes is short and broad. There is thickening of the cortex and the periosteum of the radius, thickening and proliferation of the periosteum and cortex in several regions of the

tibiae and fibulae, and small exostoses in several regions of these bones.

It was noted by comparing the photographic picture and the x-ray of the hand that the clubbing of the fingers is much out of proportion to the deviation from the normal structure of the distal phalanges. Therefore the clubbing in this case affects mainly the soft tissues.

Complete Situs Transversus With Auricular Fibrillation and Flutter

Report of a Case

By HAROLD A. ROBINSON, M D, *Detroit, Michigan*

THIS case is reported because of its interesting electro-cardiographic findings. A thorough search of the literature reveals no previous similar case reported. There are many cases reported in the literature of complete situs transversus with electrocardiographic depictions of dextrocardia. Some of them are associated with pathologic conditions of the heart, for the most part, congenital anomalies. Other case reports are of situs transversus associated with diseases other than those of the heart.

A discussion of complete situs transversus and auricular fibrillation and flutter will not be taken up here, having been thoroughly discussed in other reports in the literature.

In the absence of other congenital anomalies, there is no reason to expect an individual with complete situs transversus to differ from the normal individual in relation to health and disease. Post-mortem examinations, operative reports, study of patients with complete situs transversus afflicted with various diseases or in health, however, have shown the same manner of presentation of the heart so that it is common to find associated with some other congenital anomaly.

fibrillation and flutter, we would not expect that individual to differ from a normally developed individual with auricular fibrillation and flutter. And such is the case.

However, we would expect the electrocardiographic depictions to differ. In dextrocardia the electrocardiographic findings are inversion of P, QRS, and T waves in lead one. When associated with auricular fibrillation and flutter we would expect an inversion in lead one of the fibrillation and flutter, and such is the case. But an examination of the electrocardiogram without the history of dextrocardia would lead us to make another diagnosis as will be shown later.

CASE REPORT

S. B., a female, white and of Roumanian birth, 40 years of age, and married, was first seen April 26, 1931. Her complaints were pain in heart, shortness of breath, and palpitation of heart.

Past history.—The patient denied having had rheumatic fever, chorea, influenza, scarlet fever, diphtheria, pneumonia and pleurisy. She had had occasional lead colic and constipation in winter. An abdominal operation performed in 1918, for the removal of a large ovarian cyst. She had no other known diseases.

Examination.—Found on the examination of the heart, a normal sized heart, with a normal position of the apex, placed at the fifth intercostal space.

every 28 days, of 3 to 5 days duration. Menses have been irregular since the onset of the present illness.

Family history Her father and mother are dead, of causes unknown to the patient. She knows nothing of constitutional diseases in the family.

Marital history Her husband is living and well. They have been married 14 years. One child died at the age of 4 months. The cause of death is unknown to the patient. There were no other pregnancies.

Occupation Housework.

Present illness The patient states that previous to January 1, 1931, she felt perfectly well. At that time she suffered a bad cold and had an abscessed tooth extracted. Since then she has noticed progressively increasing dyspnea, palpitation, and edema of the lower extremities, also associated weakness and dizziness when ambulatory. For two weeks before the time when she was first seen, she noticed a "flopping around" of the heart at times, and experienced occasional sharp pain over the normal cardiac area, to the left of the sternum radiating to the region of the left scapula.

Physical examination, April 26, 1931 The patient was seen lying in bed, obese, flushed, dyspneic in bed, not appearing acutely ill with mitral-type facies, not cyanotic and of cheerful disposition. Her eyes reacted to light and in accommodation. There was a slight injection of the pharynx, the tonsils were present but did not appear diseased.

Lungs Resonance was impaired and breath sounds absent in the lower right chest anteriorly. Normal resonance and breath sounds were found in the cardiac area. Posteriorly the lung fields were clear throughout. There were no râles.

Heart The left border of dulness was located one fingerbreadth to the left of the sternal margin. The right border of dulness was in the right axillary line. The apex impulse was felt in the right fifth intercostal space, almost out to the axillary line. The heart sounds were very distant in the usual cardiac area but were heard very distinctly, also, in their corresponding positions on the right side. The rhythm had a definite irregular irregularity. No definite murmurs were heard. A_2 was greater than P_2 . There was no increase in the retromanubrial dulness.

FIG 1 Electrocardiogram, April 26, 1931. Rate 110. Auricular fibrillation and flutter, Dextrocardia. Myocardial damage. Extra systoles. Inversion P, QRS and T waves in lead I. Slurring and notching of QRS complex.

The blood pressure was 120/60 in both arms

Abdomen There was a lower right parame-dian scar, but no masses, tenderness, or rigidity. The liver dulness was on the left side. The spleen and kidneys were not palpable.

Extremities Pitting edema was present in both ankles and feet.

Laboratory data Blood hemoglobin, 86%, red blood cells, 4,550,000, white blood cells, 7,600, 81% polymorphonuclears, 17% lymphocytes, 2% monocytes. Urine yellow color; acid reaction, specific gravity, 1.015, negative for sugar, negative for acetone.

Progress notes April 29, 1931 Patient has had 26 cc of tincture of digitalis since entering the hospital. She has headaches and feels nauseated. Coupled beats are present.

May 1, 1931 Ringing ears and headache from quinidine. (See table for medication.)

May 4, 1931 Heart slow and fibrillating, but well compensated. The patient wished to go home, and was discharged with tincture of digitalis, twenty minims three times daily. No symptoms of overdigitalization were present.

X-ray reports (Dr. Reynolds) April 28, 1931 Definite dextrocardia with slight enlargement of the cardiac shadow, heart occupying a transverse position. The lung fields are clear.

April 30, 1931 Fluoroscopic study of the chest shows a definite dextrocardia, the apex of the heart being almost in contact with the thoracic wall, indicating definite enlargement of the cardiac shadow. A small quantity of opaque meal was administered, which shows the stomach on the right side and the liver on the left. This is conclusive evidence of a situs transversus.

The patient was seen at intervals after discharge from the hospital, but not as often as advised because of poor cooperation. As soon as she felt comfortable she neglected treatment. She was advised rest in bed, light diet, and tincture of digitalis, fifteen minims three times a day. On September 21, 1931 she stated that she had taken

1. The patient was seen at intervals after discharge from the hospital, but not as often as advised because of poor cooperation. As soon as she felt comfortable she neglected treatment. no medication for two weeks, and complained of return of symptoms as before. She was advised to remain in bed and continue digitalis. She was seen at intervals thereafter. While she was well compensated and went about with comfort, the auricular fibrillation and flutter were still present. In November, 1931, she decided to return to Roumania against advice. Soon after arrival there she was placed in a hospital and expired January 20, 1932.

The electrocardiographic depiction is a combination of auricular fibrillation and flutter, severe myocardial change and dextrocardia. The evidence for complete situs transversus comes from physical examination and is verified by x-ray findings which are conclusive. The electrocardiographic curves could be readily explained by mitral stenosis

with right ventricular preponderance and auricular fibrillation or impure flutter. For this reason the findings are very interesting, for no other instance of this particular combination is known to the author.

SUMMARY

1 This case is reported because of the very interesting combination of dextrocardia with auricular fibrillation and flutter.

2 With this combination a diagnosis based upon electrocardiographic evidence alone would be mitral stenosis with right ventricular preponderance and auricular fibrillation or impure flutter.

3 There is no case report in the literature of this particular combination.

A Medical Poet of the Middle Border, William Savage Pitts, M.D.

By LOUIS H. RODDIS, *Lieutenant Commander, Medical Corps,
United States Navy*

THERE are numerous English and American poets whose works are voluminous and who like Shakespeare, Milton, Byron and Longfellow are as notable for the quantity as for the quality of their verse. On the other hand there are not a few who owe their fame to almost a single song. Such are Gray with the "Elegy Written in a Country Churchyard", Cooke whose "Florence Vane" has been translated into more modern languages than there are verses in the poem, Lady Scott's "Anne Laurie", Foster's "Swanee River", and Payne's "Home, Sweet Home". In these latter the wedding of words and music has given the verses a double charm and to this fact at least some of their popularity is due.

Dr. Pitts was one of these poet-composers whose fame rests upon a single poem united with an air not soon forgotten. His song, "The Church in the Wildwood", has immortalized a little weathered frame church in a tiny Iowa village, has

made it the rival of the Little Church Around The Corner in respect to the number of weddings held there, and leads nearly a hundred thousand people to visit the locality annually. Something about the country doctor who wrote the poem and the circumstance under which it was produced may be of interest.

William Savage Pitts was born at Lums Corners, Orleans County, New York, August 18, 1830. His parents came to Wisconsin when he was a boy. His medical training was obtained at Rush Medical College in Chicago where he received his degree in medicine in 1868. After 1862 he had made his home in Fredericksburg, Iowa, and he returned there to begin the practice of medicine. In a short time his buggy was a familiar sight on the roads of Chickasaw County around Fredericksburg, Nashua, New Hampton, and Bradford. One of his old buggies is still in use on a farm near Fredericksburg. He was a great lover of horses and always had several fine animals. One of his favorites was a bay mare with white markings named "Belle". He drove her for fifteen years "through drench and dust, snow drifts and rain storms". He expected her to

For the first time in his life, Dr. Pitts, who was then a young man, was married. The wedding was held at the little church in the wildwood, and the ceremony was performed by the Rev. Mr. [illegible]. The bride was Miss [illegible], daughter of [illegible]. The groom was Dr. William Savage Pitts, M.D.

mare is just like one of the family" She was then twenty-one years old

Dr Pitts was a typical country doctor of the old school, the friend and counselor of the community as well as a physician, known to the whole countryside, their help in times of accident and sickness, birth and death. The country doctor in farming communities of the middle west in those early days saw many hardships. Called at all hours and in all weathers, to make long drives over the worst of roads, to meet all sorts of medical, surgical and obstetric emergencies with poor facilities and untrained assistants, without professional consultation and encouragement, the old country doctors had to be men with physical, mental, and moral stamina, to meet their tasks and accomplish them with credit. That they usually were such men and that they did perform well the difficult duties of their calling is well known to millions who were their patients. With our refined methods of diagnosis, our laboratories and x-rays, we are apt to disparage their diagnostic methods, but necessity sharpened their powers of observation to such an extent that in the field of physical diagnosis, particularly in inspection and palpation, they were probably vastly superior to our present generation of medical men. Some of their homely therapeutics are also not to be despised. Bread and milk, and flaxseed poultices were not bad dressings for the preincisional stage of cellulitis and the rubbing of the chest with camphorated oil and swathing in flannel gave comfort and encouragement, at least in acute pulmonary conditions. We often overlook the fact in our more scientific

methods that comfort and encouragement are valuable healing agents. Liberalunctions of goose grease made babies of the last century fat and healthy even though nothing was known of fat soluble vitamins. As a matter of fact goose greaseunctions and cod liver oil, both commonly used by the country doctors of the older generation, were going completely out of style until the discovery of vitamins brought them into use again. A hot footbath with a little mustard or a little bran in the water, a hot lemonade with a little whiskey in it, five grains of quinine or Dover's powder, and a nice warm bed are still as good treatment for a severe cold at its onset as any that we ourselves with all our laboratory training have to offer.

If the country doctor had many hardships there were many compensations as well. The position of helper in times of distress and suffering, and of holder of that vast body of confidential information that even the religious confessional does not receive gave him a unique place. He was one of the leading men in the community, probably the most respected and looked up to person in it. He always had the best that the place afforded. His compensation in money might not be munificent but it was ample, and where money was not available and he was paid in kind, the choicest garden truck, potatoes, wood, butter, cheese, bacon, ham, quarters of beef, halves of hogs, poultry, head cheese, country sausage, buckwheat honey, and other similar commodities went to his door. His home was usually the best in town. This was true of Dr Pitts. His large white house is still standing in Fred-

to build a church I will not take time to tell of the trials, the disappointments and the successes that followed, suffice it to say, by the early winter of 1864, the building was ready for dedication

"While I was holding the singing school, near its close in the spring, the class went one evening to the church. It was not then seated, but rude seats were improvised. My manuscript of the song I had brought with me from Wisconsin had never been sung before by anyone but myself. I sang it there. Soon afterwards I took the manuscript to Chicago, where it was published by H. M. Higgins. It won a speedy recognition locally and with years won its way into the hearts of the people of the world. Soon after its publication the church at Bradford which had been painted brown, (for want of money to buy better paint, some say) became known as 'The Little Brown Church in the Vale.' My hope is that it will stand for a thousand years and call the Old Man and his descendants to worship.

"Under the circumstances, what more natural than that the little church at Bradford, Iowa, painted brown, and the song, 'The Lit-

tle Brown Church in the Vale' should be wedded and known as one and the same. Some people may try to rob the little church of its fame, but as long as it stands it will be known as 'The Little Brown Church in the Vale.'"

This is the song as Dr. Pitts wrote it and as he first sang it in the newly erected "Church in the Wildwood"

There's a Church in the valley by the wild-
wood,

No lovelier place in the dale,
No spot is so dear to my childhood,
As the Little Brown Church in the vale

O, come, come, come, come,
Come to the Church in the Wildwood,
Come to the Church in the dale,
No spot is so dear to my childhood,
As the Little Brown Church in the vale

How sweet on a bright Sabbath morning,
To list to the clear ringing bell,
Its tones so sweetly are calling,
O, come to the Church in the vale

There, close by the Church in the valley,
Lies one that I loved so well,
She sleeps, sweetly sleeps, 'neath the willows,
Disturb not her rest in the vale

There close by the side of that loved one,
'Neath the tree where the wild flowers
bloom,
When the farewell hymn shall be chanted,
I shall rest by her side in the tomb

It is thus seen that the writing of the song preceded the building of the church. As Dr. Pitts states, the poem was written in 1857. The church was not begun until 1859, and not completed until 1864. Bradford, the site of the church is now deserted, but in the early 1850's it was a place of some note, was an early Indian trading point, the first county seat of Chickasaw County, and on the stage line west toward Des Moines and Council

FIG 2 The Little Brown Church near Nashua, Iowa

Bluffs There was an Academy which made it a local educational center, a brewery, a tannery, and a cabinet organ factory. The long main street was lined with stores, saloons and offices. The town was located in the valley of the Cedar River, justly celebrated as one of the most beautiful parts of Iowa. In 1859 a young Congregational minister, the Reverend J. K. Nutting, began the project of building a church on the spot near the edge of town which had attracted the attention of Dr. Pitts as a "setting of rare beauty" and which was still covered with oaks and evergreens. A "bee" was organized to quarry rock for the foundation. The breaking out of the Civil War prevented for a time the completion of the church. Finally another "bee" cut native timber furnished free by a member. The dimension lumber and sheeting were taken from fifty foot red oaks growing near the site. A local sawmill sawed the logs without charge and a volunteer force of carpenters erected the building. There was no money for the importing lumber and the pastor wrote to a friend in the east who was a pastor of a wealthier church. This was the Reverend John Todd of Pittsfield, Massachusetts. A check for \$140 from the children of the Sunday School was received and the eastern pastor closed the arrangement for a loan of \$300. The loan was not paid off until 1926, when the church had not for fifty-two years. The money was further for the construction of the building by wagon team from Bluffs. The building is the only one of its kind in the state.

ham Lincoln hanging on the north wall reminds us of the fact that the event occurred during the administration of the Civil War President. The church bell, "the clear ringing bell" of the poem, was cast in the famous Meneely bell foundry, at Troy, New York. It was hauled by team from Dubuque, hung in a frame on the wagon so that it rang almost continuously on its way to Bradford. It was the first church bell in Chickasaw County. Its coming was an event of no small importance to the settlers and they were very proud of this great acquisition to the community.

After its publication the song became known in wider and wider circles. Its inclusion in a Moody and Sankey hymn book spread its fame around the world. In England, Scotland and Wales, and in the British Colonies, in far away Australia and New Zealand, South Africa and the "Isles of the Sea", it began to be sung and loved. Translation into almost all modern languages followed. It is said to be especially popular in Germany and Scandinavia. Then people began to visit the original of the Brown Church. Times had changed since the church was built and the town of Bradford had practically ceased to exist. In 1867, when the Illinois Central Railroad was built down the valley of the Cedar River, it neared Bradford and passed through Natchez a few miles away. Most of the population moved to Natchez, and now Natchez became the center of the old town and never more a farther one. The people of the town of Bradford, however, still remember the town of the old town. It is a small town of about 100 people.

stands, is deserted and falling to pieces

But if the town declined, the church did not, and as its fame grew, more and more people began to visit it and to come there to be married. Finally in 1900 a Society for the Preservation of the Little Brown Church was organized. A pastor was assigned from the Congregational Church of Nashua and for a number of years has held both charges. Now the church in the abandoned town has become the more important of the two, with thousands of visitors and a reputation as a matrimonial Mecca. Today each new bride married in the Church in the Wildwood has the privilege of ringing the famous old bell and that it is heard pretty frequently is shown by the fact that in 1929 six hundred and forty-three couples were married there. Three hundred and twenty-one couples were married there during the first six months of 1930. On January 16, 1926, thirteen couples pronounced their marriage vows before the altar. In front of the pulpit is a little square of green carpet. This has many times been worn out and replaced. The old Bible on the altar, however, is still unchanged. An inscription on the flyleaf shows that it was presented to the church by Mrs. Mary Vinton in 1864.

The present pastor, the Reverend William Kent, has learned the marriage ceremony by heart through frequent repetition and well deserves the title of "The marrying Parson of the Middle West." Every state in the Union and many foreign countries are represented by the long chain of brides and grooms. Iowa, Minnesota, Wisconsin, the Dakotas, Nebraska, Kan-

sas, and Montana furnish the greater number. Naturally enough Iowa leads the list and the largest number are always from the state "where the tall corn grows." Brides of the Middle West seem to take special pleasure in placing "Little Brown Church in the Vale" on their wedding announcements.

A register book is kept for visitors. More than thirty thousand have registered in a year and it is estimated that nearly as many visit the church without registering. It is believed that as many as one hundred thousand people make a pilgrimage to the spot annually.

The old bracket lamps in the church and the pews are as when first installed. On the reed organ a hymn book is always open at the "Little Brown Church in the Vale", and the singing of this song is a feature of every service. On the wall is a framed copy of the verses. The bell still calls the congregation to worship, and lovers to the holy bonds of matrimony. On Sundays during the summer months the little church is too small to hold the crowds that gather under the oaks and pines that embower it and make it still "the Church in the Wildwood."

In 1916 there was held a special reunion at the church at which Dr. Pitts, then aged 87, and the Reverend J. K. Nutting, aged 84, were present so that the writer of the song and the builder of the church were brought together again after a lapse of nearly sixty years. A picture of them was taken standing side by side in the doorway of the church. Each delivered a short address and Dr. Pitts sang the

song he had written fifty-nine years before

Dr. Pitts died in a hospital in New York City, September 25, 1918

In his later years he had made his home with a son, William Stanley Pitts in New York His death which was due largely to the infirmities of age followed a brief acute illness He is buried in the beautiful Rose Hill Cemetery in Fredericksburg, Iowa, where a small stone marks his grave

The following is a list of his poems None except the Church in the Wildwood had other than local fame and a number were never published and exist only in manuscript

"Little Fred"

"The Church in the Wildwood" or
"The Little Brown Church in the
Valley"

"Sabbath Bells"

"Nellie Wildwood"

"The Old Musician and his Harp"

Some others not now known

One cannot but ask what there is about this simple poem to enable a country doctor to immortalize and make world famous a little church in an obscure deserted town To answer that question one has but to listen to it sung by a pleasing voice or to read it over to feel that it possesses that magic yet indescribable charm which makes certain lyrics linger in the memory and in the heart when

more pretentious poetry by greater poets is forgotten. The simple yet charming imagery of the "Valley in the Wildwood" and the appeal to the feelings common to all human nature such as the longing for immortality and the desire even in death to remain united with those loved in life are other reasons for its universal appeal Though his fame rests on a single song we may well add William Savage Pitts to the long and distinguished roll of medical poets.

BIBLIOGRAPHICAL NOTE

The Reverend Wm Kent, the present pastor of the First Congregational Church at Nashua, furnished much information in regard to the life of Dr Pitts and a number of pamphlets about the church and the poem A good feature article on the subject appeared in the *Minneapolis Tribune* of October 3, 1926 Lieutenant H R Hubbard, Supply Corps, United States Navy, who spent his boyhood in Fredericksburg told me Dr Pitts and his family, supplied many facts Mrs Ida Stiles of St Paul, who as a girl lived in Chickasaw County remembered Dr Pitts as their family physician When a young woman she sang in the choir of the Little Brown Church and she has contributed information of interest Dr Pitt's daughter Mrs Alex M Tuttle of Riverbank, California, has read the article in manuscript and made a number of comments and corrections Two other of Dr Pitt's children are here Mr Kate P Noble of Denver, Colorado and William Stanley Pitt of New York City

Editorials

PROGRAM OF THE SEVENTEENTH ANNUAL CLINICAL SESSION OF THE AMERICAN COLLEGE OF PHYSICIANS

Although the program of the Annual Clinical Session, which is to be held in Montreal, February 6 to 10, has been sent through the mails to all Fellows and Associates of the College, it is printed in the present issue for the added convenience of members and non-members alike. Those expecting to attend will find it very much to their advantage to study this program in advance. Attention is invited to the significant groupings of the subjects in the General Sessions, and particularly to the emphasis which is placed upon the intrinsic constitution as a factor in

determining disease. Those registering should plot their course in advance in respect to the Special Clinics and Demonstrations, some twenty-five of which are simultaneously available each morning. The necessity for early registration of choice and the wisdom of requiring clinic tickets will be apparent to all. It is to be hoped that many will avail themselves of the opportunity to visit the Library of the Medical School of McGill University, the Osler Library, and the Medical Museums at the McGill Medical Building and the Pathological Institute.

MAURICE CHARLES PINCOFFS, EDITOR OF THE ANNALS OF INTERNAL MEDICINE

It is with mingled feelings of regret and pleasure that the present editor of the *ANNALS* records the fact that his official duties end with the present number. There is regret like that at parting with a very close friend, or, as a better figure, with a member of one's own body, for it is impossible to edit, single handed, such a journal as the *ANNALS* without its becoming in a very real sense identified with one's self. There is regret at the loss of that stimulus, based on the ever-recurring necessity of surveying a long list of original papers and of periodi-

cals and books each month. And especially is there regret that the sequence of old and new contacts made each year with hundreds of authors and investigators, scattered over the continent is to be broken. Of the cooperation, forbearance, courtesy, and friendship of his authors, the editor is fully appreciative. With all of this, however, there is a sense of satisfaction in being able to announce that by the unanimous choice of the Regents of the American College of Physicians, Maurice C. Pincoffs, Professor of Medicine and Head of the

Department of Medicine, University of Maryland, Baltimore, Maryland, is assuming the editorship of the ANNALS For three months there has been a gradual shifting of the editorial duties from the old office to the new so that there will be no interruption in the sequence of issues

Doctor Pincoffs was born in Chicago in 1886, and received his elementary education in private schools in that city and in Antwerp At the University of Chicago he earned the degree of Bachelor of Science and there he completed the first two years of the medical course, during which he was awarded the Brainard prize in Anatomy. He assisted in Anatomy for one year and took special courses in Pathology under Professor Gideon Wells The medical degree he obtained from Johns Hopkins Medical School in 1912. Dr. Pincoffs was unusually fortunate in respect to the men with whom he was closely associated in his early years in Medicine As interne, resident, associate, and voluntary assistant, respectively, he worked with Doctors James B. Herrick, Thomas R. Baggs, Lewellys F. Barker, and John J. Abel From 1917 to 1919 he was in military service with the British Expeditionary Force, the American Expeditionary Force, and the American Expeditionary Force, receiving the Distinguished Service Cross and the Croix de Guerre with palm and two stars He served at Johns Hopkins Medical School as Instructor in Medicine from 1919 to 1922, assuming the full professorship in Medicine in the University of Maryland in 1922 He is also Physician-in-Chief of the University Hospital and of Mercy Hospital Elected as a Fellow in 1923, Dr Pincoffs has served the American College of Physicians as Governor Regent and First Vice President In addition to numerous articles in medical journals and transactions, he is the author of the section on Diseases of the Peritoneum in the Oxford System of Medicine, on Visceroptosis in Tice's System, and on Diseases Due to Chemical Agents in Musser's Internal Medicine Thus Doctor Pincoffs, through training and experience in clinical medicine and medical education, is peculiarly fitted for the position for which he has been chosen The ANNALS OF INTERNAL MEDICINE and the American College of Physicians are to be congratulated upon his selection and acceptance, which forecast continued success and added prestige for the official journal May we bespeak for him the same loyal support which has been given his predecessor!

Abstracts

tennis, fewer formed elements and less albumin are found than after long distance cross-country running and hockey. Even after short periods of time in the lordotic posture, the excretion of blood cells is noted. In all of these tests white blood cells were found more frequently than red blood cells, and the latter more often than casts. Any condition which tends to concentrate the urine and increase its acidity may be responsible for an increase of formed elements. The medical practitioner should be on his guard not to attribute the presence of these formed elements, in the urine of normal persons, to pathological conditions.

The Hematopoietic Response in Pernicious Anemia Following the Intramuscular Injection of Gastric Juice By ROGER S. MORRIS, M.D., LEON SCHIFF, M.D., GEORGE BURGER, M.D., and JAMES E. SHERMAN, M.D. (Am Jr Med Sc, 1932, clxxxiv, 778-782)

The results of previous researches have seemed to indicate that the normal stomach secretes a substance (probably the same as that which Castle has shown to be present) which, while without effect on the reticulocytes when administered orally, might cause a response if it could be administered parenterally. This assumption has been tested by the intramuscular injection of neutralized sterile gastric juice and also of a concentrate of normal human gastric juice obtained by evaporation *in vacuo*. The results prove the presence in normal gastric juice of a powerful bone marrow stimulant, producing not only a marked and very rapid reticulocyte increase after intramuscular injection but also a rapid maturation of the red cells. For this anti-anemic substance, which is probably a hormone, the name *addisim* is proposed. This active principle, lack of which in the gastric juice would seem to be the cause of pernicious anemia, is found in the supernatant fluid, but not in the precipitate, which forms in the process of concentrating gastric juice. It is thermolabile, dialyzable, and exhaustible. Acetone extracted gastric juice of swine has been found to give less marked local and general reactions than the preparations first used.

Diathermy in the Treatment of General Paralysis and in Wassermann-Fast Syphilis By JAY FRANK SCHAMBERG, M.D., and THOMAS BUTTERWORTH, M.D. (Am Jr Syph, 1932, xvi, 519-534)

Under malarial therapy for paresis, about one-third of the patients go into a good remission, one-third into a partial remission, and one-third show no improvement. The average mortality with malarial therapy is about eight per cent. The authors have treated 26 cases of refractory syphilis by means of fever produced by diathermy. Of nine paretics who completed the treatment, six, or 66 per cent, improved, three returned to their former occupation. The single case of taboparesis treated showed marked improvement as did also the one case of cerebrospinal syphilis. Of the three cases of tabes dorsalis, one was relieved of his pains entirely and improved physically, a second patient improved physically, his pains decreased, but there was no improvement in his ataxia, the third became progressively worse. The two cases of interstitial keratitis showed considerable improvement, but in both, diathermy was augmented by mercurialunctions and bismuth intramuscularly. Seven patients with Wassermann-fast syphilis showed no change in their serologic findings after treatment, although only one to seven months had elapsed since their discharge from the hospital.

Liver Function in Hyperthyroidism By S. S. LIGHTMAN, M.D. (Arch Int Med, 1932 1, 720-729)

Clinical evidence of disturbance of the liver in hyperthyroidism is afforded by occasional cases of icterus in association with thyrotoxicosis for which no other cause can be discovered. Hepatic changes, even a fully developed interlobular cirrhosis, have been discovered in some cases of hyperthyroidism. Thyroid substance, or thyroxin, causes the glycogen to disappear from the liver. The author investigated the liver function in a series of twenty consecutive cases of hyperthyroidism making use, among other methods, of an original cinchophen oxidation test. A disturbance in the oxidation of cinchophen was demonstrated in 16 of the 20 cases, the

results indicating moderate rather than severe impairment of the capacity of the liver to oxidize this substance. No apparent relationship between the degree of functional impairment of the liver and the basal metabolic rate, the known duration of the disease, or the percentage of weight lost was found. In individual cases, however, there appeared to be a tendency for the function of the liver cells to improve as the basal metabolic rate returned to normal. The galactose tolerance test gave no indication of a disturbance of hepatic function. There was little evidence of appreciable disturbance of the excretory functions of the liver as determined by studies on the icterus index, bilirubinemia, urobilinuria and urobilinogenuria.

Effect of Dietary Calcium and Phosphorus on Toxicity of Lead in the Rat. Rationale of Phosphate Therapy. By DAVID H. SHIMMEL, (Proc Soc Exp Biol and Med, 1932, xxx, 248-254)

The rationale of the use of calcium compounds in the treatment of lead poisoning depended upon the following facts. First, the solubility of lead phosphate was found to be analogous to that of calcium phosphate, hence it was believed that lead might be deposited in bones in the same manner that bone salts are. Second it was believed that the deposition of lead in the bones could be reversed by furthering the process of calcification through the administration of calcium. Third the groups toleration of lead coincided with the amount of administration of calcium. Hence it was thought to add additional evidence that calcium indeed had a beneficial effect. It was also thought that this could be proved by reference to the amount of lead deposited in the bones. As the amount of calcium administered increased the amount of lead deposited in the bones decreased.

and phosphorus in the dietary make it seem obvious that the addition of calcium to lead diets which contain an inadequate amount of phosphorus does not lead to improved deposition of either calcium or lead phosphate in the bones, but, on the contrary inhibits such a process. If the aim of therapy in lead poisoning is to deposit lead, or to excrete it in an insoluble, and hence innocuous, form, an abundance of phosphorus or of foods containing phosphorus should be supplied. The correctness of this assumption was tested experimentally in rats. Eight groups of animals were fed 15 gm per cent of $2PbCO_3 \cdot Pb(OH)_2$ with and without the addition of either $CaCO_3$, Na_2HPO_4 , or $MgCO_3 \cdot Mg(OH)_2$. Four of the groups received the respective diets with, and four without, the addition of viosterol. In the group not receiving vitamin D, weight and longevity were most adversely affected in the sub-group receiving lead and magnesium compounds, with decreasing effects, in order, in those receiving calcium and lead compound, lead compound alone, and lead and phosphate. In fact, those receiving Na_2HPO_4 with lead gained weight steadily and appeared normal. With the exception of those in the Na_2HPO_4 group, which lived and did well, all of the animals receiving vitamin D died sooner than the corresponding controls not receiving the vitamin. It may be that vitamin D diverted calcium phosphate into the bones and allowed lead to be combined with phosphate, to circulate freely, whereas in the Na_2HPO_4 group the phosphate was adequate for deposition and excretion of both calcium and lead as phosphate. It would seem therefore that phosphorus is a control for the deposition of lead and that subsequent detoxication can be accomplished by depositing lead in a relatively harmless phosphate form.

Reviews

Internal Medicine, Its Theory and Practice

Edited by JOHN H. MUSSER, B.S., M.D., F.A.C.P. 1316 pages, illustrated. Lea & Febiger, Washington Square, Philadelphia, 1932. Price, \$10.00, net.

The appearance of a new single-volume text book of medicine is always an event of importance in the field of medical publication. The text book of medicine is the corner stone in the building of a medical student's clinical library. It is probably more frequently referred to by the general practitioner than any other book. The consultant will read it to see what progress he may have overlooked in subjects that are not included in his special interests. There is no medical book which, if successful, will be more widely read than such a text book and none which may exert a greater influence in its generation on the level of medical practice.

The text books of recent years tend to be national in character rather than personal. Osler's text book was Osler and the experience of Osler's clinic. Cecil's text book is a summary of American medicine as Prie's is of British medicine. In this new volume Musser has brought together what might be called the medicine of American Medical Schools. The authors, including the editor, are all active teachers of medicine of professorial rank in the leading medical schools of the country. The restriction of the number of contributors to twenty-seven has allowed each one to cover completely a relatively large and relatively autonomous section of internal medicine. The reviewer feels that these sections have thereby gained something of a personal quality and a certain sense of perspective not otherwise attainable. This is, of course, particularly true of such sections as those on mental diseases and on gastro-intestinal diseases in both of which a perspective and an individual point of view are especially

desirable. Most of the authors have introduced their subject by a general discussion in which they have summarized the common features of the group of diseases to be described—their etiological factors, their pathologic physiology and, in some instances, their relative social importance. These introductions add greatly to the value of the volume. Many are models of concise clear statement of essential known facts. In future editions similar introductions might well be added to those chapters in which they are lacking.

The book is divided into four parts. Part I deals with the infectious diseases. The diseases of bacillary, coccal, virus, rickettsial, spirochetal, protozoal, metazoal and unknown etiology are dealt with in separate chapters. This is a logical arrangement. It also seems wise to have made an exception to this order in grouping in one chapter the contagious diseases of childhood. It is less easily understood why the subject of tuberculosis should be omitted from this part of the book and dealt with only under the heading of pulmonary tuberculosis. There are few criticisms to be made of these excellent chapters on the infectious diseases. The treatment of the important subject of lobar pneumonia seems too summary. In discussing the pneumococcus types only the first three and group IV are mentioned. No statement is made of possible harmful effects from digitalis. The use of concentrated sera is dismissed with the statement that Cole has said that whole horse serum is superior.

Part II covers the systemic diseases. The chapter on diseases of the heart and pericardium is clear, well proportioned, and conservative. The etiological types of heart disease are well presented, and the various valve lesions and arrhythmias are separately discussed. An equal level of excellence is maintained in most of the other chapters.

The presentation of the diseases of the endocrine glands is especially concise and informative. In the otherwise admirable chapter on the respiratory diseases the brief and inadequate account of empyema seems regrettable. Certain of the blood diseases also receive scant consideration. A surprising clinical picture of agranulocytosis is presented, certainly not that most commonly seen.

Part III is devoted to diseases of nutrition, allergy, metabolism, physical and chemical agents. These chapters are clear summaries of the more important aspects of the disease processes concerned. It is perhaps unavoidable that most of the space is given to description of the chemical, physical, metabolic and immunological backgrounds, and that the clinical descriptions are correspondingly brief.

Part IV is on diseases of the nervous system. These are dealt with in two chapters. The first on mental disorders covers this field somewhat more thoroughly than is usual in text books of medicine. The psychoses are divided into those associated with organic disease, those of toxic origin, and the functional psychoses. The limited space devoted to the chapter on the organic diseases of the nervous system has resulted in a very brief discussion of many of them. The pages given to anatomy and methods of examination could be utilized to better advantage in amplifying the clinical descriptions. It is customary to include a brief discussion of anatomy and methods of examination in a chapter on neurological diseases, but in reality it is no more appropriate than it would be to insert a general discussion of physical diagnosis or of clinical pathology in the other sections of the book. The chapters on a discussion of local anatomy and the regional given subarachnoid space are excellent features.

At the end of the book may be offered a few criticisms. The book is too large for a text book of medicine, and the price is too high for a text book of medicine. The book is too large for a text book of medicine, and the price is too high for a text book of medicine. The book is too large for a text book of medicine, and the price is too high for a text book of medicine.

Accidents, Neuroses and Compensation By JAMES H. HUBBLESON, M.D., Associate in Neurology, Columbia University, and Attending Neurologist, Neurological Institute, New York, with a Foreword by J. RAMSAY HUNT, M.D., Sc.D., Professor of Neurology, Columbia University, ix + 256 pages. Williams and Wilkins Co. Baltimore, 1932. \$4.00.

The passing of each year is accompanied by a startling increase in the legal and medical perplexities revolving about essentially psychogenic disorders resulting from or associated with physical injuries. With the steady growth of various and conflicting types of industrial compensation laws, these problems have established themselves among the most difficult ones with which the medical profession must contend. They represent a boundary zone in which honesty and knavery are most intimately mingled and keen indeed must be the physician's analysis if he is to insure justice for patient and employer. The author approaches his problem fortified by a broad background of experience replete with illustrative material. From his contact with that richest of all sources of traumatic neuroses, the World War, he is able to contribute substantially to the understanding and rationalization of many forms of neurosis. The book follows the usual form of special disease presentation; etiology, symptomatology, diagnosis, pathology, therapeutics and prophylaxis are discussed in a systematic manner. The treatment of the subject is in some respects encyclopedic, the various theories and conceptions concerning each important point being presented in a condensed manner with complete reference to the literature. Even the purely diagnostic is amplified so that the reader can select at once the book in this part of the field. To the casual reader, this method of presentation is somewhat tedious and it is to be regretted that these chapters are so long. A more concise presentation of the material would have been desirable. A few of the chapters are somewhat out of place. The chapter on "The Legal Aspect of Neuroses" is a good one, but it is out of place in a book on neuroses. The chapter on "The Social Aspect of Neuroses" is also a good one, but it is out of place in a book on neuroses. The chapter on "The Psychological Aspect of Neuroses" is also a good one, but it is out of place in a book on neuroses.

development may be the more clearly and completely apprehended

Throughout the work, the legal aspects of this medical problem are emphasized and especial stress is given the relationship between the duration and character of compensation and the severity of the disease. The direct relationship between the duration of the neurosis and the time span and expectancy of compensation forms a medico-legal association which would well justify the presentation of this volume to every judge, lawyer or commission dealing extensively with workmen's compensation and industrial insurance. Forty pages are devoted to bibliography, which with the index, constitutes nearly one-sixth of the book. This high proportion is almost necessitated by the nature of the material presented, for without these divisions, in their complete form, much of its usefulness as a reference work would be lost.

Treatment of Syphilis By JAY F SCHAMBERG, A B, M D, Professor of Dermatology and Syphilology in the Graduate School of Medicine of the University of Pennsylvania, former President of the American Dermatological Association, etc. and CARROLL S WRIGHT, B Sc, M D, Professor of Dermatology and Syphilology in the Temple University School of Medicine, Associate Professor of Dermatology and Syphilology in the Graduate School of Medicine of the University of Pennsylvania, former President of the Philadelphia Dermatological Society, etc. xxiv + 658 pages, 62 illustrations. D Appleton and Company, New York and London, 1932. Price, \$8.00.

To those who appreciate the complexity of the problems arising in the management of syphilis and at the same time are aware of the incidence of this disease, a book of generous size on the *treatment* of syphilis need occasion no surprise. It is believed with good reason that the 200,000 cases of syphilis which are reported annually to Public Health authorities in this country represent not more than one-fifth or one-fourth of those actually under medical care each year. In addition there are the other

tens, and probably hundreds, of thousands who remain undiagnosed, or if diagnosed, are not receiving treatment. There is no practitioner nor specialist into the field of whose endeavors syphilis does not obtrude. The authors of this book believe that 15 to 20 per cent of chronic invalids in the wards of general hospitals are there because of the chronic effects of syphilis upon the internal organs. A comprehensive survey of present knowledge and experience in the management of this disease is to be welcomed. While the authoritative position of the authors in their special field would entitle them to *ex cathedra* utterance, they have given full recognition to the opinions of others. Thus an analytical survey of the entire field is presented. The clinical illustrations are well chosen but not always as well reproduced as they deserve. Little need be added as to scope of the contents of this book. It is in every respect adequate. Full discussion of "cured" syphilis and of the ever-recurring question of syphilis and marriage is provided. It is a pleasure to recommend this thoroughly scholarly book to all interested.

A Descriptive Atlas of Radiographs An Aid to Modern Clinical Methods By A B BERRWISTLE, M D, Ch B, F R C S. Ed. Second edition, revised and enlarged. xxviii + 552 pages, 767 illustrations. C V Mosby Company, St Louis, 1932. Price, \$13.50.

There are many text-books and monographs for those who are specializing in Radiology, but few which are sufficiently fundamental and yet broad enough in scope to serve the needs of those who are engaged in general or special practice but who are not themselves radiologists. For such the need of sufficient knowledge to be able to understand the interpretations of others and, on occasion, to form worthwhile judgments of their own, is obvious. An extended chronology of the outstanding achievements in radio-diagnosis serves as an historical introduction. The illustrative plates, with short clinical and descriptive notes make up almost the entire volume. Plates of normal structures are placed on left hand pages and those of pathological

The presentation of the diseases of the endocrine glands is especially concise and informative. In the otherwise admirable chapter on the respiratory diseases the brief and inadequate account of empyema seems regrettable. Certain of the blood diseases also receive scant consideration. It is customary to include a brief discussion of anatomy and methods of examination in a chapter on neurological disease, but in reality it is no more appropriate than it would be to insert a general discussion of physical diagnosis or of clinical pathology in the other sections of the book. The inclusion of a discussion of head injuries and the emphasis given subarachnoid hemorrhage seem excellent features.

Minor criticisms which may be offered do not affect the estimate of the book as a whole. It is a valuable presentation of the present status of our knowledge of internal medicine. It is unusually readable and stimulating. The reviewer feels that it can be highly recommended to students, to teachers, and to practitioners of medicine.

Full discussion of "cured" syphilis and of the ever-recurring question of syphilis and marriage is provided. It is a pleasure to recommend this thoroughly scholarly book to all interested.

A Descriptive Atlas of Radiographs An Aid to Modern Clinical Methods By A B BERTWISTLE, M D, Ch B, F R C S Ed Second edition, revised and enlarged xxviii + 552 pages, 767 illustrations C V Mosby Company, St Louis, 1932 Price, \$13 50

There are many text-books and monographs for those who are specializing in Radiology, but few which are sufficiently fundamental and yet broad enough in scope to serve the needs of those who are engaged in general or special practice but who are not themselves radiologists. For such the need of sufficient knowledge to be able to understand the interpretations of others and, on occasion, to form worthwhile judgments of their own, is obvious. An extended chronology of the outstanding achievements in radio-diagnosis serves as an historical introduction. The illustrative plates, with short clinical and descriptive notes make up almost the entire volume. Plates of normal structures are placed on left hand pages and those of pathological

conditions on right hand pages only. Thus confusion is avoided and comparison facilitated. The first 57 figures are of normal skeletal structures, and include an exposition of silhouette radiographs, combining the advantages of demarcation of the soft parts with adequate detail in the bone. Congenital abnormalities are represented by 15 figures, fractures, by 99, inflammatory disease of bone, by 79, neoplasms of bone, by 27, injuries and diseases of joints, by 61, the nasal and dental regions with related structures, by 45, the alimentary system, by 171, the urinary system, by 51, the respiratory system, by 72, the nervous system, by 50, the vascular system, by 12, the thyroid system, by 8, the female generative system, by 8, and the muscles, by 11. Much of interest and value to the medical man who is not a "radiologist" can be found in this book.

Fungous-Diseases. A Clinico-Mycological Text. By HARRY P. JACOBSON, M.D., Attending Dermatologist and Member of the Malignancy Board, Los Angeles County General Hospital. With Introductions by JAY FRANK SCHAMBERG, M.D., Professor of Dermatology and Syphilology, Graduate School of Medicine, University of Pennsylvania, and HOWARD MORROW, M.D., Clinical Professor of Dermatology, University of California Medical School. xiv + 317 pages, 153 illustrations. Charles C. Thomas, Springfield, Illinois, and Baltimore, Maryland. 1932. Price, \$5.50, postpaid.

Clinical mycology is presented by Jacobson with emphasis on the clinical aspect. Thus the major divisions of his book are based upon the character of the disease process, rather than upon a botanical classification. Division A is for the "primary cutaneous mycoses with (usually) no definite systemic involvement." This includes the ringworms and related condition. Division B includes the "primary cutaneous and or mucous membrane infections with frequent systemic involvement." Under this heading are found moniliasis, maduromycosis, sporotrichosis, blastomycosis, actinomycosis, and coccidioidal granuloma. The third division, C, for torulosis and asper-

gillosis, is characterized as "primary systemic infections with occasional instances of skin or mucous membrane involvement." The author writes from an extensive and rich experience. The subjects treated do not include all of the mycotic diseases of man of this country, but, as is evident from the foregoing lists, all of the important ones and some of the less common are presented. The clinical and bacteriological illustrations are good, those of histopathologic features are not particularly informative. This is sure to prove an extremely useful book to both practitioners and laboratory workers, for it brings together a large material much of which was hitherto available only in original sources.

A Guide to Human Parasitology for Medical Practitioners. By D. B. BLACKLOCK, M.D. (Edin.), D.P.H. (London), D.T.M. (Liverpool), Professor of Parasitology, Liverpool School of Tropical Medicine, the University of Liverpool, formerly Director of the Sir Alfred Lewis Jones Laboratory, Freetown, Sierra Leone, West Africa, and T. SOUTHWELL, D.Sc., Ph.D., A.R.C. Sc., F.Z.S., F.R.S.E., Lecturer in Helminthology, School of Tropical Medicine, Liverpool, formerly Director of Fisheries to the Government of Bengal, and Bihar and Orissa, Scientific Advisor and Inspector of Pearl Banks to the Ceylon Company of Pearl Fisheries, and Honorary Assistant, Zoological Survey of India. viii + 271 pages, 2 colored plates and 122 illustrations. William Wood and Company, New York, 1932. Price, \$4.00.

A Guide to Human Parasitology is intended as a guide for a medical practitioner who has had no experience in the subject and the studies are made with such simple equipment as anyone practicing medicine could have at hand. Sources of material for practice are suggested and the importance of good preparations is stressed in these words, "the making of good blood or feces films is half the battle." The microscope and its use is explained in considerable detail, a point which scarcely seems necessary to the average present day medically trained person. Inspection of the table of contents at once reveals that the authors have arbi-

trarily limited the scope of their subject to the spirochetes and the animal parasites of man. This should be shown in the title as its present form is highly misleading. Are the pathogenic bacteria any less "parasitic" than the protozoa? More than half of the book is devoted to parasitic worms. Numerous charts and figures illustrate the diagnostic characters of the worms and their pathogenicity to man. The discussion of human trichinosis is inadequate for the needs of practitioners in this country. There is no mention of the cardiac complications, of the finding of larvae in the cerebrospinal fluid, or of the value of biopsy of muscle in doubtful cases. Clever "pictographs" are used to make clear the complete life-history of the infecting organism. To the student these graphic presentations must prove of very great value. A few pages on myiasis follow. Near the end of the book is included an outline of treatment with a table of dosage for the diseases mentioned previously, and also a list of apparatus and chemicals needed in the study of parasites. This Guide is worth reading and will be useful to anyone particularly interested in parasitic worms. The charts and illustrations, particularly the "pictographs," add much to this book. Whether treatment should be taken up in such a brief manner is a question.

R. C. W.

A Handbook of Experimental Pathology. By GEORGE WAGONER, M.D., Associate in Pathology, and R. PHILIP CUSTER, M.D., Associate in Research Medicine, The School of Medicine, University of Pennsylvania. Foreword by Professor EDWARD BELL KRUMBHAR. Illustrations by ERWIN F. FABER. xv+160 pages, 22 illustrations. Charles C. Thomas, Springfield, Illinois, 1932. Price, \$4.00 postpaid.

A handbook dealing with the materials and methods of experimental pathology is timely for its aids in steering a course between utter neglect of this important aid to the study of the nature of disease on the one hand and ill-advised experimentation on the other. Throughout, care is taken to give methods which cannot be subject to deserved criticism as inhumane. After a very

useful section on the housing and management of animals, technical methods are described in a general way and tables of normal blood findings in laboratory animals are provided. More than one hundred experiments in general and special pathology are described with stimulating questions and selected references for most of them. The illustrations of apparatus serve their purpose, but those showing the microscopical appearances of tissues are unsatisfactory. This book, the outgrowth of five years' experience, will prove a useful guide to teachers and students seeking to develop a dynamic conception of the processes of disease in the living body.

Diseases of the Thyroid Gland with Special Reference to Thyrotoxicosis. By CECIL A. JOLL, M.S., B.Sc. (Lond), F.R.C.S. (Eng.); Senior Surgeon to the Royal Free Hospital and the Miller General Hospital; Surgeon to the Cancer Hospital; Consulting Surgeon to the Royal Buckinghamshire Hospital; Late Hunterian Professor, Royal College of Surgeons. xviii+682 pages, 284 text figures, 24 colored plates. C. V. Mosby Company, St. Louis, Missouri, 1932. Price \$20.00.

One wonders, in advance of examination of the book, at the temerity of the American distributors of this very expensive English text on diseases of the thyroid. Have we not felt that we have kept a little ahead of our colleagues in Great Britain in this very field of investigation? Close scrutiny of the book itself explains the venture. Although we may differ with the author on various questions, and particularly regret that he has not given fuller consideration to the constitutional pathology of Graves' disease, we recognize in Joll's treatise an orderly and well digested compilation of a huge material. Lack of recognition of the probable significance of lymphoid tissue in the thyroid is revealed by a glance at figure 12 which is labeled "normal thyroid gland" although it shows a "lymphorrhage". The acceptance of the conception of lymphadenoid goiter has similar significance. Critical analysis of the many chapters is impossible here. The numerous illustrations and particularly the fine

colored plates explain the relatively high cost of this volume. As an important reference book this monograph should be in every medical library and at the disposal of all who are especially concerned with diseases of the thyroid gland.

Oral Spirochetes and Related Organisms in Fusio-Spirochetal Disease. By DAVID T. SMITH, A.B., M.D., Associate Professor of Medicine, Duke University, School of Medicine, Durham, N. C.; formerly Bacteriologist and Pathologist to the New York State Hospital for Incipient Tuberculosis, Ray Brook, N. Y. xii+243 pages; 53 illustrations. The Williams and Wilkins Company, Baltimore, 1932. Price, \$4.50.

"There is no evidence either clinical or experimental that the oral spirochetes alone can produce disease in man. But they are probably the most important member in a symbiotic group of anaërobic organisms which is capable of initiating a severe and often fatal disease. The first five chapters of this book deal with the biological characteristics of the mouth organisms. These are followed by presentation of the clinical aspects of the morbid states with which the fusio-spirochetal complex is associated. These are grouped by regions. While reference to the association of these conditions, and particularly the anginal group, with various pathological states of the blood is made, it would seem to be timely to give more emphasis and attention to the problem of granulocytopenia. Numerous historical references add interest; treatment is adequately considered, and a bibliography of 822 items (but without titles) brings this excellent monograph to a close. It is an important and useful text for clinicians, pathologists and laboratory workers.

An Introduction to Dermatology. By RICHARD L. SUTTON, M.D., Sc.D., LL.D., F.R.S. (Edin.), Professor of Diseases of the Skin, University of Kansas School of Medicine; and RICHARD L. SUTTON, Jr., A.M., M.D., Visiting Dermatologist to the Kansas City General Hospital. xvi+565 pages, 183 illustrations. The C. V. Mosby Company, St. Louis, 1932. Price \$5.00.

This abridged text in dermatology is based on the eighth edition of *Diseases of the Skin* by the senior author. It is intended primarily for the student, and gives him the essential material requisite for his knowledge without that huge mass of information found in the larger texts, much of which is useful only to the specialist. The abridgement has been accomplished, not by the omission of diseases, but by reducing the general descriptions, the discussions, and statistical material. The illustrations are very well selected for their value in differential diagnosis, and are well reproduced. The book has a certain freshness of style and directness of approach which commend it most strongly. It should prove of great value to the practitioner as well as to the medical student.

Diabetes in Childhood and Adolescence. By PRISCILLA WHITE, M.D., F.A.C.P., Physician at the New England Deaconess Hospital, Boston, Massachusetts. With a Foreword by ELLIOTT P. JOSLIN, M.D., F.A.C.P., Clinical Professor of Medicine, Harvard Medical School; Consulting Physician, Boston City Hospital; Physician at the New England Deaconess Hospital, Boston, Massachusetts. xiv+236 pages, 25 engravings and a colored plate. Lea & Febiger, Philadelphia, 1932. Price, \$3.75.

Over 500 living cases of diabetes in the juvenile age period formed the basis of the material in this book. Throughout, the thesis is developed that the *living* diabetic child is the most outstanding medical accomplishment of the past decade. From nearly 100 per cent the mortality of diabetes in childhood has dropped nearly to the vanishing point. All phases of diabetes and of the physiology of the diabetic child are considered. The treatment of the disease itself and of its common complications is fully set forth. Not the least interesting is the chapter giving the present physiological, economic and social status of 76 diabetic children who have survived ten or more years. This book deserves a sympathetic reception and careful study. It reflects energetic study, achievement of a high order, and optimism.

A Text-book of Pathology. By W. G. MACCALLUM, Professor of Pathology and Bacteriology, The Johns Hopkins University, Baltimore. Fifth edition, thoroughly revised. xvi+1212 pages, 652 illustrations, many in color. W. B. Saunders Company, Philadelphia and London, 1932. Price, \$10.00.

A new edition of MacCallum's well-known textbook requires no introduction nor any explanation of its worth. Well-written, well-illustrated and well-printed, this work has been maintained at a high level of excellence by frequent revisions. For student and clinician alike it continues to provide a highly satisfactory foundation in the principles of general and special pathology. "A constant effort has been made to speak of the disturbances of function and of chemical interchange in the course of disease, as far as that was possible, and even to describe symptoms. If this makes the book seem like a treatise on clinical medicine, it is only because pathology and clinical medicine are, after all, the same thing viewed from slightly different angles."

The Sputum: Its Examination and Clinical Significance. By RANDALL CLIFFORD, M.D., F.A.C.P., Associate in Medicine, Peter Bent Brigham Hospital; Assistant in Medicine, Harvard Medical School; formerly Associate Physician and Director of Pulmonary Clinic, Massachusetts General Hospital. xx+167 pages, 21 text figures and 7 plates in colors. The Mac-Millan Company, New York City, 1932. Price, \$4.00.

Clifford's book is a complete practical guide to the collection and study of the sputum. Macroscopic and microscopic features, technical methods of examination, and methods of disinfection of the contents of the sputum cup are given in satisfactory detail. About fifty pages are devoted to a discussion of the character and clinical significance of the sputum in some twenty of the more common diseases of the bronchi and lungs. Both the black and white figures and the colored plates are well chosen and well reproduced. This book can be confidently recommended to students and practitioners.

Die Ernährung des Herzens und die Folgen ihrer Störung. [The Nutritional Mechanism of the Heart, and the Results of Interference with It.] Ergebnisse der Kreislaufforschung, Band III. By Dr. Med. Luigi Condorelli, Professor in the University of Naples. xii+230 pages, 70 illustrations, in part colored. Theodor Steinkopff, Dresden and Leipzig. 1932. Price, in paper, R M 18.80; bound, R M 20.00.

This monograph is divided into four major parts. The first describes in full the anatomy of the coronary circulation and of the lymphatics of the heart. In the second there is a broad treatment of the physiology of the vessels of the heart, including the effects of various drugs. The third chapter deals with the experimental pathology of the coronary system. In this section is included much original work by the author on modifications in the electrocardiogram following infarction of known areas in the myocardium. The final division presents the pathology in man associated with coronary disease, including the less well known forms of coronary arteritis. Each section has an extensive bibliography.

Experimental Pharmacology and Toxicology: A Selected Laboratory Course. By HENRY G. BARBOUR, A.B., M.D., Yale University, New Haven, Connecticut. 141 pages, 14 illustrations. Lea & Febiger, Philadelphia, 1932. Price, \$2.75, net.

Barbour's manual presents a selected laboratory course in pharmacology based on twenty years of experience. Naturally, its field of interest will be found to be largely restricted to teachers of this subject. It is a neat, well printed book, interleaved in blank for the taking of notes, and presents more than forty well chosen experiments.

Annual Report of the Surgeon General of the Public Health Service of the United States for the Fiscal Year 1932. vi + 199 pages.

United States Government Printing Office, 1932. For sale by the Superintendent of Documents, Washington, D.C. (Treasury Department Document No. 5053). Price, \$1.00 (cloth).

College News Notes

AMENDMENTS TO THE BY-LAWS

The Board of Regents of the American College of Physicians submits herewith recommended amendments to the By-Laws, to be acted upon by the Fellows and Masters at the next Annual Business Meeting, Montreal, February 9, 1933.

The purposes of these amendments are:

1. To make the Editor of the official journal of the College an *ex officio* member of the Board of Regents;
2. To provide for a single Committee on Credentials, consisting of three appointees from the Board of Regents and three appointees from the Board of Governors, in order to promote unity in the application of admission standards and in, order to simplify the procedure for the election of Associates.

It is, therefore, recommended that the following articles, or sections thereof, shall be amended to read as follows (*italics indicate insertions or changes*):

BY-LAWS, ARTICLE II, Section 1

"The Board of Regents shall consist of *twenty-four* members as follows: The President, the President-Elect, the Vice-Presidents, Secretary-General, Treasurer, Chairman of the Board of Governors, *Editor of the official journal*, and fifteen members elected from among the Masters and Fellows."

BY-LAWS, ARTICLE II, Section 4

"The Board of Regents shall appoint *three members to serve on the Committee on Credentials* whose duty it shall be to pass upon the qualifications of those proposed for Fellowship or Associateship, and recommend those considered eligible to the Board of Regents. *This Committee shall consist of six members, three appointed by the Board of Regents and three appointed by the Board of Governors, in such manner as to provide for continuity of service, with not more than one new member each year from each Board.*"

BY-LAWS, ARTICLE IV, Section 2

"The Board of Governors shall meet in executive session annually at the time and place of the annual meeting of the American College of Physicians for the transaction of such business as may come before it." (*Omit balance of paragraph.*)

BY-LAWS, ARTICLE IV, Section 6

"The Board of Governors shall appoint *three members to serve on the Committee on Credentials* whose duty it shall be to pass upon the qualifications of those proposed for Fellowship or Associateship, and recommend those considered eligible to the Board of Regents."

BY-LAWS, ARTICLE V, Section 3 (c), paragraph 4

"The credentials of candidates for Fellowship shall be considered first by the Committee on Credentials, which Committee shall report to the Board of Regents for election, deferment or rejection."

BY-LAWS, ARTICLE VI, Section 2, sentence 2.

"..... After 1931, he may be required to present himself for personal examination, the character of which shall be determined by the Committee on Credentials."

"The credentials of candidates for Associateship shall be considered first by the Committee on Credentials, which Committee shall report to the Board of Regents for election, deferment or rejection."

BY-LAWS, ARTICLE VI, Section 3, paragraph 2, sentence 2

" At the expiration of three years, he shall be notified in writing by the Committee on Credentials of his eligibility for election to Fellowship during the next two years, provided he shall meet within that time the requirements necessary for Fellowship. If not elected to Fellowship within five years, his Associateship will automatically cease."

Respectfully submitted,

COMMITTEE ON CONSTITUTION
AND BY-LAWS

Sydney R. Miller, Chairman

Alfred Stengel

S. Marx White

Abstracts of Minutes of the Meeting of the

BOARD OF REGENTS

Philadelphia, Pa.

November 13, 1932

The Board of Regents of the American College of Physicians met at the College Headquarters in Philadelphia at 11:00 A.M., November 13, and was presided over by Dr. F. M. Pottenger, President.

Those present included Dr. F. M. Pottenger, Dr. George Morris Piersol, Dr. Maurice C. Pincoffs, Dr. Charles G. Jennings, Dr. William D. Stroud, Dr. William Gerry Morgan, Dr. Walter L. Biering, Dr. George E. Brown, Dr. John H. Musser, Dr. O. H. Perry Pepper, Dr. James S. McLester, Dr. Jonathan C. Meakins, Dr. James H. Means, Dr. James Alex. Miller, Dr. Sydney R. Miller, Dr. David P. Barr, Dr. James B. Herrick, Dr. Clement R. Jones, Dr. S. Marx White and Dr. W. Blair Stewart. Dr. Charles H. Cocke, Dr. Ernest B. Bradley, members of the Committee on Credentials, and Dr. Alfred Stengel and Dr. Charles F. Martin, members of special Committees, were present as guests. The Executive Secretary, Mr. E. R. Loveland, acted as Secretary of the meeting.

The Executive Secretary read abstracted minutes of the meetings of the Board of Regents held at San Francisco, April 4-8.

The resignation of Dr. William Gerry Morgan, dated April 7, 1932, as a member of the Board of Governors was read, and upon motion regularly adopted, the resignation was accepted, in view of the fact that Dr. Morgan is now the Secretary-General of the College.

Eighteen special cases of members of the College, concerning illness, inability to pay dues, change of status, etc., were reviewed by the Secretary-General, Dr. Morgan, and individual action taken.

The resignations of five Fellows and two Associates were read by the Executive Secretary, and discussed by the Regents. Upon motion by Dr. McLester, seconded by Dr. Biering, and regularly adopted, it was

RESOLVED, that action on the resignations of the members named be postponed until the Montreal meeting in view of the fact that the dues of the College are to be reduced and some of these members may desire to continue their memberships.

The Executive Secretary announced the following deaths, which had been reported since the last meeting of the Board of Regents:

Fellows:

Byron Fuller Barker, Bath, Maine	April 29, 1932
Ray Carrington Blankinship, Madison, Wis.	August 23, 1932
A. J. Burrige, Winnipeg, Man.	March 15, 1932
Luther C. Davis, Fairmont, W. Va.	September 5, 1932
Charles Joseph Durand, Colfax, Calif.	July 6, 1932
Elmer H. Funk, Philadelphia, Pa.	May 13, 1932

Alfred Leftwich Gray, Richmond, Va.	October 13, 1932
William C. Heussy, Seattle, Washington	March 21, 1932
John A. Lichty, Clifton Springs, N.Y.	May 2, 1932
Charles G. Lucas, Louisville, Ky.	July 7, 1932
Frederick Wilmot Mann, Houlton, Maine	June 16, 1932
Orlando H. Petty, Philadelphia, Pa.	June 2, 1932
James Manara Rector, Columbus, Ohio	September 17, 1932
Lorraine Schwartz, Pittsburgh, Pa.	July 25, 1932
Benjamin F. Shuttleworth, Clarksburg, W. Va.	March 31, 1932
Leonard F. C. Wendt, Detroit, Mich.	June 11, 1932

Associates:

Edwin Massie Bell, Allenwood, Pa.	August 20, 1932
Charles Rollin Grandy, Norfolk, Va.	June 10, 1932
Alexander B. Kalbaugh, Westernport, Md.	May 15, 1932
Joseph W. Malone, Brooklyn, N.Y.	September 10, 1932
George Henry Sherman, Detroit, Mich.	April 19, 1932

On motion by Dr. White, seconded by Dr. James Alex. Miller, it was

RESOLVED, that the Secretary-General shall prepare appropriate resolutions for Dr. John A. Lichty, Dr. Charles G. Lucas and Dr. Elmer H. Funk, as past members of the Board of Regents, said resolutions to be submitted at the next meeting of the Board of Regents.

Letters by Dr. William J. Kerr, Dr. J. N. Hall, Dr. G. Gill Richards, Dr. James R. Arneill and Dr. C. T. Burnett, concerning the time of our Annual Clinical Sessions with regard to date were presented. A resolution was adopted that these letters be received.

Dr. E. A. Broughton, of Toronto, and Dr. Harold E. Waxman, of Pittsburgh, were reinstated as a Fellow and an Associate, respectively.

The following candidates were regularly elected to Fellowship in the College:

Anderson, Edward Waldemar	Des Moines, Iowa
Cecil, Russell L.	New York, N.Y.
Fort, Wetherbee	Baltimore, Md.
Fox, Leon Alexander	Washington, D.C.
French, Harry T.	Hanover, N.H.
Gottlieb, Julius	Lewistown, Maine
Hamilton, James	Providence, R.I.
Hamilton, John Richard	Nassawadox, Va.
Kolmer, John Albert	Philadelphia, Pa.
Riven, Samuel Saul	Nashville, Tenn.
Schoenheit, Edward William	Asheville, N.C.
Swann, Walter Clifford	Huntington, W. Va.

The Executive Secretary was requested to report upon the financial operation of the College for the current year. He presented the comparative cost analyses of the ANNALS OF INTERNAL MEDICINE for Volumes III, IV and V, showing a great improvement in the financial status of Volume V over Volume IV, due to a reduction in the volume of the News Notes Section, due to an increase in circulation, and due to a reduction in printing cost. He pointed out, too, that his office has been able to maintain, in fact slightly to increase, the amount of paid advertising in the journal over previous years, in spite of the financial situation. He then presented a comparative cost analysis for conducting the last four Clinical Sessions, this statement disclosing that the San Francisco Clinical Session for the current year cost \$8,129.80 more than any previous Clinical Session, due to an increase in the traveling expenses of guest program speakers and members of the Board of Regents, and due, also, to certain increased local costs in San Francisco. In commenting on the other expenditures for 1932, he pointed out that the expenditures for his office had been reduced by securing a reduction of \$240.00 in rental for the Executive Offices, and by a re-

duction in the office staff of a secretarial assistant whose salary was \$1200.00 per annum. Other economies had also been put into effect, so that had we not had the increase in the cost of the San Francisco Clinical Session and the added expenses of the Phillips Memorial Prize, which in itself amounted to a total of \$1878.82, which had not been granted in previous years, the surplus for 1932 would be approximately as large as for any preceding year, in spite of the fact that the income from initiation fees has been reduced at least fifty per cent. The application of the new provision of the By-Laws requiring all new members to come in first as Associates eliminates at this time the larger initiation fees paid in previous years, the shrinkage in income from this source alone for 1932 amounting to approximately \$9000.00. It is estimated that there will be a surplus of income over expenditures at the end of 1932 of \$5587.52. The Executive Secretary further asserted that the salaries of his office staff were not above the present level. In fact, that in the case of his Secretary, he considered her underpaid.

Dr. William D. Stroud presented the Treasurer's report, including the following bank balances as of October 31, 1932:

On deposit in closed banks:

Bank of Pittsburgh	\$ 7,797.16	
Exchange National Bank, Pittsburgh	3,887.12	
Highland National Bank, Pittsburgh	6,627.51	\$ 18,311.79

On deposit in open accounts:

Colonial Trust Company, Pittsburgh	7,398.86	
Commonwealth Trust Co., Pittsburgh	989.62	
First National Bank, Pittsburgh	2,486.83	
Girard Trust Co., Philadelphia	21,770.96	32,646.27
		<u>\$ 50,958.06</u>

He recommended authorization by the Board of Regents to open an account in a Montreal bank for convenience in depositing Canadian checks and for the payment of Canadian bills during the period of the forthcoming Clinical Session. He further reported the elimination of practically all costs in conducting the Treasurer's office, since his assumption of the Treasurer's duties, due to the fact that he requires no secretarial assistance, such work being done in the Executive Secretary's office. His summarized report follows:

Endowment Fund, January 1, 1932	\$ 52,400.00	
General Fund, January 1, 1932	57,166.00	
		<u>\$109,566.00</u>
Income, January 1, 1932, to October 31, 1932	\$ 39,563.17	
Expenditures, January 1, 1932, to October 31, 1932	29,370.65	
	<u>\$ 10,192.52</u>	
Excess income over expenses, October 31, 1932	4,605.00	5,587.52
Estimated expenses for November and December, 1932		
This, plus Endowment Fund and General Fund of January 1, 1932, gives a total balance of		<u>\$115,153.52</u>

Dr. Stroud further reported that two of the closed banks had paid dividends during the year, and that the ex-Treasurer, Dr. Jones, had expressed the opinion that the closed banks in Pittsburgh, in which balances of College funds remain, would eventually pay the College in full.

Dr. Clement R. Jones, Chairman of the Finance Committee, then presented his report, which was freely discussed by all present. In connection with expenses, Dr. James Alex. Miller inquired concerning a control of the expenses of the annual meetings, and was informed that the expenses of the Executive Secretary only were budgeted and limited, and that there had been no budget control or recommendations for the General Chairman.

local committees and the President. Dr. Miller recommended that when the meeting place for 1934 is selected, the Finance Committee shall prepare a budget for the General Chairman and for the President, limiting the expenditures that may be made.

The following resolution was regularly adopted

- RESOLVED: (1) That the annual dues for Fellows shall be reduced to \$15.00, and of Associates to \$12.00, per annum, for the year 1933;
- (2) That the Treasurer shall recommend to the Finance Committee an additional depository in Philadelphia and one in Montreal;
- (3) That the securities of the College now held in Pittsburgh shall be transferred to a Philadelphia bank;
- (4) That the John Phillips Memorial Prize for 1933 be in the sum of \$1000.00, plus the expenses of the recipient to the Seventeenth Annual Clinical Session;
- (5) That the Treasurer shall be authorized to purchase with approximately \$1000.00, representing interest on securities now on deposit, a Government bond either of the United States or of Canada;
- (6) That \$50.00 per month for November and December shall be transferred from the Treasurer's budget for 1932 for the payment of secretarial services of the new Editor of the ANNALS OF INTERNAL MEDICINE, Dr. Maurice C. Pincoffs;
- (7) That there be a temporary reduction in the salary of the Executive Secretary, of ten per cent as an estimated equivalent to the present reductions in costs of living, and that the matter of the reduction in the budget for his office staff be left to his discretion;
- (8) That the salary of the Editor of the ANNALS OF INTERNAL MEDICINE be reduced ten per cent per annum;
- (9) That the President-Elect be authorized to secure any appropriate reduction in rent;
- (10) That the Finance Committee following the selection of the meeting place each year be instructed to prepare a budget for the President and the local General Chairman, controlling the expenses for their respective programs.

Dr. James H. Means, Chairman of the Committee on the John Phillips Memorial Prize, reported that in accordance with the regulations governing the award of the Phillips Memorial Prize, his Committee had selected a candidate for 1933 and presented the following resolution, which was duly seconded and regularly approved by the Board:

RESOLVED, that the John Phillips Memorial Prize for 1933 be awarded DR. WILLIAM B. CASTLE, of Boston, for his series of studies showing the relation of gastric digestion to the pathogenesis of anemia, the demonstration of the rôle of extrinsic and intrinsic factors in hematopoiesis, and finally in the demonstration that the extrinsic factor in treating pernicious anemia can be obtained from yeast as well as meat, suggesting that it is closely related to vitamin B.

Dr. Maurice C. Pincoffs, Chairman of the Committee on ANNALS OF INTERNAL MEDICINE, reported that the Executive Secretary had assembled estimates from ten different printers, including the Ann Arbor Press, for printing the ANNALS OF INTERNAL MEDICINE, and that the estimates submitted disclosed that material saving could be made during the coming year, either by continuing with the Ann Arbor Press, who had submitted a lower price than that at which they are now printing the journal, or by changing the printers. In view of the desirability of keeping the present volume with the same format, arrangement, etc., and, further, in view of the fact that going on with the present printers would be an aid to him in the formative period of his Editorship, Dr. Pincoffs wished to recommend that the Ann Arbor Press continue to print the journal up to and including the June, 1933, number. His Committee had further considered certain changes,

such as the elimination of abstracts and the enlargement of book reviews; also the matter of the size of the type page and various other details which they felt might somewhat improve the journal. Dr. Pincoffs asked for an expression of opinion by the Board as to the obligation to print every paper presented on the General Program of the Annual Clinical Sessions, expressing the feeling that he felt it was not desirable so to do, but that the Editor should have the same privilege of selection as he has with the acceptance of papers from those submitted directly.

The following resolution was regularly adopted:

RESOLVED, that it is the sense of the Board of Regents that a statement be sent to each essayist on the General Program that there is a requirement of the Board that their manuscripts be submitted in completed form at the time of delivery at the meeting for consideration for publication by the Editor of the ANNALS OF INTERNAL MEDICINE.

Dr. Sydney R. Miller, Chairman of the Committee on Constitution and By-Laws, reported that three matters had been referred to his Committee for consideration in regard to amendments to the By-Laws:

- (1) The making of the Editor of the ANNALS OF INTERNAL MEDICINE an *ex officio* member of the Board of Regents instead of continuing a precedent of having the Editor continuously act as the First Vice-President of the College;
- (2) An amendment to the By-Laws in regard to a resolution adopted by the Board of Regents on April 6, 1932, and referring to a provision for the appointment of a Finance Committee of three from the Board of Regents to perform certain duties;
- (3) Advisability of amending the present provisions for two separate Committees on Credentials, and to provide for one Committee, consisting of three appointees from the Board of Regents and three appointees from the Board of Governors, with provision for the continuity of their service, and with an amendment to the By-Laws with respect to the method of election of Associates.

Dr. Miller reported that the first and third items, in their opinion, fully merited amendments to the By-Laws, but that the second item is unnecessary, since the present By-Laws, Article II, Section 3, fully provide that it is within the province and authority of the Board of Regents "to create, appoint and direct all standing Committees". His Committee recommended that the Board of Regents provide for a standing Committee of three members, appointed in such manner as to provide that one member shall retire each year, his vacancy being filled on appointment by the President, and that the Finance Committee shall be advisory, and its duties and powers defined from time to time by the Board of Regents.

RESOLVED, that the Board of Regents approves of the recommendations by the Committee on Constitution and By-Laws, and hereby instructs that Committee to prepare the detailed amendments and publication of same at least one month in advance of the next General Business Meeting in February.

Dr. Charles G. Jennings, Chairman of the Committee on Public Relations, reported the receipt of a number of communications asking for an investigation of the activities of Fellows of the College who are connected with certain groups, or clinics, which appear to be inconsistent with the ethical standards of the College. Cases also submitted dealt with group practice and contract medicine. The Committee recommended that the Board of Regents advise these correspondents that the College has no adequate method of determining the character of these criticized activities; and that the Board delay action upon them pending action by local medical bodies. The Committee on Public Relations further recommended that the Board of Regents suggest to the Committee on Credentials that it give full consideration to participation in these activities by applicants for membership in the College. The Committee considered, without formal action, questions in reference to abuses that may exist in the operation of the Veterans' Compensation Bureau and the Workingmen's Compensation Acts. Further information will be secured concerning the working of these bodies, in order that the Committee may be better prepared to consider them in the future. The report of the Committee was formally approved by the Board of Regents.

Doctors Pottenger and Meakins presented reports concerning the program for the Seventeenth Annual Clinical Session at Montreal.

Dr. James B. Herrick presented an invitation from all the grade A medical schools in Chicago, the Chicago Medical Society, the Illinois State Medical Society, the Chicago Association of Commerce, and the Mayor of Chicago, for the American College of Physicians to meet in the City of Chicago in 1934. The Board, as a body, expressed their appreciation of the invitation and assured Dr. Herrick that when the matter of the next meeting city is considered during the forthcoming Montreal Session, his invitation from Chicago will be most carefully considered.

The following resolution was regularly adopted:

RESOLVED, that the President appoint a member to fill the vacancy on the Committee on Credentials for Fellowship, due to the death of Dr. John A. Lichty.

President Pottenger announced the reappointment of Dr. W. Blair Stewart as a member of the Committee on Public Relations; his new term to terminate with the 1936 Session.

The following resolution was regularly adopted:

RESOLVED, that the President appoint Dr. James H. Means as the official delegate of the American College of Physicians to attend the International Goiter Conference at Berne, dependent upon the development of his plans to attend this Conference.

Adjournment.

At a recent meeting in Chicago, the directors of Alpha Omega Alpha Honor Medical Society adopted resolutions in recognition of the eminent services of the late Dr. William W. Root, Slaterville Springs, New York, the founder of the society and secretary-treasurer since its organization in 1902. The present officers of the society are Walter L. Bierring (Fellow), Des Moines, president; Austin A. Hayden, Chicago, vice-president; Josiah J. Moore (Fellow), Chicago, secretary-treasurer. Mrs. Root will continue as assistant secretary. In addition to the officers, the directorate includes Ray Lyman Wilbur, Washington, D.C.; Waller S. Leathers (Fellow), Nashville; Louis B. Wilson, Rochester, Minn., and Willard C. Rappleye (Fellow), New York City. The committee on extension and policy comprises Elias P. Lyon, Minneapolis, chairman; William Pepper, Philadelphia; Irving S. Cutter, Chicago; Frederick C. Waite, Cleveland, and Thomas C. Routley, Toronto.

Dr. Ray M. Balyeat (Fellow), Oklahoma City, addressed the 35th annual meeting of the Santa Fe Railway Medical and Surgical Society at Topeka, December 5, 1932, on "Allergic Diseases: With Special Reference to Symptoms Due to Allergy Simulating Surgical Conditions".

Dr. Herman B. Allyn (Fellow), Philadelphia, was made the guest of honor at the annual dinner of the Association of Ex-resident and Resident Physicians of the Philadelphia General Hospital, held at the Philadelphia Country Club on December 6, 1932. Dr. Allyn had been successively Intern, Registrar and Visiting Physician to the hospital, serving in all about thirty-five years. At the time of his retirement from active service he was President of the Medical Board of the Hospital. He is now Consulting Physician.

Doctor Wm. M. James (Fellow), Panama, is the author of two papers which have appeared in the Annual Report for 1931 of the Medical Department of the United Fruit Company. In this same volume there are also two papers by Doctor Ricardo Aguilar (Fellow), Quirigua, Guatemala; and a book review by Doctor Lawrence Getz (Fellow), Panama.

Doctor Julius Friedenwald (Fellow), Baltimore, has been elected President of the Baltimore City Medical Society for the year 1933-34.

Dr. David Riesman (Fellow), Philadelphia, delivered an address on "The Oldest Medical School in America" before the Society of the County of Kings in Brooklyn, New York, on December 20, 1932.

PROGRAM SEVENTEENTH ANNUAL CLINICAL SESSION OF THE AMERICAN COLLEGE OF PHYSICIANS

Montreal, Can., February 6-10, 1933

Francis M. Pottenger, President
General Sessions

Jonathan C. Meakins, General Chairman
Clinical Program

E. R. Loveland, Executive Secretary
133-135 South Thirty-sixth Street
Philadelphia, Pa.

GENERAL AND HOTEL HEADQUARTERS: WINDSOR HOTEL,

Dominion Square, Montreal, Can.

LIST OF MONTREAL HOTELS

All Prices Are for Rates per Day, European Plan

<i>Windsor</i> (Headquarters)	(Capacity 610)
Single room without bath	\$2.50
Single room with bath	4.00
Double room without bath	4.00
Double room with bath	7.00
<i>Mount Royal</i>	(Capacity 1050)
Single room with bath	\$3.00 up
Double room with bath	6.00 up
<i>Ford</i>	(Capacity 750)
Single room without bath	\$1.50 to \$2.00
Single room with bath	2.00 to 2.50
Double room without bath	3.00 to 3.50
Double room with bath	4.00 to 5.00
<i>Queen's</i>	(Capacity 350)
Single room without bath	\$2.00 to \$2.50
Single room with bath	3.00 to 4.00
Double room without bath	4.00 to 5.00
Double room with bath	6.00 to 8.00
<i>Hotel De LaSalle</i>	(Capacity 250)
Single room with bath	\$3.00 to \$6.00
Double room with bath	4.00 to 7.00
<i>Ritz-Carlton</i>	(Capacity 218)
Single room with bath	\$4.00 up
Double room with bath	8.00 up
<i>Place Viger</i>	(Capacity 118)
Single room without bath	\$2.50 to \$3.50
Single room with bath	3.50 to 5.00
Double room without bath	4.00 to 6.00
Double room with bath	7.00 to 10.00

WHO MAY REGISTER—

- (a) All members of the American College of Physicians in good standing for 1933 (dues, if not paid previously, may be paid at the Registration Desk).
- (b) All newly elected members.
- (c) Members of the Montreal Medico-Chirurgical Society, La Société Médicale, Montreal Clinical Society, L'Association des Médecins du Nord, L'Association des Médecins del l'Est and L'Action Médicale, without registration fee, upon presentation of their 1933 membership cards.
- (d) Medical students pursuing courses at McGill University and the University of Montreal, without registration fee, upon presentation of matriculation cards, or other evidence of registration at these institutions.
- (e) House Officers of the hospitals participating in the program, upon presentation of proper identification.
- (f) Members of the Medical Corps of Public Services of the United States and Canada, without registration fee, upon presentation of proper credentials.
- (g) Qualified physicians who may wish to attend this Session as visitors. Such visiting guests shall pay a registration fee of \$12.00, and shall be entitled to one year's subscription to "Annals of Internal Medicine" (in which the proceedings will be published), included within such fee.

REGISTRATION BUREAU.—Located in the Rose Room, Windsor Hotel. Hours: 8:00 A.M. to 6:00 P.M., daily, February 6-10.

REGISTRATION BLANKS FOR ALL CLINICS AND DEMONSTRATIONS are sent to members with the official program. Guests will secure registration blanks at the Registration Bureau during the Session.

TRANSPORTATION—A reduction to one and one-half fare for the round trip on the "Identification Certificate Plan" will apply for physicians and dependent members of their families.

Members are privileged to make the going journey by one route and return by another route. The fare for children of five and under twelve years of age will be one-half of the round trip fare for adults; children under five years of age free when accompanied by parents or guardian. Stop-overs will be allowed at all stations within final limit on either going or return trip, or both, on application to conductors.

Before purchasing tickets, members must secure from the Executive Secretary an Identification Certificate, to entitle them to the reduced fares.

In general, tickets will be sold from January 28 to February 10, depending upon the relative distance from Montreal, with a return limit of thirty days in addition to date of sale.

All tickets must be validated by a special railroad agent at the Montreal headquarters from February 6-10.

BANKING FACILITIES

Arrangements have been made with the Royal Bank of Canada to exchange money and cash cheques for the registered visitors to the Clinical Session. The Bank has made these special arrangements in their Branch at the corner of St. Catherine and Stanley Streets, which is two blocks removed from the Headquarters in the Windsor Hotel.

THE GENERAL BUSINESS MEETING OF THE COLLEGE will be held at 4:30 P.M., Thursday, February 9, immediately following the general scientific program of the afternoon. All Masters and Fellows of the College are urged to be present.

There will be the election of Officers, Regents and Governors, the reports of the Treasurer and of the Executive Secretary and the induction to office of the new President, Dr. George Morris Piersol, Philadelphia, Pa.

SPECIAL FEATURES

Monday, February 6, 1933

The John Phillips Memorial Oration will be delivered by Dr. William B. Castle, of Boston, Mass., at the evening General Session at 9 o'clock. After this a *Smoker* will be held in the Prince of Wales Salon of the Windsor Hotel. There will be a program of entertainment, and refreshments will be served. Members of the College, guests and visitors are cordially invited to attend, as it is hoped that this informal function will provide an opportunity early in the Session for members and guests to meet each other.

Tuesday, February 7, 1933

A Hockey Match between "The Canadiens" of Montreal and "The Maple Leafs" of Toronto, in the National Hockey League, will be played at the *Forum* (corner of St. Catherine Street and Atwater Avenue) at 8:00 P.M. A block of seats has been reserved for the Fellows and visitors, and tickets may be obtained at the Information or Registration Bureaus before 1:00 P.M., Tuesday.

Wednesday, February 8, 1933

CONVOCATION OF THE COLLEGE—8:00 o'clock, Windsor Hall. All Masters and Fellows of the College and those to be received in Fellowship should be present. Newly elected Fellows who have not yet been received in Fellowship are requested to occupy the central section of seats especially reserved for them. As this is the most formal meeting of the College, it is urged that all appear in evening dress.

The Convocation is open to all physicians and their families generally, and to such of the general public as may be interested.

Following the Convocation Ceremony, the President of the College will present the John Phillips Memorial Prize for 1933 to Dr. William B. Castle, of Boston, Mass.

Sir Andrew MacPhail, Professor of the History of Medicine, McGill University, will deliver an address on "The Source of Modern Medicine."

The President, Dr. Francis M. Pottenger, of Monrovia, Calif., will then deliver the annual presidential address to the Masters, Fellows and Associates of the College.

The Presidential Reception will follow immediately after the program. Newly inducted Fellows should sign the Roster and secure their Fellowship Certificates during the interim between the Convocation and the Reception.

Thursday, February 9, 1933

THE ANNUAL BANQUET OF THE COLLEGE will be held at the Windsor Hotel at 7:30 P.M. All members of the College and its Officers, physicians of Montreal and visitors attending the Session, with their wives, are invited to be present at the Banquet.

Dr. Charles F. Martin will act as Toastmaster, and Dr. Stephen Leacock, William Dow Professor of Political Economy, McGill University, will deliver an address on "The Waste Spaces of Modern Education."

Tickets for the Banquet, \$5.00 per person, may be purchased at the Registration or Information Bureaus before 10:00 A.M., Thursday.

ENTERTAINMENT FOR VISITING WOMEN

A program has been arranged for the entertainment of the visiting women in attendance at the meeting, but ample time has also been allowed for individual excursions and shopping. Shopping lists, including the names of the principal shops, will be issued by the Local Committee for the Entertainment of Visiting Women.

POST-CONVENTION TOURS

In order that those attending the Session may have an opportunity of visiting historic Quebec City in its splendid winter garb and enjoy the winter sports, the railways will offer reduced week-end rates. In addition, the Chateau Frontenac Hotel, so beautifully situated

on the bold cliff overlooking the city and river, is making a special rate of seven dollars (\$7.00) a day, American Plan, for any who may wish to visit Quebec City on a post-convention trip.

Similar arrangements have been made with the Seignior Club at Lucerne-in-Quebec for the rate of eight dollars (\$8.00) a day, American Plan. The Seignior Club, Lucerne-in-Quebec, is built around one of the old French-Canadian seigneuries with buildings including the old Manor House, the Log Chateau (with accommodation for 300 members and guests), a year-round swimming pool and sports Club House. It is situated in the Laurentian Mountains, seventy-five miles from Montreal.

THE EXPOSITION AND COMMERCIAL EXHIBIT will be located in the Concourse and Rose Room of the Windsor Hotel, in close proximity to Windsor Hall, the meeting hall for the General Sessions.

Exhibits, consisting of medical literature and texts, pharmaceutical products, apparatus and appliances, special foods, etc., will be shown by leading American and Canadian publishers and manufacturers. These exhibits afford an opportunity for physicians to examine the latest literature and the newest products in the field of medicine generally; their educational value should not be overlooked. Every attendant at the Session is urged to visit each of the booths, for he cannot help but find something new, interesting and scientifically valuable. Intermissions in the general program have been arranged from Tuesday to Friday, inclusive, for the purpose of providing a definite time for the inspection of exhibits.

CLINICAL PROGRAM

Full advantage has been taken of the excellent facilities for clinical teaching which are afforded by the hospitals attached to the two Medical Schools in Montreal. It has been found possible to provide ample accommodation for the Clinical Session in eight places which are practically all within a short distance of the Headquarters. They consist of four large general hospitals, two pediatric hospitals, and the Biological Building, Pathological Institute, and Medical Building of McGill University. Daily bedside and theatre clinics have been arranged in all of these hospitals and demonstrations in the University buildings.

Medical Libraries—The Medical Library of McGill Medical School and the Osler Library, the gift of the late Sir William Osler, will be open to visitors daily, both morning and afternoon. There will be found in both a large collection of medical books, both ancient and modern. All who are interested in rare editions are advised to pay these libraries a visit.

Medical Museums—The Medical School of McGill University has for several generations been very rich in its museum collections. These are now housed at the McGill Medical Building and also at the Pathological Institute.

Special exhibits of "Congenital Heart Disease," Sir William Osler's collection of pathological specimens with their biographies which he compiled during his period as Pathologist at the Montreal General Hospital, and a collection illustrative of Medical History covering many parts of the world, will be arranged for daily inspection by the Fellows and visitors.

DEMONSTRATIONS AT THE MCGILL MEDICAL BUILDINGS

Demonstrations have been arranged in the laboratories of the Departments of Pharmacology, Biology, Physiology and Anatomy. These will cover the special work that is occupying the attention of these various departments and should interest many of the Fellows and visitors.

Clinico-pathological Conferences will be held each morning at the Montreal General Hospital. These conferences have been held for many years and hold a unique position in the medical activities of this institution.

At the Royal Victoria Hospital Professor Oertel will conduct the Conference, on Thursday morning. On the other mornings there will be demonstrations by the Staff of the Pathological Institute dealing with a variety of pathological subjects.

EXPERIMENTAL MEDICINE

In the laboratories of the University Clinic at the Royal Victoria Hospital there will be demonstrated each morning at 11 o'clock interesting results in various problems of Medicine.

PEDIATRICS

A varied program for those interested in Pediatrics has been provided at both the Children's Memorial Hospital and the Hôpital Ste. Justine. The symposia at the former institution on lead poisoning and rheumatic fever in childhood should be particularly attractive.

PSYCHIATRY AND NEUROLOGY

In addition to a number of clinics on neurological subjects, there have been arranged two symposia. One deals with the influence of emotional factors in organic disease, while the other is devoted to the problem of epilepsy.

GENERAL CLINICS

Many clinics have been arranged in cardiovascular, gastro-intestinal, pulmonary, and blood diseases, as well as diseases of the ductless glands and of metabolism.

There will be clinical symposia on diseases of the biliary passages, diabetes, goitre, collapse therapy in pulmonary tuberculosis, syphilitic cardiovascular disease, nephritis, and essential hypertension.

In addition to the small bedside clinics, larger ward clinics have been arranged by the Senior Members of the Staff at the Montreal General Hospital. At the Royal Victoria Hospital one ward has been set aside each day for the demonstration of interesting cases. The Fellows and visitors are invited to visit these wards at their leisure when they may examine and discuss the problems they present with members of the Staff.

GENERAL SESSIONS

In preparing the program for the General Sessions we have attempted to make it reflect the best work that is being done in medicine. The place which the College holds in the minds of medical men can well be estimated from the ready response of those invited to present papers. The response on the part of those who were able to attend the meetings was almost 100 per cent. While the contributors come from various parts of the country it was necessary in constructing the program this year to bear in mind the deterrent effect of long journeys.

There are several features of the program which require emphasis.

That physiological studies are coming more and more to the fore in medical work will be emphasized by the fact that there is a thread of physiology both normal and pathological running through most of the discussions in this program.

Constitutional factors of both an anatomical and physiologic nature will be discussed. The physiological activity of the cell will be presented from both a theoretical and practical standpoint. The difference in chemical constitution favorable to various diseases and the manner in which diseases may be influenced by altering body chemistry will be dwelt upon.

The place of the two correlating mechanisms of the body—the chemical in the form of hormones, and the nervous as represented by both the somatic and visceral nervous systems—is discussed, and the relationship of these systems to normal and pathological function will be stressed.

Endocrinology—A special feature is the symposium on endocrinology, in which the papers will be presented by investigators to whom we are indebted for original work in the particular field discussed. With the new work which is being brought out in this field many of the enigmas of metabolism, growth and development are now being solved, and the body reactions heretofore inexplicable are now being understood.

The Nervous System—Neurology and the psychical side of medicine will be stressed in several important papers dealing with problems of both an organic and functional nature. Epilepsy and schizophrenia will be treated from special standpoints. The part which the autonomic nervous system plays in disease will be presented in practical form.

Pulmonary diseases will be discussed from several angles. Tuberculosis will be presented from the standpoint of the internist as well as the specialist. The suppurative lesions of the chest will be presented by our distinguished French guest and by America's pioneer chest surgeon. The lung will also be discussed from the standpoint of being a focus of systemic infection.

The Heart and Arterial System hold the attention of medical men in a special manner, because of their increased morbidity now that so large a percentage of people are living beyond middle life. Angina pectoris will be treated from both the medical and surgical aspects. Papers on electrocardiography, endocarditis, valvular lesions, the effect of hyperthyroidism on the heart and pulsus alternans will be presented.

Lesions of the peripheral vascular system will be presented. The fact that these affections have recently been treated more or less successfully by operative procedure, based on a better understanding of vascular neurology, adds an ever increasing interest to the subject.

Miscellaneous Subjects—The rôle which sensitization plays in immunity is an important and fascinating subject, and will be presented in an authoritative manner. There will also be discussions of the so-called allergic diseases, diabetes, diseases of the blood, diseases of the pancreas and liver, neurosyphilis, and other problems which are met daily by clinicians. The history and philosophy of medicine will be presented by a paper on the Source of Modern Medicine.

The John Phillips Memorial Prize Oration will be given on Monday evening by William B. Castle, of Boston, for his series of studies showing the relationship of gastric digestion to the pathogenesis of anemia, the demonstration of the rôle of extrinsic and intrinsic factors in hematopoiesis, and finally in the demonstration that the extrinsic factor beneficial in pernicious anemia can be obtained from yeast as well as meat suggesting that it is closely related to Vitamin B.

Through the courtesy of the Provincial Government we are especially fortunate in having a distinguished Parisian physician participate in our program.

OPENING GENERAL SESSION

Monday Afternoon, February 6, 1933
2:00 o'Clock

WINDSOR HALL

1. Addresses of Welcome:

The Honourable L. A. Taschereau, K.C., Premier of the Province of Quebec.
The Honourable Fernand Rinfret, Mayor, City of Montreal.
Charles F. Martin,† Dean, Faculty of Medicine, McGill University.
L. de L. Harwood, Dean, Faculté de Médecin, Université de Montréal.

2. Response to Addresses of Welcome:

F. M. Pottenger,* President of the American College of Physicians.

3. The Diagnostic Use of Iodine in Thyrotoxicosis.

James H. Means,* Boston, Mass.

4. Irradiation Treatment of Hyperthyroidism.

George E. Pfahler,* Philadelphia, Pa.

5. Some Aspects in Cell Physiology.

W. J. V. Osterhout, New York, N.Y.

(Guest)

6. The Effect of Vitamins and the Mergonic Elements on the Growth and Resistance to Disease in Children.

Alan Brown, Toronto, Ont.

(Guest)

†M.A.C.P. *F.A.C.P.

7. A Study of the Ultra Violet Rays in the Western and Southwestern Portions of the United States.
Meldrum K. Wylder,* Albuquerque, N.M.

SECOND GENERAL SESSION
Monday Evening, February 6, 1933

8:00 o'Clock

WINDSOR HALL

1. Spontaneous Versus Artificial Regulation of Constitution for the Control and Prevention of Disease.
Millard Smith, Boston, Mass.
(Guest)
2. The Rôle of Desensitization in Recovery from Bacterial Infections.
William B. Wherry, Cincinnati, Ohio.
(Guest)

9:00 o'Clock

JOHN PHILLIPS MEMORIAL PRIZE ORATION
"The Etiology of Pernicious Anemia and Related Macrocytic Anemias."
William B. Castle,* Boston, Mass.

10:00 o'Clock

SMOKER
Prince of Wales Salon

THIRD GENERAL SESSION
Tuesday Afternoon, February 7, 1933
2:00 o'Clock

WINDSOR HALL
Presiding Officer

Jonathan C. Meakins,* Montreal, Que.

1. Treatment of Polycythemia Vera.
Ernest Falconer,* San Francisco, Calif.
2. Polycythemia Associated with Pulmonary Disorders
James J. Waring* and W. B. Yegge,* Denver, Colo.
3. The Platelets and Platelet Volume in Blood Dyscrasias.
H. Z. Giffin* and K. K. Nygaard, Rochester, Minn.
4. Observations on Addison in Diseases of the Blood.
Roger S. Morris,* Cincinnati, Ohio.
5. Anatomy and Physiology of the Cerebral Circulation.
Stanley Cobb, Boston, Mass.
(Guest)
6. The Patient as a Person.
A. H. Gordon, Montreal, Que.
(Guest)
7. The Influence of Diets High in Fat upon the Insulin Treated Cases of Diabetes.
Henry Rawle Geyelin, New York, N.Y.
(Guest)
8. Lower Fat Diet in Diabetes.
Joseph H. Barach,* Pittsburgh, Pa.

9. Complications of Diabetes.
Lea A. Riely,* Oklahoma City, Okla.
10. Gastro-intestinal Allergy in Children.
Horton Casparis,* Nashville, Tenn.
11. Clinical Observations on Some of the Causes, Organic and Other, of Abdominal Pain and Distress.
S. Franklin Adams,* New York, N.Y.

FOURTH GENERAL SESSION

Tuesday Evening, February 7, 1933
8:00 o'Clock

WINDSOR HALL

Presiding Officer

David Preswick Barr,* St. Louis, Mo.

1. Carbohydrate and Fat Metabolism.
C. H. Best, Toronto, Ont.
(Guest)
2. The Biochemistry and Physiology of the Follicular Hormone.
E. A. Doisy, St. Louis, Mo.
(Guest)
3. Studies on the Function and Clinical Use of Cortin.
Frank A. Hartman, Buffalo, N.Y.
(Guest)
4. Physiology of the Anterior Pituitary and Relationship of Pituitary to Placental Hormones.
J. B. Collip, Montreal, Que.
(Guest)
5. Therapeutic Use of Placental Hormones.
A. D. Campbell, Montreal, Que.
(Guest)
6. Differentiating the Functions of the Anterior Pituitary Hormones.
Oscar Riddle, Cold Spring Harbor, L.I., N.Y.
(Guest)
7. Effect of Hormones on Cellular Permeability.
Ernest Gellhorn, Chicago, Ill.
(Guest)

FIFTH GENERAL SESSION

Wednesday Afternoon, February 8, 1933
2:00 o'Clock

WINDSOR HALL

Presiding Officer

James Alex. Miller,* New York, N.Y.

1. Pulmonary Tuberculosis in General Practice.
Reginald Fitz, Boston, Mass.
(Guest)
2. Conservatism the Keynote in the Treatment of Tuberculosis.
Charles H. Cocke,* Asheville, N.C.
3. The Indications for Collapse Therapy in Pulmonary Tuberculosis.
Isidor David Bronfin,* Denver, Colo.

4. Reflections Concerning the Treatment of Chronic Purulent Bronchiectasis.
Edward W. Archibald, Montreal, Que.
(Guest)
5. Collapse Therapy of Bronchiectasis.
E. Rist, Paris, France.
(Guest)
6. The Rheumatic Lung.
C. P. Howard, Montreal, Que.
(Guest)
7. Hereditary Abnormalities and Constitutional Traits in Experimental Animals.
Wade H. Brown, New York, N.Y.
(Guest)
8. The Value of the Galactose Test in the Diagnosis and Prognosis of Intrahepatic Icterus.
George Morris Piersol,* Philadelphia, Pa.
9. The Differential Diagnosis of Diseases of the Liver and Spleen by the Aid of Roentgenography after Intravenous Injection of Thorium Dioxide Sol.
Wallace M. Yater,* Washington, D.C.
10. Some Clinical Aspects of the Acid Base Balance of the Body.
Samuel M. Alter,* Los Angeles, Calif.
11. Radiotherm Therapy in Neurosyphilis.
Walter M. Simpson,* Dayton, Ohio.

ANNUAL CONVOCATION
Wednesday Evening, 8:00 o'Clock

WINDSOR HALL

The general profession and the general public are cordially invited. No special admission tickets are required. Evening dress is recommended.

1. Convocation Ceremony.
2. Address: "The Source of Modern Medicine."
Sir Andrew MacPhail, Montreal, Que.
3. Presentation of the John Phillips Memorial Prize.
4. President's Address.
F. M. Pottenger, Monrovia, Calif.

PRESIDENTIAL RECEPTION

The Reception will follow immediately after the program. Newly inducted Fellows should sign the Roster and secure their Fellowship Certificates during the interim between the Convocation and the Reception.

SIXTH GENERAL SESSION
Thursday Afternoon, February 9, 1933
2:00 o'Clock

WINDSOR HALL
Presiding Officer
Noble Wiley Jones,* Portland, Ore.

1. The Nervous Patient.
George C. Hale,* London, Ont.
2. Schizophrenia from the Physiological Point of View.
R. G. Hoskins, Boston, Mass.
(Guest)

3. The Evidence for a Cerebral Vascular Mechanism in Epilepsy.
Wilder Penfield, Montreal, Que.
(Guest)
4. The Relationship of the Autonomic Nervous System to General Medicine.
Thomas P. Sprunt,* Baltimore, Md.
5. The Internist as His Own Psychiatrist.
Alfred Stengel,† Philadelphia, Pa.
6. Experimental Uremia.
B. O. Raulston,* Los Angeles, Calif.
7. The Management of Edema.
Charles A. Elliott,* Chicago, Ill.
8. A Study of the Correlations between Physical Aspects of the Body and Disease Susceptibility.
Walter Freeman,* Washington, D.C.
9. The Treatment of Chronic Intractable Asthma with Pollen Extracts.
George L. Waldbott,* Detroit, Mich.

The Annual General Business Meeting of the College will be held immediately after the last paper. All Masters and Fellows are urged to be present. Official reports from the Executive Secretary and Treasurer will be read; new Officers, Regents and Governors will be elected, and the President-Elect, Dr. George Morris Piersol, will be inducted into office.

Thursday Evening, 7:30 o'Clock
WINDSOR HALL

THE ANNUAL BANQUET OF THE COLLEGE
(Procure Tickets at the Registration Bureau)

Toastmaster: Charles F. Martin,† Montreal, Que., Dean, Faculty of Medicine, McGill University.
Address: "The Waste Spaces of Modern Education."
Dr. Stephen Leacock, Montreal, Que., William Dow Professor of Political Economy, McGill University.

FINAL GENERAL SESSION
Friday Afternoon, February 10, 1933
2:00 o'Clock

WINDSOR HALL
Presiding Officer
George Morris Piersol,* Philadelphia, Pa.

1. Evaluation of Various Types of Therapy in Chronic Arthritis Based on Results in One Thousand Cases.
W. Paul Holbrook,* Tucson, Ariz.
2. Research in Electrocardiography.
William Reid,* Boston, Mass.
3. A Standard Test for Measuring Blood Pressure Variability: Its Significance as an Index of Prehypertensive States.
George E. Brown,* Rochester, Minn.
4. Chronic Arterial Occlusion of the Extremities.
Duncan Graham, Toronto, Ont.
(Guest)
5. The Protean Nature of Subacute Bacterial Endocarditis.
John H. Musser,* New Orleans, La.

6. Clinical and Experimental Observations upon the Heart in Hyperthyroidism.
E. Cowles Andrus,* Baltimore, Md.
7. The Diagnosis and Medical Treatment of Angina Pectoris.
Paul D. White,* Boston, Mass.
8. Experimental and Clinical Studies on the Surgical Treatment of Angina Pectoris.
James C. White, Boston, Mass.
(Guest)
9. Pulsus Alternans.
John E. Greiwe,* Cincinnati, Ohio.
10. Aortic Stenosis, a Clinical and Pathological Consideration.
Louis F. Bishop, Jr.,* New York, N.Y.

SPECIAL CLINICS AND DEMONSTRATIONS

Clinics and demonstrations will be held in the forenoons from 9:00 to 12:00 daily, Tuesday to Friday, inclusive.

Tickets will be required for each and every one of the special clinics, ward rounds and demonstrations. The co-operation of everyone in securing his clinic tickets will assist greatly in distributing the attendance according to the capacity of each program. It is self-evident that a ward round arranged for twenty-five will lose its value for all if forty or fifty are present. Ticket registration naturally is the only effective method of keeping the attendance within the capacities indicated.

To all members of the College, registration blanks for the clinics and demonstrations are distributed with the official program. These registration blanks should be filled out and returned to the Executive Secretary at once. Reservations by mail cannot be made after January 20, but reservations may be made in person at the Registration Bureau on the evening preceding any clinic day. *Guests will kindly register for clinics at the Registration Bureau upon arrival at Montreal.*

A-I

Tuesday, February 7, 1933

ROYAL VICTORIA HOSPITAL (Pine Avenue, West) Medical Theatre (Capacity—100)

- 9:00- 9:45 Metabolic Aspects of Progressive Muscular Dystrophy.
W. S. McCann, Rochester, N.Y.
- 9:45-10:30 Treatment of Complications in Diabetes Mellitus.
E. H. Mason.
- 10:30-11:15 X-Ray Examination of the Heart.
T. Homer Coffen, Portland, Ore.
- 11:15-12:00 Therapeutics of Acute Circulatory Failure.
G. R. Brow.

A-II

ROYAL VICTORIA HOSPITAL (Pine Avenue, West) Surgical Theatre (Capacity—150)

- 9:00- 9:45 Peripheral Vascular Disease.
Mark Kaufmann.
- 9:45-10:30 Visceral Pain.
F. A. C. Scrimger.
- 10:30-11:15 Treatment of Pain in Buerger's Disease.
James C. White, Boston, Mass.
- 11:15-12:00 Lesions Due to Scalene Pressure and Their Treatment.
William V. Cone.

Tuesday, February 7, 1933 (Continued)

A-III

ROYAL VICTORIA HOSPITAL
(Pine Avenue, West)
Nurses' Theatre
(Capacity—250)

- 9:00- 9:45 Syphilitic Heart Disease.
John H. Musser, New Orleans, La.
9:45-10:30 Thoracic Aneurysm.
Reginald Fitz, Boston, Mass.
10:30-11:15 Pathogenesis of the Symptom Complex of Tabes.
C. K. Russel.
11:15-12:00 Treatment of Cardiovascular Syphilis.
E. Cowles Andrus, Baltimore, Md.

A-IV

ROYAL VICTORIA HOSPITAL
(Pine Avenue, West)
Ward B
(Capacity—15)

- 9:00- 9:45 Bedside Clinic: The Common Cold.
W. Blair Stewart, Atlantic City, N.J.
9:45-10:30 Bedside Clinic: Sinusitis and Asthma.
A. T. Henderson.
10:30-11:15 Bedside Clinic: Chronic Arthritides.
W. Paul Holbrook, Tucson, Ariz.
11:15-12:00 Bedside Clinic: Neurological Clinic.
Arthur W. Young.

A-V

ROYAL VICTORIA HOSPITAL
(Pine Avenue, West)
Ward D
(Capacity—50)

- 9:00-11:30 A selected group of interesting cases will be continuously demonstrated for all members who may be interested to examine them between these hours.

A-VI

ROYAL VICTORIA HOSPITAL
(Pine Avenue, West)
Ward K
(Capacity—15)

- 9:00-10:00 Bedside Clinic: Metabolism in Bone Diseases.
W. de M. Scriver.
10:00-11:00 Bedside Clinic: Myxoedema.
David P. Barr, St. Louis, Mo.

A-VII

ROYAL VICTORIA HOSPITAL
(Pine Avenue, West)
Medical Laboratories
(Capacity—15)

- 11:00-12:00 Studies in Biochemistry.
1. Fat Digestion and Absorption.
A. Krakower.

Tuesday, February 7, 1933 (Continued)

2. Blood Fats and Their Variations.
David Slight.
3. The Liver and Pancreas in Fat Metabolism.
Mrs. Venning.
4. Analytical Biochemical Methods.
R. U. Harwood.

B-I

MONTREAL GENERAL HOSPITAL
(66 Dorchester St., East)
Surgical Theatre
(Capacity—200)

- 9:00- 9:45 Thoracic Pain.
C. A. Peters.
- 9:45-10:30 Bronchiectasis.
James Alex. Miller, New York, N.Y.
- 10:30-11:15 Pick's Disease.
Paul D. White, Boston, Mass.
- 11:15-12:00 Irradiation Treatment of Cancer about the Mouth.
George E. Pfahler, Philadelphia, Pa.

B-II

MONTREAL GENERAL HOSPITAL
(66 Dorchester St., East)
Out-door Theatre
(Capacity—30)

- 9:00- 9:45 Cardiovascular Renal Syndrome.
G. C. Hale, London, Ont.
- 9:45-10:30 Asthma.
H. E. MacDermot.
- 10:30-11:15 Oxygen Therapy.
A. M. Burgess, Providence, R.I.
- 11:15-12:00 Stricture of Oesophagus.
R. E. Hodge.

B-III

MONTREAL GENERAL HOSPITAL
(66 Dorchester St., East)
Pathological Theatre
(Capacity—60)

- 10:30-12:00 Pathological Conference.
J. E. Pritchard.

B-IV

MONTREAL GENERAL HOSPITAL
(66 Dorchester St., East)
Ward A
(Capacity—50)

- 9:00-10:00 Ward Demonstration: Heart Disease in Pregnancy.
D. Grant Campbell.
- 10:00-11:00 Ward Demonstration: Placental Extracts in Gynecology.
A. D. Campbell.

Program of the Montreal Meeting

Tuesday, February 7, 1933 (Continued)

B-V

MONTREAL GENERAL HOSPITAL
(66 Dorchester St., East)
Ward C
(Capacity—50)

- 9:00-10:30 Ward Rounds.
A. H. Gordon.
10:30-12:00 Simultaneous Record of Heart Beat and Heart Sounds.
C. C. Birchard and Staff.

B-VI

MONTREAL GENERAL HOSPITAL
(66 Dorchester St., East)
Ward E
(Capacity—50)

- 9:00-10:00 Ward Demonstration: Selected Cases of Skin Lesions.
F. J. Burgess.
10:00-11:00 Ward Demonstration: Essential Hypertension.
Joseph H. Barach, Pittsburgh, Pa.

C

McGILL UNIVERSITY MEDICAL SCHOOL
Biological Building
Department of Pharmacology, Fifth Floor
(Capacity—75)

- 9:00- 9:30 Moving Picture Film of Coronary Blood Flow.
R. L. Stehle.
9:30-10:00 Action of Pituitary Extract on Different Portions of the Gastro-intestinal Tract.
K. I. Melville.
10:00-10:30 Uric Acid Eliminants.
Hermann Schroeder.
10:30-10:45 Experimental Demonstration of the Effects of Coronary Constriction.
R. L. Stehle.
10:45-11:00 Chronic Mercury Poisoning.
K. I. Melville.
11:00-11:30 Moving Picture Film of Coronary Blood Flow.
R. L. Stehle.

D

McGILL UNIVERSITY MEDICAL SCHOOL
Pathological Institute
(3775 University St.)
Lecture Theatre
(Capacity—125)

- 9:00- 9:45 Bronchogenic Carcinoma (A Clinical, Bronchoscopic and Pathological Study).
L. H. Clerf and B. L. Crawford, Philadelphia, Pa.
9:45-10:30 Vegetal Foreign Bodies in the Bronchi.
D. H. Ballou.
10:30-11:15 Some Features in the Pathology of Coronary Disease of the Heart.
Oskar Klotz, Toronto, Ont.
11:15-12:00 Hemopoietic Effect of Nuclear Extractives Obtained from the Red Blood Cells of the Fowl.
Noble Wiley Jones, Portland, Ore.

Tuesday, February 7, 1933 (Continued)

E-I

NOTRE DAME HOSPITAL
(1560 Sherbrooke St., East)
Clinical Theatre
(Capacity—150)

- 9:00- 9:45 Title to be supplied later.
E. Rist, Paris, France.
9:45-10:30 Cardiac Insufficiency.
A. LeSage.
10:30-11:15 Electrocardiography in Cardiac Insufficiency.
A. de Guise.
11:15-12:00 Radiology in Cardiac Disease.
A. Laquerrière.
-

E-II

NOTRE DAME HOSPITAL.
(1560 Sherbrooke St., East)
Out-Door Department
(Capacity—50)

- 10:00-12:00 Demonstration of Cases in Dermatology and Syphilis.
Alberic Marin and Assistants.
-

E-III

NOTRE DAME HOSPITAL
(1560 Sherbrooke St., East)
Out-Door Department

- 10:00-12:00 Neurological Clinic.
Jean Saucier and Roma Amyot.
-

E-IV

NOTRE DAME HOSPITAL
(1560 Sherbrooke St., East)
Medical Wards
(Capacity—15)

- 10:00-12:00 Bedside Clinics.
E. P. Benoit and Assistants.
-

F-I

HOTEL DIEU
(65 Pine Avenue, West)
Clinical Theatre
(Capacity—150)

- 9:00- 9:45 Gastro-intestinal Clinic.
Frank Smithies, Chicago, Ill.
9:45-10:30 Treatment and Prevention of Congestive Cardiac Failure.
J. E. Dubé.
10:30-11:15 Collapse Therapy in Pulmonary Tuberculosis.
J. P. Dworetzky, Liberty, N.Y.
11:15-12:00 Spontaneous Pneumothorax.
Guy Hamel.

Tuesday, February 7, 1933 (Continued)

F-II

HOTEL DIEU
(65 Pine Avenue, West)
Medical Wards
(Capacity—15)

- 9:00-10:00 Bedside Clinic.
J. R. Pepin.
10:00-11:00 Bedside Clinic: Treatment of Peptic Ulcer.
Logan Clendening, Kansas City, Mo.
11:00-12:00 Bedside Clinic: Cardiac Clinic.
E. Tetreault.
-

G-I

CHILDREN'S MEMORIAL HOSPITAL
(1415 Cedar Avenue)
Medical Theatre
(Capacity—100)

- 9:00-10:00 Tuberculosis in Children.
Horton Casparis, Nashville, Tenn.
10:00-11:30 Clinical and Pathological Features of Rheumatic Fever in Children.
H. B. Cushing and L. J. Rhea.
11:30-12:00 An Estimate of the Value of Certain Observed Phenomena in Determining the
Activity of Rheumatic Infection.
R. R. Struthers.
-

G-II

CHILDREN'S MEMORIAL HOSPITAL
(1415 Cedar Avenue)
Baby Ward
(Capacity—15)

- 9:00-10:30 Ward Rounds.
Alton Goldbloom.
-

G-III

CHILDREN'S MEMORIAL HOSPITAL
(1415 Cedar Avenue)
Medical Ward
(Capacity—15)

- 10:30-12:00 Ward Rounds.
L. M. Lindsay.
-

(3640 University St.)
Department of Anatomy, Third Floor
No Program on Tuesday

Tuesday, February 7, 1933 (Continued)

I-II

McGILL UNIVERSITY MEDICAL SCHOOL

Medical Building
(3640 University St.)
Osler Library, Third Floor
(Capacity—75)

- 9:30- 1:00 The Osler Library will be open between these hours, when Sir William Osler's collection may be inspected. A special exhibit of books famous in the history of Medicine and Science has been arranged.
- and
- 2:30- 5:00 The Librarian, Dr. W. W. Francis, will be present to receive all visitors.

I-III

McGILL UNIVERSITY MEDICAL SCHOOL

Medical Building
(3640 University St.)
Pathological Museum, Second Floor
(Capacity—75)

- Special exhibits will be set out consisting of:
- Collection on the Clinical Classification of Congenital Heart Disease recently presented at the Centenary Meeting of the British Medical Association:
 - Representative series from the Medical Historical Museum. These will include (1) Sir William Osler's Canadian Pathological collection, consisting of some 150 specimens, with its Bibliography; (2) other special exhibits illustrative of general Medical History.
- Maude E. Abbott.

Wednesday, February 8, 1933

A-I

ROYAL VICTORIA HOSPITAL

(Pine Avenue, West)
Medical Theatre
(Capacity—100)

- 9:00- 9:45 Heart Disease from the Obstetrician's Point of View.
John R. Fraser.
- 9:45-10:30 Handling of Heart Disease in Pregnancy.
S. Marx White, Minneapolis, Minn.
- 10:30-11:15 Factors Operative in Circulatory Failure.
Jonathan C. Meakins.
- 11:15-12:00 Some Aspects of the Etiology of Hematuria.
D. W. MacKenzie.

A-II

ROYAL VICTORIA HOSPITAL

(Pine Avenue, West)
Surgical Theatre
(Capacity—150)

- 9:00- 9:45 Physiology of Pulmonary Collapse.
Ronald V. Christie.
- 9:45-10:30 Results and Causes of Failure in Collapse Therapy.
Charles H. Cocke, Asheville, N.C.

Wednesday, February 8, 1933 (Continued)

- 10:30-11:15 Indications for Surgical Interference in Pulmonary Tuberculosis.
Lawrason Brown, Saranac Lake, N.Y.
- 11:15-12:00 Results of Surgical Treatment of Pulmonary Tuberculosis.
E. W. Archibald.
-

A-III

ROYAL VICTORIA HOSPITAL
(Pine Avenue, West)
Nurses' Theatre
(Capacity—250)

- 9:00-10:00 Neurogenic Factors in Epilepsy.
Stanley Cobb, Boston, Mass.
- 10:00-11:00 A Discussion of the Etiology and Treatment of Epilepsy.
Henry Rawle Geyelin, New York, N.Y.
- 11:00-12:00 Focal Epilepsy—Its Diagnosis and Treatment.
Wilder Penfield.
-

A-IV

ROYAL VICTORIA HOSPITAL
(Pine Avenue, West)
Ward B
(Capacity—15)

- 9:00- 9:45 Bedside Clinic: Blood Transfusion (A Demonstration)
Henry F. Stoll, Hartford, Conn.
- 9:45-10:30 Bedside Clinic.
W. F. Hamilton.
- 10:30-11:15 Bedside Clinic: Acute Pulmonary Tuberculosis.
J. R. Byers.
- 11:15-12:00 Bedside Clinic: Gastro-intestinal Clinic.
C. J. Tidmarsh.
-

A-V

ROYAL VICTORIA HOSPITAL
(Pine Avenue, West)
Ward D
(Capacity—50)

- 9:00-11:30 Demonstration of Dermatological Cases.
Philip Burnett.
-

A-VI

ROYAL VICTORIA HOSPITAL
(Pine Avenue, West)
Ward K
(Capacity—15)

- 9:00-10:00 Bedside Clinic: Atypical Renal Glycosuria.
E. H. Mason.
- 10:00-11:00 Bedside Clinic: Diabetes.
Joseph H. Barach, Pittsburgh, Pa.

Wednesday, February 8, 1933 (Continued)

A-VII

ROYAL VICTORIA HOSPITAL
(Pine Avenue, West)
Medical Laboratories
(Capacity—15)

- 11:00-12:00 Demonstrations in Cardiac Physiology:
1. The Continuous Registration of the Heart and Respiratory Rate in Man.
Ronald V. Christie and G. H. Shepherd.
 2. Studies of the Electrocardiographic "T" Wave.
G. R. Brow and D. V. Holman.
 3. Animal Studies of Acute Heart Failure.
Gerald Evans.
 4. Visualization of Liver and Spleen by X-Ray with Thorium Dioxide.
R. Gottlieb.
-

B-I

MONTREAL GENERAL HOSPITAL
(66 Dorchester St., East)
Surgical Theatre
(Capacity—200)

- 9:00- 9:45 Liver Function and Laboratory Tests in Biliary Disease.
T. B. Magath, Rochester, Minn.
- 9:45-10:30 X-Ray versus Clinical Diagnosis in Biliary Disease.
W. L. Ritchie.
- 10:30-11:15 The Management of Hepatic Disease.
Charles A. Elliott, Chicago, Ill.
- 11:15-12:00 Surgical Aspects of Diseases of the Biliary Passages.
A. T. Bazin.
-

B-II

MONTREAL GENERAL HOSPITAL
(66 Dorchester St., East)
Out-Door Theatre
(Capacity—30)

- 9:00- 9:45 Cardiac Clinic.
Wm. D. Reid, Boston, Mass.
- 9:45-10:30 Renal Glycosuria with Acidosis.
A. F. Fowler.
- 10:30-11:15 Splenomegaly.
E. H. Falconer, San Francisco, Calif.
- 11:15-12:00 Problems in Hematology.
E. S. Mills.
-

B-III

MONTREAL GENERAL HOSPITAL
(66 Dorchester St., East)
Pathological Theatre
(Capacity—60)

- b) Representative series from the Medical Historical Museum. These will include (1) Sir William Osler's Canadian Pathological collection, consisting of some 150 specimens, with its Bibliography; (2) Other special exhibits illustrative of general Medical History.
Maude E. Abbott.

OBITUARIES

DOCTOR ALFRED LEFTWICH
GRAY

Dr. Alfred Leftwich Gray (Fellow), died at his home in Richmond, Va., October 13, 1932, after an illness of eighteen months.

Dr. Gray was born October 2, 1873, at Palmyra, Va., and received his academic and medical training at the University of Virginia, from which he was graduated in 1897. In 1899 he joined the faculty of the University College of Medicine, where he served as Professor of Physiology from 1901 until that school was merged with the Medical College of Virginia in 1913. He was a pioneer in Roentgenology and in 1916 became Professor of Roentgenology in the Medical College of Virginia, a position he continued to fill until his death. In addition to teaching and private practice he was Roentgenologist to the Hospital Division of the Medical College of Virginia, St. Luke's Hospital and Pine Camp Hospital, and was Dean of the Medical College of Virginia from 1913 to 1919.

At the beginning of the World War Dr. Gray was commissioned Major in the Medical Reserve Corps and, as commanding officer, organized and conducted the Richmond School of Military Roentgenologists. He was an active member of numerous medical organizations and served as president of the Richmond Academy of Medicine, Medical Society of Virginia, American College of Roentgenology and American Roentgen Ray Society. He had been a Fellow of the Ameri-

can College of Physicians since 1920. While a recital of the posts he held indicates a life of accomplishment far beyond the ordinary, it fails to portray fully those qualities of mind and heart that will linger longest in the memories of those who knew him. To few, indeed, is it given to attain the degree of confidence and affection in which Dr. Gray was held by his fellow physicians. His ability, energy and sense of fairness marked him as a leader and he was chosen often to represent the various professional and educational organizations with which he was connected. Especially in times of stress, when men lose their heads and passion rules, his innate tact and sound judgment shone brilliantly. Of his time and talents he gave generously. To the hundreds of physicians and students with whom he labored he was ever the sympathetic friend and genial companion, who was always accessible and always willing to help.

In the passing of Dr. Gray the State has lost one of its most useful sons; the medical profession a most loyal and devoted member; and his associates a wise counsellor and faithful friend.

(Furnished by J. MORRISON HUTCHINSON, M.D., F.A.C.P., Governor for Virginia)

DOCTOR EDWARD BATES
BLOCK

Dr. Edward Bates Block (Fellow). Atlanta, Ga., died October 25, 1932; aged, fifty-eight years.

Dr. Block received his medical de-

College News Notes

gree from the University of Virginia Department of Medicine in 1895. Thereafter he was Assistant Resident Physician at Johns Hopkins Hospital from 1895 to 1897; Assistant Pathologist and Bacteriologist, University of Minnesota, 1897 to 1898; Assistant in Neurology at the University of Strassburg from 1898 to 1899; Volunteer Assistant, University of Prague, 1899 to 1900; Assistant Neurologist, Johns Hopkins Hospital, 1900 to 1901; Professor of Neurology and Psychiatry, Emory University School of Medicine, 1901 to the date of his death. He was also Visiting Neurologist to the Grady Memorial Hospital and Visiting Neurologist and Psychiatrist to the Wesley Memorial Hospital, both of Atlanta.

Dr. Block was the author of a large number of publications. He was an ex-President of the Fulton County (Ga.) Medical Society, ex-President of the Atlanta Neurological Association, a member of the Medical Association of Georgia, a member of the Southern Interurban Clinical Club, a member of the Southern Medical Association, a member of the American Neurological Association, a member of the Association for Research in Nervous and Mental Diseases, a member of the American Medical Association, a Fellow of the American Association for Advancement of Science, and had been a Fellow of the American College of Physicians since 1928.

NUMBER 8

The Anatomy of the Autonomic Nervous System With Special Reference to the Innervation of the Skeletal Muscles and Blood Vessels*

By S. W. RANSON, M.D., *Chicago, Illinois*

I will avoid confusion if at the beginning of this symposium we recognize that the sympathetic nervous system as defined in descriptive anatomy is not exactly what the physiologist has in mind when he uses this much abused term. The anatomist thinks of the system as he sees it in the dissecting room, and we shall begin with this simple approach and later define the term in the more restricted sense in which Dr. Cannon will probably use it.

The sympathetic nervous system, in the anatomical sense, is an aggregation of ganglia, nerves, and plexuses through which the viscera, glands, heart, blood vessels, and smooth muscle in other situations receive their innervation. The most conspicuous feature of the system is a pair of ganglionated nerve cords, or sympathetic trunks, which extend vertically through the neck, thorax, and abdomen. Each

sympathetic trunk is composed of a series of ganglia bound together by short nerve strands. Every spinal nerve is connected with the sympathetic trunk of its own side by one or more gray rami communicantes through which it receives sympathetic fibers for the control of blood vessels, sweat glands, and smooth muscles of the hair follicles (Figure 1). The majority of the nerve fibers taking origin in the ganglia of the sympathetic chain are distributed through the gray rami and the spinal nerves. The ganglia of the thoracic and abdominal portions of the chain are less concerned with visceral activity than with constriction of the peripheral blood vessels, erection of the hairs, and secretory activity of the sweat glands. But the cervical ganglia bear an intimate relation to the viscera of the head, neck, and thorax.

The thoracic and the upper lumbar nerves are connected with the sympathetic chain by white as well as gray rami communicantes. These white rami contain visceral efferent fibers

*Read before the American College of Physicians, San Francisco, California, April 8, 1932.

which take origin from cells in the gray matter of the spinal cord, travel through the ventral roots and white rami, and enter the sympathetic system, to terminate in synaptic relation with the nerve cells found in the sympathetic ganglia. These fibers are often designated as preganglionic fibers, while those that arise in the ganglia and relay the impulses onward are called postganglionic. The gray rami contain postganglionic fibers most of which have no myelin sheaths; the

of descending fibers from the white rami of the lower thoracic and upper lumbar spinal nerves.

Those fibers of the white rami, which are concerned with the innervation of the abdominal viscera, pass into the splanchnic nerves and end in the celiac ganglion. These fibers reach the splanchnic nerves after passing through the lower half of the thoracic sympathetic chain; but they are not interrupted in the chain ganglia through which they pass.

FIG. 1. Diagram of pre- and postganglionic nerve fibers.

white rami contain preganglionic fibers, which are all of small caliber and myelinated.

The majority of the preganglionic fibers turn either upward or downward in the sympathetic chain, and run for varying distances within it before ending in its ganglia. The cervical sympathetic trunk is composed almost exclusively of preganglionic efferent fibers, derived through the white rami from the upper thoracic nerves and ascending to terminate in the cervical sympathetic ganglia. The lumbar and sacral portions of the trunk are composed in the major part

The sympathetic nervous system, as defined anatomically, receives additional fibers from the spinal cord by way of the visceral branches of the third and fourth sacral nerves. These make no connection with the sympathetic chain but join with the hypogastric nerves to form the vesical plexus, which is situated lateral to the neck of the bladder and from which fibers are distributed to the pelvic viscera.

The peripheral sympathetic plexuses are joined by fibers from certain of the cranial nerves. Of these the vagus makes the largest contribution. It

gives off several cardiac branches. The superior cardiac branch of the left vagus runs in front of the arch of the aorta and enters the superficial part of the cardiac plexus. The other cardiac branches from the left vagus and all from the right vagus enter the deep part of the cardiac plexus which is situated behind the aortic arch. In these plexuses the vagal fibers are joined by others from the cervical sympathetic ganglia and are distributed along with these sympathetic fibers through the plexuses accompanying the coronary arteries.

Each vagus gives off two or three small branches, which join the anterior pulmonary plexus in front of the root of the lung, and then pass behind the bronchus, giving off numerous branches which are joined by filaments from the thoracic sympathetic chain to form the posterior pulmonary plexus. Below the root of the lung the two vagi break up into branches which form a plexus surrounding the esophagus. Fibers from the left vagus supply the anterior surface of the stomach and some run through the hepatic branch to the left lobe of the liver. Fibers from the right vagus are distributed to the posterior surface of the stomach, and to the celiac plexus. Through the celiac plexus fibers from the right vagus reach the liver, gall-bladder, pancreas, spleen, kidneys, suprarenal glands, and intestines.

There are then three streams of preganglionic visceral efferent fibers: (1) a cranial stream from the third, seventh, ninth, and tenth cranial nerves; (2) a thoracolumbar stream from the thoracic and upper lumbar spinal nerves by way of the white

rami; and (3) a sacral stream from the second, third, and fourth sacral nerves. The cervical and lower lumbar nerves contain no visceral efferent fibers and thus serve to separate the three streams.

These three groups of preganglionic visceral efferent fibers, and the postganglionic neurones which are associated with them, constitute what is known as the autonomic nervous system. In other words, this term is used to designate the aggregate of all visceral efferent neurones, both pre- and postganglionic, irrespective of whether they are associated with cerebral or spinal nerves. It is through this system that the glands, heart, and smooth muscle receive their efferent innervation. Two principal divisions of the autonomic system are recognized, namely thoracolumbar and craniosacral. These divisions are also known as the sympathetic and parasympathetic systems. Now we are using the term sympathetic system in its restricted physiological sense, not for something which can be isolated in the dissecting room, but to designate a particular group of visceral efferent neurones.

The preganglionic fibers of the thoracolumbar or sympathetic division leave the cord by way of the thoracic and upper lumbar spinal nerves, run by way of the white rami to the sympathetic chain and end either in the ganglia of this chain or in the prevertebral ganglia. The preganglionic fibers of the craniosacral or parasympathetic division do not join the sympathetic chain but end in terminal ganglia situated either in or close to the organ supplied. In their

failure to make connections with the sympathetic chain, and in their relation to the terminal ganglia, the fibers of the cranial and sacral streams agree with each other and differ from those of the thoracolumbar outflow. Also in their response to drugs like atropin and adrenalin the two former agree with each other and differ from the latter. There are, therefore, good reasons for grouping the cranial and sacral divisions of the autonomic system together under the designation of the parasympathetic system.

The rami communicantes, sympathetic chain, and splanchnic nerves contain no parasympathetic fibers; but in most of the peripheral plexuses sympathetic and parasympathetic fibers are intermingled. In this way the viscera receive fibers of both types and thus have a double nerve supply. The parasympathetic postganglionic neurones have their cells of origin in ganglia situated either in or close to the organ which they supply. These postganglionic fibers are therefore, as a rule, much shorter than the postganglionic fibers of the sympathetic division whose cells of origin are located in the vertebral or prevertebral ganglia. In many of the peripheral plexuses, therefore, preganglionic parasympathetic fibers are accompanied by postganglionic sympathetic fibers.

The cells of origin of the visceral efferent fibers differ from ordinary motor cells, like those in the hypoglossal nucleus, in their smaller size, less abundant cytoplasm, and smaller Nissl bodies. Cells of this type are found in the Edinger-Westphal nucleus, which gives rise to the fibers of

the third nerve that innervate through the ciliary ganglion the intrinsic musculature of the eye. Such cells are also found in the salivator nuclei which give rise to the fibers of the seventh and ninth nerves that control the flow of saliva, and in the dorsal motor nucleus of the vagus which gives rise to fibers for the thoracic and abdominal viscera. Neurones of the same type are found in the intermediolateral cell column of those segments of the cord which are associated with white rami, and in the lateral part of the gray matter of the lower sacral segments. The last mentioned group of cells gives rise to efferent fibers for the pelvic viscera.

The autonomic nervous system which we have described as the sum total of all visceral efferent neurones is by definition purely an efferent system; but this does not mean that there are not also visceral sensory fibers. These are found in great numbers in the vagus, white rami, and visceral branches of the second, third, and fourth sacral nerves. These fibers have their cells of origin in the cerebrospinal ganglia and, though they usually pass through one or more sympathetic ganglia on their way to their terminations in the viscera, they make no connections in these ganglia. Visceral reflexes, therefore, travel arcs of at least three neurones. The impulses reach the central nervous system over visceral afferent fibers and leave along preganglionic visceral efferent fibers. These end in sympathetic ganglia, and the impulses which they carry are relayed to involuntary muscle and glandular tissue by postganglionic fibers.

The ganglia, with the possible exception of those in the enteric plexuses, do not serve as reflex centers, but only as relay stations in the conduction pathways from the central nervous system to the viscera.

INNERVATION OF BLOOD VESSELS

The blood vessels of the abdominal cavity are surrounded by sympathetic nerves which branch and reunite about the vessels in such a way as to form dense plexuses. The individual strands composing these plexuses are so large that they may be seen and followed in the dissecting room. These strands are composed chiefly of unmyelinated post-ganglionic fibers from the celiac ganglion, but they contain also vagal fibers and sensory fibers from the splanchnic nerves. Around the origin of the celiac artery this network is especially dense and forms along with the two celiac ganglia the celiac plexus. From this as a central point subordinate plexuses extend in all directions along the hepatic, gastric, and splenic arteries and along the mesenteric and other branches of the abdominal aorta, and follow these vessels into the organs which they supply. A plexus accompanies the abdominal aorta and divides below into the two hypogastric plexuses which join the vesical plexus in the pelvis.

The nervous investment of the thoracic aorta is much more delicate; but in close relation to the aortic arch lie the superficial and deep cardiac plexuses from which strands are given off that accompany the coronary arteries.

It should be emphasized that the vessels of the extremities are not ac-

companied by similar plexuses. Leriche, when he advocated periarterial sympathectomy, did not realize the profound difference which exists in this respect between visceral and somatic vessels. In most instances the nerve supply for a viscus accompanies the artery and is distributed to the organ along the arterioles. But in the extremities not even the branches of the arterial tree are supplied in this way. It is true that a plexus continuous with that surrounding the aorta is found on the common iliac artery and that some bundles of fibers are continued along the external iliac to the femoral artery beyond which they cannot be followed. With the exception of these few fibers the vessels of the leg receive their innervation in an entirely different manner, namely by way of branches from neighboring somatic nerves.

In a recent study of the innervation of the vessels of the hind limb of small mammals by Woollard¹ the nerve fibers were stained with methylene blue and the entire arterial tree dissected out and arranged on a slide as a whole mount. In such a preparation he was able to trace a plexus from the aorta along iliac vessels. Individual bundles of fibers could be traced to the femoral artery where they became reduced in size and finally disappeared. The fibers in these bundles were almost all unmyelinated post-ganglionic sympathetic fibers, and for this reason these bundles could readily be distinguished from those derived as branches from adjacent somatic nerves since these twigs contained large numbers of myelinated sensory fibers.

Dr. Burns² has recently been studying the distribution of sympathetic fibers to the hind limb of the cat after complete degeneration of the somatic fibers following section of the lumbar and sacral nerves distal to the spinal ganglia. In both the cutaneous and muscular nerves of the extremity he found large numbers of unmyelinated sympathetic fibers. More than 8000 such fibers were counted in the femoral nerve alone. But in the walls of the larger vessels such as the femoral, popliteal, and anterior tibial relatively few longitudinally coursing fibers were found. His preparations support the view that the sympathetic fibers enter the limb intermingled with the somatic fibers in the nerves, from which they are given off in small twigs to the blood vessels (Figure 2). After reaching the arteries they run for relatively short distances in the nerve plexus of the adventitia before joining the terminal plexus in the media. It is, therefore, evident that periarterial sympathectomy does not denervate the peripheral vessels. In order to destroy their sympathetic innervation it is necessary to remove the sympathetic ganglionated cord or section the appropriate gray rami.

The vessels and particularly the arteries are sensitive to pain. They receive their sensory fibers from the spinal nerves (Wiedhopf³).

The cerebral vessels, like those which supply the abdominal viscera, are accompanied by plexuses of nerve fibers. Most of the fibers are unmyelinated and derived from the superior cervical sympathetic ganglion by way of the carotid plexus or from the inferior cervical ganglion by

FIG. 2. Diagram of innervation of peripheral blood vessels.

way of the plexus on the vertebral artery. Some are sensory fibers derived from recurrent branches of cranial nerves and a few come in small bundles directly from the brain stem. The fibers can be followed along the small arteries and arterioles which ramify within the pia mater (Stöhr⁴). Hassin⁵ found these fibers most abundant in the pial vessels at the base of the brain, i.e., over the pons, cerebellum, medulla, and cerebral peduncles. He could not find nerve fibers following the blood vessels into the substance of the brain, and Stöhr was also of the opinion that the blood vessels within the central nervous system are not accompanied by nerve fibers. More recently Clark⁶ has been able to follow these fibers along the small arteries that penetrate into the brain substance.

Until quite recently there was no satisfactory evidence to show that intracranial blood vessels are under vasomotor control, but this now appears to have been furnished by Forbes and Wolff.⁷ They observed the pial vessels through a window set in an opening in the skull and were able to see the small arteries of the pia contract immediately after stimulation of the cervical sympathetic trunk, and dilate after stimulation of the central end of the cut vagus nerve. Many clinicians believe that cerebral vascular spasm may cause transient hemiplegia, aphasia, migraine, and convulsions. This view receives support from these recent anatomical and physiological studies of the meningeal vessels.

INNERVATION OF SKELETAL MUSCLE

I am glad to be able to tell you that the fundamental facts regarding the

innervation of skeletal muscle may be stated correctly in very simple terms, in fact in the same simple terms which were used prior to 1910. In that year Boeke⁸ described an accessory innervation of striated muscle by unmyelinated sympathetic fibers, and in a long series of subsequent papers he has attempted to support that view. Because of Boeke's recognized ability as an investigator and because his observations received more or less support from the investigations of Agduhr,⁹ Kulchitsky,¹⁰ and Kuntz,¹¹ the idea that striated muscle receives part of its innervation through sympathetic fibers came to be generally accepted. Hunter¹² and Royle¹³ by advocating sympathectomy as a measure for relief of spastic paralysis gave wide publicity to the idea that the muscles receive their tonic innervation from the sympathetic system.

But beginning with the important contribution of Hinsey¹⁴ in 1927 there have appeared during the last four years a series of papers, which have definitely shown that skeletal muscles are not innervated by sympathetic fibers, although a considerable number of such fibers is found on the intramuscular blood vessels. Hinsey, in three sets of experiments, isolated by degeneration methods the different types of fibers. First, by section of the spinal nerves distal to the spinal ganglion he caused the degeneration of all somatic fibers in the hind limb and was able to study the distribution of the sympathetic fibers. He also studied the sensory fibers after the degeneration of all motor and sympathetic elements, and the motor fibers

after degeneration of the other two types. The results of his studies are summarized graphically in figure 3. The ordinary muscle fibers receive only one type of nerve fiber, somatic motor, arising from cells in the an-

terior gray column of the spinal cord and terminating in motor end plates. The muscle spindles, which are specialized sense organs, receive both somatic motor and somatic sensory fibers. The sympathetic fibers which go to the muscles are confined to the intramuscular blood vessels. None of them end in the musculature itself.

FIG. 3. Diagram of innervation of skeletal muscle.

terior gray column of the spinal cord and terminating in motor end plates. The muscle spindles, which are specialized sense organs, receive both somatic motor and somatic sensory fibers. The sympathetic fibers which go to the muscles are confined to the intramuscular blood vessels. None of them end in the musculature itself.

Wilkinson¹⁵ had the opportunity of studying Boeke's preparations and was

unable to find in them any satisfactory evidence of sympathetic accessory fibers. The most recent studies on this subject support the conclusions reached by Hinsey and Wilkinson. Tower¹⁶ found that in the mammal every end-

The Functional Organization of the Involuntary Nervous System and Its Humoral Mediators*†

By W. B. CANNON, M.D., *Boston, Massachusetts*

WE naturally think of ourselves as air inhabiting animals, but even a slight examination would show that we are separated from the air which surrounds us by a layer of dead cells in the outer horny portion of the skin or by a layer of mucus. All that is alive within these lifeless surfaces is bathed in a salty fluid—the “*milieu interne*”, as Claude Bernard called it, or the *fluid matrix*, as we may designate it. Thus our bodies have not only the external environment which other objects have but our living parts have also an internal environment composed of the rapidly flowing blood and the more slowly flowing lymph.

In relation to the external and internal environments we may separate the nervous system into two grand divisions. The division with which we are commonly acquainted, the so-called “voluntary system”, attached to the bony skeleton, serves to change the external environment and our relations to it. This system also is supplied with surface sense organs, or exteroceptors,

serving to acquaint us with our surroundings. Since our reactions to these surroundings are directed toward objects in the outer world, we may speak of this grand division of the nervous system as the *exteroffective* system. The second grand division is the so-called “involuntary”, “vegetative”, or “autonomic” system which brings about changes in the internal environment. It may be regarded, therefore, as having *interoffective* functions.

THE FUNCTIONAL CHARACTERISTICS OF THE AUTONOMIC SYSTEM

The functional characteristics of the interoffective or autonomic division of the nervous system may be briefly summarized as follows.¹ Typically it innervates glands and the smooth muscles of the viscera, blood vessels, and skin. Whether it affects skeletal muscle is in question. Interposed between the smooth muscle or gland cell and the neurones reaching forth from the central nervous system there is invariably an outlying neuron, all of which is external to the central system. I have suggested¹ that this neuron may serve as an adapter or transformer of the nerve impulses so as to render them suitable for the visceral structures, which are more slowly act-

*Read before the American College of Physicians, San Francisco, California, April 8, 1932.

†From the Laboratories of Physiology, the Harvard Medical School.

ing than skeletal muscle. The outlying neurones, whose cell bodies are commonly gathered in ganglia, are connected with the central nervous system by three sets of outreaching neurones, making three divisions—the cranial from the brain, the sacral from the sacral cord, and the sympathetic or thoracolumbar division from the spinal cord between the brachial and lumbar enlargements. The nerve fibers of these outreaching neurones, before coming to the outlying ganglia, are called *preganglionic*. Those passing from the ganglia to the viscera are called *postganglionic*. Commonly a single viscus is doubly innervated, by neurones from the middle or thoracolumbar division and from one of the terminal divisions. Thus the heart is supplied from the cranial division by the vagus nerves and also by fibers from the ganglia of the sympathetic. As a rule in this double innervation the representatives of the two divisions are opposed in action. For example, the vagus inhibits the heart beat and the sympathetic causes acceleration.

It is typical of the cranial and sacral divisions that their preganglionic fibers, reaching from the central nervous system to the outlying neurones, end in or near the viscera which they innervate. The fibers of the vagus nerves, for instance, pass directly into the heart muscle before meeting the relay. This arrangement is such as to provide for direct and particular action of these nerves without relation to one another. Thus the contraction of the pupil by way of the third cranial nerve, the flow of saliva by way of the seventh nerve, and the slowing of the

heart by way of the tenth nerve are obviously separate and unrelated. The situation is quite different in the organization of the sympathetic or thoracolumbar division. In that division the preganglionic fibers reach out to a chain of ganglia, arranged on either side of the midline, from the superior cervical ganglion, near the corner of the jaw, through the chest and abdomen to the pelvis. These preganglionic fibers, after entering the nearest ganglion, pass through it and may reach downward or upward along the chain through two or three ganglia before coming to an end. This arrangement of the preganglionic fibers results in an overlapping of their distribution; in any ganglion there may be fibers from four or five different segments of the spinal cord. Or, to put it differently, fibers from any segment of the spinal cord may pass through four or five different ganglia of the sympathetic chain, giving off, in each one, collateral branches. This mode of organization has two effects. It greatly increases the area of distribution of the impulses coming out by any single fiber, and it also provides for diffuse distribution of impulses throughout the organism.

Confirmation of the idea that the sympathetic division is organized for diffuse distribution of effects is found in the facts that this division causes secretion of the substance adrenin into the blood, and that the circulating adrenin has practically everywhere in the body the same effects on the viscera as those produced by sympathetic impulses themselves. Obviously, even though the nerve fibers were not ar-

ranged for diffuse effects, the secreted adrenin would have such effects. The recent discovery of *sympathin*, which has, so far as we know, the same influence as adrenin, further emphasizes the view that the sympathetic division is organized for diffuse activity. In order to consider the rôle of *sympathin* it will be necessary to step back about twelve years and survey briefly the history of humoral transmission of autonomic nerve impulses.

THE HUMORAL TRANSMISSION OF VAGAL AND SYMPATHETIC IMPULSES

In 1921 Loewi² reported the observation that Ringer solution, which has been in contact with a frog heart (A), while that heart has been under the influence of the vagal nerves, acquires a new property. When applied to frog heart (B), the Ringer solution as such has the same effect as the nerve impulses, i.e., it causes inhibition of (B). Loewi also found that when the frog heart (A) is subjected to sympathetic influence, the Ringer solution in contact with it when applied to heart (B) causes acceleration. Loewi's observations have been confirmed by others and have been reported as characteristic of other hearts than that of the frog. In 1930 Finkleman³ published the interesting observation that when an excised piece of rabbit intestine (A), still supplied with its nerves, is placed so that Ringer solution which drops upon it will drip on another piece of excised rabbit intestine (B), the stimulation of the nerves of (A) causes inhibition of its spontaneous contractions and thereupon the spon-

taneous contractions of (B) are likewise inhibited. It appears that there is a substance given off from the intestine (A), when subjected to sympathetic impulses, that transfers to intestine (B) the effect of these impulses.

Further analysis of the substance produced when the vagus is stimulated has proved that it is dialyzable, that it is insensitive to acid but remarkably sensitive to alkali, and that, although quite stable while existing normally in undisturbed tissue, it becomes highly unstable when freed from such tissue by stimulation or when the tissue containing it is minced. These characteristics and also the mode of action of this "vagus substance" indicate that it is an ester of choline, and the conclusion has been drawn that it is probably acetyl choline.

The substance given off when the sympathetic supply to the heart is stimulated has many of the features of adrenin. Like adrenin it is destroyed when, after the addition of eosin, it is exposed to ultraviolet light; it is destroyed likewise by standing in air, and by being heated to boiling. It not only causes acceleration of the heart as adrenin does but also constriction of the arterioles.

The Belgian physiologist, Demoor,⁴ has criticized the inference that these substances have any physiological significance, at least as circulating substances. He pointed out that the irrigation of isolated tissues with salt solution subjects these tissues to quite unnatural conditions and that under the circumstances cell permeability may be altered in such a way that ma-

terial may escape from the cells in a manner not at all physiological. So far as the "sympathetic substance" is concerned, that criticism can now be set aside, for it has been demonstrated that a material given off from smooth muscle when subjected to sympathetic influences may be carried in the blood stream to remote structures and there have typical effects.¹² In order to bring out this evidence we must consider the use of the denervated heart as an indicator.

THE DENERVATED HEART AS AN INDICATOR OF INCREASED ADRENIN IN THE BLOOD

The heart may be wholly disconnected from the central nervous system by removing the upper thoracic sympathetic chains, by severing the right vagus nerve below the recurrent laryngeal branch (which is left to innervate the larynx), and by severing all of the cardiac branches of the left vagus trunk (which is left to control the gastrointestinal tract). Animals on which this operation is performed with careful surgical precautions live quite normally, and for many weeks there is no regrowth of nerve fibers to the heart.⁵ The heart thus denervated is highly sensitive to circulating adrenin. It responds by a faster beat when adrenin is present in the almost incredible dilution of one part in 1,400,000,000 parts of blood.⁶ By means of this sensitive signal of an increase in the concentration of adrenin in the blood stream it has been possible to show that adrenin is especially secreted when an animal is exposed to cold,⁷ when it exhibits emo-

tional excitement or exercises or moves about even slightly,⁸ when it is subjected to asphyxia,⁹ or is disturbed by hypoglycemia.¹⁰ After momentary emotional excitement, for example, the heart rate may increase immediately 70 or even 100 beats a minute.

Now, if the adrenal influence is removed by extirpation of one adrenal gland and denervation of the other, the immediate increase of heart rate after excitement disappears. But after an emotional disturbance there is still seen a delayed cardiac acceleration which reaches a maximum in about three minutes. The explanation of this phenomenon was for a long time a mysterious and tantalizing problem. This delayed increase in the rate of the denervated heart continued after extirpation of the medulla from the remaining adrenal gland, after removal of accessory adrenal tissue in front of the aorta, after the destruction of the pituitary body, and after exclusion of thyroid, parathyroid, and gonadal influences. It seemed obvious that the effect must be due to some action of the sympathetic system because that was the system most prominently concerned with emotional expression. The phenomenon still continued, however, after both abdominal chains and all of the thoracic chains except a few ganglia in the lower thorax had been removed. The natural next step, therefore, was the removal of these remnants from the thorax. When that operation was performed the phenomenon disappeared. It seemed probable, therefore, that a substance was given off into the blood stream when the sympathetic was stimulated and this

substance was the cause of the delayed increase of the heart rate.¹¹

THE PRESENCE OF SYMPATHIN AND
THE ABSENCE OF "VAGUS SUB-
STANCE" IN THE CIRCULATING
BLOOD

Experimental proof of the surmise which has just been expressed was obtained in an animal with the heart denervated, the adrenals excluded from participation, and the spinal cord transected in the midthoracic region. The hind part of the animal was thus isolated from the fore part (i.e., the brain), and could be experimented upon, therefore, without anesthesia. By this procedure it was found that stimulation of the sympathetic fibers governing the smooth muscles of the tail hairs would cause the typical belated acceleration of the heart and, associated therewith, an increase of blood pressure.¹² The same phenomenon occurred when the smooth muscles of the hairs of a patch of skin on the flank were stimulated. A check of the blood flow into and from the tail region, and also the removal of the patch of skin on the flank, caused the stimulation to become ineffective. Furthermore, it was found that the denervated salivary glands and denervated nictitating membrane could likewise be made to exhibit characteristic activities on exciting the smooth muscles of hairs in the hind part of the body.¹³

The substance that is thus discharged from stimulated smooth muscle resembles adrenin in acting on denervated structures just as the nerve impulses themselves act and, as has been re-

cently learned, in being more effective after the injection of cocaine.¹⁴ Since the substance does not come from the adrenal glands, however, but comes from other organs when subjected to sympathetic stimulation, it has been named "sympathin". Obviously, since sympathin is given off into the blood stream and since it acts like adrenin and coöperates with adrenin in mimicking sympathetic nerve impulses, its general distribution by the blood stream supports the view that the sympathetic division of the autonomic system is normally arranged for diffuse action over the widely spread sympathetic endings.

Success in demonstrating in the blood stream the presence of a sympathetic substance naturally raised the question whether it would not be possible to demonstrate by a similar method the presence of the vagus substance. In order to test this possibility we¹⁵ used the denervated iris, submaxillary gland, and heart, as well as the denervated tongue and the normal blood pressure. We stimulated the entire distribution of the vagus nerve below the level of the heart. Furthermore, we arranged a by-pass for the portal blood so that it flowed into the inferior vena cava and thereby avoided the liver, which is destructive to acetylcholine.¹⁶ Moreover, we used a variety of anesthetics and in some experiments excluded (by operations which rendered the animal incapable of experiencing pain) the necessity of using anesthesia. In spite of these very careful and thoroughgoing efforts, all our results were negative. We obtained no

general or remote effects as a consequence of vagus stimulation. It would appear, therefore, that the parasympathetic or vagal substance has a quite local influence. This conclusion, as will be noted, is in harmony with the view that the parasympathetic innervation serves for specific and narrowly localized action and not for diffuse effects.

It is of interest to observe that the organization of the autonomic system outlined above permits all sorts of variations, both general and individual. Thus, the heart, for example, may be made to beat less rapidly or more rapidly by varying the "tone" of the vagal influence up or down, without influencing other organs having a parasympathetic supply. Or, it may be made to beat less rapidly or more rapidly by varying the "tone" of the sympathetic supply; but in this case, because of the diffuse distribution of sympathetic influences, many other organs are involved in the reaction. I have elsewhere likened the condition to that of a piano. A note may be made louder by the vigor of the blow on a single key, or many keys may be influenced by pressing on the loud or soft pedal.

THE GENERAL SERVICES OF THE AUTONOMIC SYSTEM

At the outset the statement was made that the autonomic nervous system is interofective because it regulates conditions of the internal environment. Each of its three divisions has distinctive general functions. We obtain insight into those functions by considering the circumstances under which the

several divisions are brought into action and also the effect which each produces. The sympathetic division is so specially concerned with preservation of constancy in the fluid matrix that we shall deal with it in detail. The other two divisions play an adjuvant rôle.

The functions of the *sacral division* may be summarized by the statement that they consist of a group of reflexes for emptying hollow organs which are periodically filled. Thus, sacral autonomic impulses cause contraction of the rectum and distal colon and also contraction of the urinary bladder. In both instances the effects are induced reflexly by a stretching of the tonically contracted viscera by their accumulating contents. Waste from organic activities is thereby eliminated. Distension of the seminal vesicles, though associated with more elaborate reactions, stimulates the *nervi erigentes* of the sacral division, and may thereby result in behavior which reflexly leads to a discharge of the accumulated fluid. To what degree the contractions of the distended uterus can be brought into this scheme is not quite clear. The fact that parturition can occur normally in the absence of the sympathetic division¹⁷ indicates either that there is an intrinsic government of uterine contractions which is quite adequate, or that there are influences working by way of sacral fibers which have not yet been traced.

The functions of the *cranial division*, like those of the sacral, can be summarized as mainly a group of reflexes—reflexes protective, conserva-

tive, and up-building in their service. By narrowing the pupil of the eye the cranial division protects the retina from excessive light. By providing for the flow of saliva and gastric juice and by supplying the muscular tone necessary for the periodic contractions of the alimentary canal, it assures the essential basis for proper digestion and absorption of the energy-yielding material required for all bodily activity. By vagus control of insulin secretion it may play a rôle in the storage of glycogen in the liver. Further evidence of its conservative value is seen in the assurance of time for rest and recuperation of cardiac muscle by the tonic vagal slowing of the heart rate. The cranial division, like the sacral, has uncomplicated reflexes, such as the narrowing of the pupil, and likewise activities associated with affective states. The pleasurable taste and smell of food are accompanied by the so-called "psychic" secretion of the digestive juices, and by a tonic contraction of the stomach and intestines.

The two divisions—sacral and cranial—are similar in being largely subject to interference by striated muscle. Contraction of the bladder and rectum can be aided or frustrated by impulses from the cerebral cortex, much as the reactions of the pupil can be induced or modified by voluntary acts. Indeed, as a rule, the workings of the sacral and cranial divisions involve the coöperation of the cerebrospinal nervous system to a much greater degree than do the workings of the sympathetic division, because they are much concerned with external orifices surrounded by striated muscles.

THE RÔLE OF THE SYMPATHETIC DIVISION IN STABILIZING THE INTERNAL ENVIRONMENT

In considering the services of the sympathetic division it is important to recognize the truth of the dictum laid down by Claude Bernard that just insofar as there is assurance of uniformity and stability of the internal environment, the organism is freed from the influence of changes in the external environment. The rôle of the sympathetic division of the autonomic system in governing the conditions of the internal environment can be clearly demonstrated in animals (cats, dogs, monkeys) which have had the sympathetic system entirely removed.¹⁷ Let us consider some of the phenomena exhibited by such animals as compared with normal animals.

When a normal warm-blooded animal is exposed to cold surroundings there is an erection of hairs (if the animal is provided with that covering), a contraction of surface vessels which protects from heat loss, and a discharge of extra adrenin which accelerates metabolism and thus by production of extra heat serves to keep the temperature even.⁷ Because of this arrangement for stable bodily temperature, warm-blooded animals are liberated from the limitations of inactivity that are imposed on cold-blooded animals during the winter season. Sympathectomized animals are clearly defective when exposed to cold. Pilo-motor muscles are of course not under control and therefore the hairs are not erected. The smooth muscles of the blood vessels likewise are no longer

under nervous government. Cold has no local contractile effect on either of these structures. For these reasons there is no check on the heat loss from the body. Furthermore, the organism is unable to increase the secretion of adrenin and thereby to accelerate heat production when the body temperature tends to fall. The behavior of a sympathectomized animal in cold weather is in accord with this lack of physiological efficiency. During the winter it lives almost continuously in the neighborhood of sources of heat. If placed in a cold room having a temperature near freezing, the animal undergoes a rapid drop of the body temperature which brings about vigorous shivering. Shivering is the only resource, except exercise, that is left to protect sympathectomized animals from a seriously low temperature. It is noteworthy that what is lacking in such animals is the function of the sympathico-adrenal apparatus.

Not only does the sympathico-adrenal system protect against dangers from disturbing external conditions, it also protects against possible dangers from internal changes. Thus, as can be readily shown by giving insulin, the blood sugar may be reduced to a perilous degree. If it drops from approximately 100 mgms. per cent to 45 mgms. per cent, convulsions are likely to occur, and if the condition continues coma and death result. Ordinarily no such drop in blood sugar is permitted to occur. As soon as the concentration is reduced to a degree which approximates danger the sympathico-adrenal system is brought into action and sugar is liberated from the store in the

liver.¹⁰ The value of this arrangement can be easily demonstrated in animals from which the sympathetic has been removed or in which the adrenal glands have been rendered ineffective. Such animals have no means of increasing the blood sugar when it is reduced by insulin, and in consequence are extremely sensitive to action of that agent.¹⁷

Another internal situation from which dangers may arise is that of prolonged and vigorous physical struggle. Such struggle is accompanied by a great production of heat. The extra heat, which, if allowed to accumulate, would be disastrous, is eliminated by the pouring out of sweat on the body surface and the flow of blood through the surface vessels which have been cooled by evaporation of the sweat. Sympathetic activities are here always involved. Again, prolonged vigorous effort requires sugar as a source of energy. This is set free from the liver, —again by sympathico-adrenal influences. Furthermore, there is danger from the development of acid metabolites, especially lactic acid, arising from prolonged and vigorous muscular activity. This may result in markedly defective functioning of the neuromuscular system. It can be largely avoided by an abundant supply of oxygen which is used to burn the non-volatile lactic acid into volatile carbonic acid. The volatile acid, unlike the non-volatile, is easily discharged from the body. The extra oxygen is supplied to the tissues by a faster beating of the heart, by a faster blood flow owing to an increased blood pressure from splanchnic stimulation, and by the

availability of an additional number of circulating red blood corpuscles which has been set free from storage in the spleen. In all these adjustments the sympathetic or the sympathico-adrenal system plays an essential rôle. When animals are deprived of the service of this system, the adjustments are impossible. In consequence the ability of these animals to work is greatly reduced.¹

Other illustrations might be given to show the ways in which the sympathetic division serves to keep uniform and stable the internal environment despite the potency of both external and internal disturbing conditions. Whenever the exteroceptive system goes into action and upsets the steady state which prevails in the fluid matrix while the organism is at rest, the interoceptive sympathetic system at once becomes an agent for restoration of the normal state. Unless it is overwhelmed it is quite efficient in maintaining the fitness of the internal environment for continued activity of the organism.¹⁹

THE DISTURBING EFFECTS OF EMOTIONAL EXCITEMENT

It is a matter of some moment that the bodily changes which occur in great emotional excitement are similar to those which occur in association with strenuous physical effort. The heart beats faster, the blood pressure rises, blood sugar is set free from the liver, there is a discharge of extra corpuscles from the spleen, and there may be sweating.²⁰ These striking alterations in the excited individual are best explained as preparation for action.

That is, they are an exhibition of preparedness of the sympathetic division to protect the fluid matrix in case of struggle. Probably this association of sympathetic activity with excitement has developed in the course of myriads of generations of our ancestry. In wild life, where the struggle for existence is unmitigated, the emotion of fear is associated with the instinct to flee, and the aggressive feeling of rage is associated with the instinct to attack. If there is an attack, the organism attacked must either fight back or run. If there is flight, there is likely to be pursuit. In either situation the organisms involved may be engaged in a life-or-death struggle. Obviously the preparatory alterations of the body for such struggle would be useful.

For human beings who live in civilized society, the circumstances have been largely altered. There are occasions for great excitement and for the attendant bodily changes, but relatively few occasions for the struggle which naturally follows the excitement. Actual observations on students undergoing examination have shown that they are intensely wrought up and may have an increase of blood sugar to a degree that is seen in mild diabetes. In such conditions, also, digestion may be upset, the heart may beat at an unduly fast rate, and the other changes which we have been considering may be brought about. But there is no consequent action. The body prepares for a struggle when there is no struggle to be engaged in. The whole mechanism of reinforcing the body for great effort is set at work quite uselessly. The mechanisms which would keep

the internal environment fit now act in such a way as to be really disturbing. The result is that the complex group of emotional reactions which are valuable in more primitive conditions of existence may become a real menace.

The logical treatment of such a situation as has just been described may take two different directions. The situation may be regarded reasonably and the individual may say to himself, "There is nothing that I can do; consequently I will not get excited and stirred up. Being excited is proper when there is something that requires action, but that is not now." This sug-

gestion of a rational attitude may seem an impossible counsel of perfection, but actually tests have shown that it can be made to work. If, however, it does not work and the agitation continues, the physiological mode of dealing with the situation is that of recognizing that the changes owing to excitement are directed towards efficient activity. The changes can best be met by going into action. Through sane and vigorous exercise the emotional disturbances have their natural consequences and the organism is not disturbed but is maintained in a stable state.

The Autonomic Control of the Heart, Lungs, and Bronchi*†

By H. L. ALEXANDER, M.D., *St. Louis, Missouri*

IN this presentation, the control of the heart, lungs, and bronchi by the autonomic nervous system will be considered from the clinical viewpoint. To accomplish this, it would seem permissible and, indeed, necessary to review briefly the development of the clinical conception of the subject.

HISTORICAL

Prior to 1909, although anatomical and physiological investigations on the autonomic nervous system had progressed far, there had been only occasional reference to the possible application of this knowledge to clinical medicine.^{1,2,3,4,5} Higier⁶ contends that clinicians were slow to grasp the significance of the autonomic nervous system because injury to parts of its structural mechanism usually does no great harm, whereas a similar lesion in the cerebrospinal system causes damage that attracts far more attention.

The first comprehensive attempt to apply knowledge of the autonomic nervous system to clinical medicine originated with Eppinger. He, togeth-

er with Hess,⁷ was led to believe that certain constitutional abnormalities in man were due to a heightened tone of either the parasympathetic or of the sympathetic elements of the autonomic nervous system. By the use of pharmacodynamic tests, they separated individuals giving an exaggerated response to pilocarpine, a parasympathetic stimulant, from those who appeared sensitive to adrenalin, which acts specifically on the sympathetics. To the first group, the word "vagotonia" was applied since these individuals manifested such symptoms as bradycardia, sinus arrhythmia, bronchial asthma, cardiospasm, and other disorders produced by vagus stimulation. The second group manifested symptoms of sympathetic irritability.

This attractive innovation in clinical medicine was soon followed up by other investigators^{8,9,10} and promptly found to be erroneous in that, although abnormal responses to pilocarpine and to adrenalin were noted, these usually appeared in the same subject. Consequently, the precise separation of vagotonic from sympathotonic individuals found little confirmation. Despite this refutation, the work of Eppinger and Hess proved to be of great importance in that it directed attention to

*Read before the American College of Physicians, San Francisco, California, April 8, 1932.

†From the Department of Medicine, Washington University Medical School, and Barnes Hospital, St. Louis, Missouri.

the clinical possibilities inherent in an understanding of the autonomic nervous system. Moreover, these investigators emphasized the fact, known to physiologists for many years, that parasympathetic and sympathetic fibers innervating any given organ usually have an opposing action.

There was born, then, a rather simple and elementary clinical conception of the autonomic nervous system, based essentially on the idea that this system is made up of two elements each of which opposes the other in its action. This is still the popular clinical viewpoint, and every therapeutic measure directed at autonomic control is based on this theory.

Since Eppinger and Hess' first contribution, a voluminous bibliography dealing with the study of the autonomic nervous system in man has been built up. Obviously, methods are limited. At first, observations of the effects of various specific drugs were continued. Eventually, however, largely through physiological research, it became recognized that the results obtained were unreliable because many drugs do not have the same degree of action on all the fibers of the system tested, and some drugs are reversible in their action.¹¹ Many other findings that were determined by physiologists were applied to man. Cognizance was taken, particularly by Dr. Cannon, of the part played by the autonomic nervous system in maintaining the body economy under conditions of stress. Important information came from observations made during operative procedures on patients.

In 1926, a symposium on the auto-

nomous nervous system in man was held before the Seventh International Neurological Congress in Paris, wherein a review of the subject was presented.^{12,13} By that time it had become evident that the clinical viewpoint required revision, for it was appreciated that in many respects autonomic control in man appears to be different from that in lower animals. In man there is more variability in response to specific drugs that are used to test sympathetic and parasympathetic irritability, and controls are difficult to establish. Also, surgical procedures on the autonomic nervous system at times produce effects quite contrary to the expected. Furthermore, many pathological conditions in patients introduce new problems of autonomic nervous system behavior unmatched by experience with lower animals. Recently, attention has been paid to these facts and a more guarded attitude concerning autonomic control has developed. The discrepancies which have arisen between clinical observations and physiological understanding of the subject as yet seem to justify nothing but an open mind.

CONTROL OF THE HEART

In considering control of thoracic organs by the autonomic nervous system, emphasis is placed on the fact that this system is essentially efferent in its direction and regulatory in its action. It regulates contractions of the muscles and secretions of the glands that it innervates. It does this largely in response to afferent and central stimulation. Although afferent fibers travel within autonomic nerve trunks,

they probably are not an integral part of the autonomic system. Consequently, this presentation is limited to the effects of efferent impulses, however they may be initiated.

The efferent nerves to the heart come from the sympathetics and from the vagus trunks. Sympathetic innervation is derived from the superior, middle and inferior cervical ganglia and the first to the fifth or sixth thoracic ganglia, from which fibers reach the two cardiac plexuses in the aortic wall. Fibers running to the heart from dorsal ganglia as low as the fifth have been discovered only recently

both in lower animals and in man.^{14,17,18} Cardiac branches from the vagi intermingle with those of the sympathetics in the cardiac plexuses and both then travel down the aorta to the heart. Although they may be traced along the coronary arteries, there is uncertainty concerning their identification in the heart wall. This is due to the presence there of intrinsic nervous tissue made up of ganglia and fibers which are difficult to differentiate from filaments of the extrinsic nerves.

Anatomical and physiological research suggests that the auricles and the auriculo-ventricular bundle are

FIG 1. Schematic drawing of the extrinsic nerves to the heart

supplied both by sympathetic and parasympathetic fibers, whereas the ventricles receive largely sympathetic and little, if any, parasympathetic innervation.¹⁷ In mammals, it appears that the right vagus manifests its action mainly on the sino-auricular node (the "pacemaker"), and the left vagus particularly on the bundle of His.

The autonomic nervous system mediates impulses which modify the rate and force of the heart beats and the conductivity of cardiac muscle. In general, parasympathetic or vagus impulses slow the heart, and sympathetic impulses accelerate it. These actions are influenced by drugs and physical agents, a fact made much use of in therapeutic considerations of various abnormalities of cardiac action. Lewis¹⁸ states that in man far more is known concerning the vagus participation in these processes than is known of the rôle of the sympathetics.

INFLUENCE ON HEART RATE

In particular, various abnormalities in rate and rhythm are influenced by the autonomic nerve impulses to the heart. Several examples may be stated. In congestive heart failure, digitalis slows the rate not only by increasing the tone and contractility of cardiac muscle, but also by stimulating the vagus both centrally and peripherally. As a result, the sino-auricular node reduces its tempo and the vagus fibers in the bundle of His serve as a brake to auricular impulses on their way to the ventricles. Relief of paroxysmal tachycardia by pressure over the vagus nerve in the neck is due presumably to a flooding of the auricle with inhibi-

tory impulses. The ectopic focus temporarily loses its irritability, which permits the pacemaker again to resume control and normal rhythm to become reëstablished. Although vagus pressure in the neck may be, in reality, a carotid sinus effect,¹⁹ pressure over the eyeball, which often achieves the same result, doubtless acts reflexly through vagus stimulation. Of interest is a recent observation that pressure over the right vagus slows the heart more effectively than pressure over the left. The explanation offered is that the right vagus, particularly, influences the pacemaker.

The tachycardia of organically normal hearts, that occurs during fright and other emotional disturbances, is known to be due largely to sympathetic stimulation from adrenal secretion.²⁰ Of interest, in this connection, is the type of heart action that is seen in patients with so-called "effort syndrome". Many of these individuals have a tachycardia; others have an abnormally slow heart. Fraser and Wilson²¹ tested a group of such patients with small doses of pilocarpine and adrenalin and obtained an exaggerated response to each. Such a reaction has been considered by many to represent an autonomic imbalance which clinically presents symptoms and signs that are usually interpreted as a neurosis.

In cases of tachycardia not associated with congestive heart failure, there is no drug which will adequately slow the rate through vagus stimulation. No parasympathetic hormone analogous to adrenalin has as yet been definitely demonstrated, although

Loewi²² has shown that a parasympathetic stimulant may exist. Such drugs as pilocarpine, physostigmine, and apomorphine either exert their influence more on parasympathetic fibers elsewhere than on those of the heart, or side effects prevent their routine use. Acetyl choline is a powerful parasympathetic stimulant; and a choline derivative has been used by Stepp²³ with effect in cases of paroxysmal tachycardia. As yet, however, choline derivatives have not found therapeutic favor.

When bradycardia occurs in the presence of organic heart disease, it is almost always due to heart block. Under these circumstances, especially in complete block, advantage has been taken of the fact that the ventricles have sympathetic innervation, and temporary benefit from the use of adrenalin has been reported.^{24,25} In organic heart disease, digitalis may bring on heart block through its action on the vagus. In these cases, release may be secured with atropin. Although experimentally heart block may result from vagus stimulation alone, this is a questionable clinical manifestation.²⁶

Bradycardia in the absence of heart disease is essentially parasympathetic in origin. This is exemplified by its appearance in convalescence, in youth, and in intracranial pressure wherein the vagus presumably is stimulated centrally. Cardiac arrhythmias of vagus origin are well known. Lewis²⁷ recognizes a vagus effect wherein there is an abrupt and profound slowing of the heart, associated with an independent lowering of blood pressure. This

combined disturbance is often responsible for attacks of faintness and actual loss of consciousness. According to Lewis, it is, by far, the commonest cause of fainting attacks in both men and women, and occurs both in individuals otherwise healthy and in those who suffer from heart disease in its several forms.

ANGINA PECTORIS

The autonomic nervous system is involved either directly or reflexly in cardiac abnormalities other than disturbances in rate and rhythm. Of particular clinical interest in recent years, has been the rôle of the autonomic nerves in angina pectoris. Various procedures designed to block both efferent and afferent pathways in this condition have produced a wealth of data, much of which is difficult to interpret. A particular handicap is our lack of accurate knowledge concerning the source of pain. The successful results obtained by removing the lower two left cervical sympathetic ganglia, and by injecting alcohol and procaine about the thoracic ganglia, may be attributed merely to an interruption of pain impulses traveling from the heart through or near to these structures. This implies no participation of autonomic fibers.

There are instances, however, where it appears that sympathetic stimulation influences the pain of angina pectoris. Leriche²⁸ isolated the lower portion of the left cervical sympathetic chain in a patient who had never had angina. Electrical stimulation and pinching of the left inferior cervical sympathetic ganglion caused an intense pain over the precordium in the second and third

intercostal spaces. Novocainization of the ganglion prevented this effect. It is interesting that in two similar patients, stimulation of the superior pole of the ganglion provoked a very intense radiation of the pain into the arm of the corresponding side; whereas when the lower half was stimulated, the precordial region was most affected. In still another patient subject to angina pectoris, an attack occurred before the stellate ganglion had been completely exposed. Infiltration with novocaine about the ganglion produced immediate cessation of pain. Although it is quite possible in this instance that novocaine blocked pain impulses traveling to the cord, it is difficult to interpret the results in the other cases. Possibly electrical stimulation of the lower cervical sympathetic ganglion overflowed into contiguous afferent

nerves, but one would hardly expect to excite afferent impulses from the arm in this location.

Another clinical indication of the possible participation of efferent fibers in angina pectoris is the relief of pain that has resulted after removal of the superior cervical sympathetic ganglion alone.²⁹ Although sensory fibers are found high in the sympathetic chain,³⁰ fibers in the superior cardiac nerve from this ganglion are largely efferent. There has been a sufficient number of successful results in angina pectoris from superior cervical ganglionectomies to warrant attention.^{31,32} The implication has been that in patients so relieved, efferent impulses from the superior cervical ganglion produced a peripheral effect that caused precordial pain. As an explanation, it has been suggested repeatedly³³ that the superior

FIG. 2. Schematic representation of nerve pathways from the cervical ganglion to the heart.

cardiac nerve carries vasomotor fibers to the coronary arteries, and that sympathetic stimulation causes coronary spasm. A disturbing element of this theory, however, lies in the fact that numerous investigators^{34,35,36,37} agree that in mammals, at least, sympathetic stimulation does not cause constriction of the coronary arteries, but dilatation, whereas it is vagus stimulation that induces contraction.

If angina pectoris be due to coronary spasm, then cervical sympathectomy for its relief, although successful clinically in many cases, is a highly illogical procedure according to physiological experimentation. The answer to this riddle must await further knowledge of the autonomic nervous system in man and, especially, of how it functions in disease.

CONTROL OF THE LUNGS

The autonomic nervous system controls the lungs largely through its action on the bronchi. Parasympathetic

monary plexuses which communicate. From these plexuses, fibers follow the bronchi and bronchial vessels in their ramifications far down into the lungs in an elaborate intrinsic system of networks in which many small ganglia appear.

There is general uniformity of opinion that peripheral vagus stimulation causes bronchoconstriction, and recently it has been shown that mucous secretion from the bronchial glands occurs also.³⁵ Vagus stimulation likewise inhibits constriction of the bronchial vasculature. Sympathetic stimulation, on the other hand, brings on bronchial dilatation, diminished mucous secretion, and constriction of the bronchial vessels. There is little evidence that the autonomic nervous system exerts important vasomotor control over the pulmonary vessels. This does not hold true for the bronchial artery which is derived from the aorta. Schematically, autonomic control of the lungs is represented as follows:

TABLE I

Bronchial	Vagus Stimulation	Sympathetic Stimulation
Muscles	Contraction	Relaxation
Glands	Secretion	Inhibition
Vessels	Dilatation	Constriction

innervation is derived from the pulmonary branches of the vagus nerves, and sympathetic impulses arise in the second, third, and fourth thoracic ganglia. Both vagus and sympathetic fibers intermingle at the roots of the lungs to form the anterior and posterior pul-

Although normal respiration is essentially a voluntary process involving cerebrospinal nerve impulses, yet respiratory movements are subject to voluntary control only within limits. It has long been known that the vagus has an influence over the process of

breathing.³⁹ Section of both vagi in the neck immediately increases the amplitude of inspiration and retards the rate. There is little doubt that vagus section interrupts afferent impulses which influence respiratory movements through central action. Whether any important efferent fibers necessary to normal respiration are affected, is a moot question. Recently, much evidence has been presented to indicate that the bronchial muscles contract during expiration and thus assist in expelling air from the lungs. Miller,⁴⁰ from his reconstruction models of the bronchi, thought this to be so. Hudson,⁴¹ by serial X-ray studies, believes that a peristaltic motion of the bronchi during breathing can be visualized. Luisada,⁴² by placing an electrode far down the bronchial tree, has secured electrical tracings which, he presumes, record action currents in the bronchial muscles during respiration. He terms these tracings "Electrobronchograms". They show a definite vagus effect during expiration which has been found in man as well as in lower animals. Heinbecker⁴³ and Mac-lin⁴⁴ also believe that during inspiration the bronchi lengthen and, at the same time, widen. Although it would appear that these actions involve efferent nerve impulses, it has been suggested that the numerous ganglia within the bronchial walls may, in part, initiate muscular movement. Until further information on this interesting process becomes available, one must consider the question of control of respiration through efferent nerve fibers as yet unanswered.

PULMONARY DISORDERS

The autonomic nervous system participates reflexly in many diseases of the lungs and bronchi. This is exemplified by such reflex manifestations as digestive disturbances and bradycardia,⁴⁵ that occur in pulmonary disorders. Likewise, in asphyxia, the autonomic nervous system is called into play to widen the bronchi through sympathetic stimulation, and thereby facilitate breathing.⁴⁶ An outstanding example of autonomic disturbance is bronchial asthma.

For years, there had been controversy as to whether an asthmatic paroxysm was due to spasm of the bronchial muscles, to edema of the bronchial mucosa, or to hypersecretion of the bronchial glands. With a better understanding of the control of bronchial structures through the autonomic nervous system, it became apparent that all three factors play a part, for each results from vagus stimulation. (Table I) In allergic asthma, it appears that an attack is initiated by direct stimulation of the nerve endings in the bronchi, whereas in so-called emotional asthma, nasal asthma, and other reflex asthmas, impulses travel through the vagus nucleus to the bronchial muscles, blood vessels, and glands. Of interest is the fact that patients with bronchial asthma have been shown to give exaggerated responses both to pilocarpine and to adrenalin.⁴⁷ This indication of autonomic imbalance is probably responsible for the theory that asthma is essentially a neurosis. Since an asthmatic attack appears to be entirely a vagus

or parasympathetic effect, one would predict that adrenalin, through its powerful stimulating action on the sympathetics, should be a useful therapeutic drug. That this is so, is well known. Atropin, by paralyzing vagus nerve endings, is likewise effective, but it must be given in doses far larger than those ordinarily employed.

As surgery of the autonomic system developed, it came to be applied to cases of bronchial asthma, and considerable data on this type of treatment has accumulated.⁴⁸ The results of vagus nerve section have been indifferent. This, perhaps, is the expected result. Cases of reflex asthma should be helped by this procedure, for efferent impulses descending from the vagus nuclei are interrupted. In allergic asthma in which vagus nerve endings are stimulated directly, section of the nerve trunk would not be expected to cause immediate cessation of attacks, at least, not until the distal end of the nerve had degenerated. Cervical sympathectomies for the relief of bronchial asthma have been performed in many cases. Inasmuch as asthma is evidently a vagus effect which is controlled by sympathetic stimulation, destruction of sympathetic pathways appears to be a very unreasonable pro-

cedure. Moreover, since sympathetic control of the bronchi is derived from the second, third, and fourth thoracic ganglia, one is at a loss to explain the possible effect of cervical ganglionectomy. The surprising fact is that this operation, beyond question, has been proven to be of benefit in many cases.

From this, one may infer that our understanding of the mechanism of an asthmatic attack is incomplete. It is more probable that our ideas concerning the behavior of the autonomic nervous system in man, and especially in disease, are elementary. To make them more complete, it becomes necessary to study human response in each instance where data derived from animal experimentation is applied directly to man. Consequently, the clinical approach to the subject is developing more and more into an effort to explain phenomena actually observed by operation and at the bedside. These methods of study have already revealed facts which may prove to be of much significance. They offer promise of increasing contributions to the wealth of knowledge of the autonomic nervous system already assembled through anatomical and physiological research.

The Results of Sympathectomy in the Treatment of Peripheral Vascular Diseases, Hirschsprung's Disease, and Cord Bladder*†

By ALFRED W. ADSON, M.D.; *Rochester, Minnesota*

SYMPATHECTOMY in its various forms is growing in its field of usefulness as our knowledge of the physiology of the autonomic nervous system is increased. The altered function of this nervous system gives rise to and determines the course of many diseases; for, in addition to carrying afferent pain fibers, the autonomic nervous system influences blood flow, smooth muscle activity and glandular function. The correlation of disease with its anatomic and physiologic aspects may give rise to various opinions; hence, one should analyze carefully all facts before advocating or condemning the newer ideas concerning the disease and the method of treatment. Progress has been made in the surgical treatment of angina pectoris, spastic lesions in striated muscles, and trophic and painful lesions of the extremities. Most satisfactory results have been accomplished by sympathetic ganglionectomy and trunk resection in the treatment of peripheral vascular diseases, such as Raynaud's

disease,^{1-5,16,20,22,26} thromboangiitis obliterans^{2,22,26} with vasomotor spasm of the collateral arteries, acral scleroderma^{7,17} developing subsequent to Raynaud's disease, and periarticular arthritis^{8,8,9,31,60,61,62} in the hands and feet, associated with vasospastic phenomena of cold, clammy, pale, and cyanotic extremities. The sectioning of sympathetic fibers to the internal sphincter muscles of the rectum and bladder,^{36,57,72,73} and of sympathetic fibers carrying inhibitory impulses to the large bowel and to the detrusor muscles of the bladder has materially aided the expulsive forces of both the rectum and bladder, thus offering assistance in the treatment of congenital megacolon and cord bladder.^{43,44} Trophic changes of both organs are likewise improved, since vasomotor fibers which are intermingled with the presacral and mesenteric nerves are also necessarily sectional.

Numerous studies are being carried on by various investigators in the hope of relieving visceral pain,^{10,28,34,63} malignant hypertension,⁵⁹ asthma,^{50,53} retinitis pigmentosa,⁶⁷ optic atrophy, nephritic conditions,^{30,62} cardiospasm, pylorospasm,⁴⁴ and of influencing endocrine secretions. Many of these

*Read before the American College of Physicians, San Francisco, California, April 8, 1932.

†From the Section on Neurologic Surgery, The Mayo Clinic.

endeavors will probably be fruitless but it is fair to assume that a *central* influence, acting through the autonomic nervous system, is directly or indirectly responsible for the production of these diseases.

I shall not attempt to analyze in detail my colleagues' and my own experience in the treatment of these various disorders, for this would necessitate the inclusion of a rather large series of cases, which have been previously reported by various members of the staff of The Mayo Clinic.

ANATOMY

The sympathetic nervous system is an aggregation of ganglia, nerves, and plexuses through which the viscera, glands, heart, blood vessels, and smooth muscles in other situations receive their innervation. The most conspicuous feature of the system is a pair of ganglionated nerve cords, or sympathetic trunks, which extend vertically through the neck, thorax, and abdomen. Each sympathetic trunk is composed of a series of ganglia bound together by short nerve strands. Every spinal nerve is connected with the sympathetic trunk of its own side by one or more gray rami communicantes through which it receives sympathetic fibers for the control of blood vessels, of sweat glands, and of the smooth muscle of the hair follicles situated within the territory of its distribution. The majority of the nerve fibers that take origin in the ganglia of the sympathetic chain are distributed through the gray rami and the spinal nerves.

The thoracic and upper lumbar nerves are connected with the sympathetic chain by white as well as gray rami communicantes. These white rami contain both afferent and efferent fibers. The latter take origin from cells in the gray matter of the spinal cord, travel through the ventral root and white rami, and enter the sympathetic system to terminate in synaptic relation with the nerve cells found in the sympathetic ganglia. They are often designated as preganglionic fibers, while those fibers which arise in the ganglia

and relay the impulses onward are called postganglionic. The gray rami contain postganglionic fibers and the white rami, preganglionic fibers.

The majority of the preganglionic fibers turn either upward or downward in the sympathetic chain, and run for varying distances within it before ending in its ganglia. The cervical sympathetic trunk is composed exclusively of preganglionic efferent fibers, derived through the white rami from the upper thoracic nerves and ascending to terminate in the cervical sympathetic ganglia. The lumbar and sacral portions of the trunk are composed in the major part of descending fibers derived through the white rami from the lower thoracic and upper lumbar spinal nerves.

Those fibers of the white rami which are concerned with the innervation of the abdominal viscera pass into the splanchnic nerves and end in the celiac ganglion. They reach the splanchnic nerves after passing through the lower half of the thoracic sympathetic chain, but they are not interrupted in the chain ganglia through which they pass. They eventually reach the viscera by following the arterial supply to these organs, or by direct extension as postganglionic fibers from the various plexiform arrangements or sympathetic ganglia. The thoracic viscera receive their postganglionic sympathetic rami from the upper thoracic sympathetic chain in a similar arrangement.

The autonomic nervous system, in addition to the sympathetic thoracolumbar outflow, contains two streams of preganglionic visceral efferent fibers called the parasympathetic system; the cranial stream arises from the third, seventh, ninth and tenth cranial nerves, the sacral stream from the second, third, and fourth sacral nerves.

According to Ranson, and Kuntz,⁴¹ most of the sympathetic nerves contain, in addition to the fibers already considered, sensory fibers which convey impulses from the viscera to the spinal cord. These sensory fibers have their cells of origin in the spinal ganglia and reach the sympathetic system by way of the white rami. Visceral reflexes therefore travel arcs of at least three neurons each. The impulses reach the spinal cord along visceral afferent fibers through

white rami and the dorsal roots. These afferent sympathetic fibers end in sympathetic ganglia, and the impulses which they carry are relayed to involuntary muscle and glandular tissue by postganglionic fibers. The ganglia of the sympathetic trunk do not serve as reflex centers, but only as relay stations⁵² in the conduction pathways from the spinal cord to the viscera.

The vasomotor innervation of the arteries of the extremities and of the trunk was once believed to be centrifugal⁴⁶ in its arrangement, but the work of Kramer and Todd, and Potts has proved rather conclusively that the distribution corresponds to the musculo-cutaneous somatic distribution, except for short distances where the principal arteries leave the aorta. Therefore, it is apparent that complete vasodilating effects are accomplished only when all vasomotor fibers are interrupted by section of a sympathetic trunk, by ganglionectomy, or by complete ramisection.

SURGICAL PROCEDURES

Surgical procedures affecting the sympathetic nervous system date back to 1899, when Jaboulay attempted to relieve painful conditions of the lower extremities by performing periarterial sympathectomy. This procedure was not given serious consideration until Leriche reported his experiences in 1913, when he advocated periarterial sympathectomy for numerous peripheral vascular, trophic, and painful lesions. Following his teaching many surgeons became interested in the subject of sympathectomy and employed his procedure for similar lesions in addition to attempting the treatment, by sympathectomy, of exophthalmic goiter, glaucoma, and epilepsy. Jonnesco removed the stellate ganglion for angina pectoris by the anterior-superior approach with moderate success. In 1923 Brüning employed Jonnesco's operation in the treatment of one case of Raynaud's disease and one case of scleroderma, both of the upper extremities, and reported success. Unfortunately, a similar good result has not been obtained by other surgeons, including myself. It is true that periarterial sympathectomy and removal of the stellate ganglion by the Jonnesco method did afford some relief of symptoms and

improvement of the circulation but it failed to give complete relief.⁴⁶

Royle⁶³ in 1924 advocated and performed ramisection for relief of spasticity of the muscles of the extremities, but difficulty was encountered in duplicating his results. I have obtained some reduction of the spasticity by abdominal transperitoneal lumbar sympathetic ganglionectomy and trunk resection, which I first performed May 20, 1924. I am inclined to believe, however, that the results are due to the increased blood supply following thorough interruption of vasomotor fibers, rather than to section of sympathetic nerves to striated muscle, for numerous investigators doubt the existence of sympathetic innervation of striated muscle in mammals.

Orbeli believes that the sympathetic fibers augment cerebrospinal responses. Von Gaza in 1924, Archibald in 1928, and Scrimger in 1929 performed, with some success, paravertebral ramisection of the splanchnic nerves for visceral pain. This problem is undergoing much investigation at this time.

Davis and Kanavel,²¹ and I were among those who attempted to duplicate the results Royle reported in 1924. On May 20, 1924, I employed the method mentioned above, and it was following this that I observed that the temperature of the skin of the lower extremities remained permanently increased. Royle reported that the cutaneous temperatures in the first case in which he performed ramisection were increased only temporarily, but later stated that a slight increase remained permanently. This suggested that the more extensive operation of ganglionectomy and trunk resection included all of the vasomotor fibers to the extremities. This phenomenon reopened the field of surgical treatment of peripheral vascular diseases. Davis and Kanavel, Diez, and Fulton subsequently reported experiences similar to mine following ganglionectomy and trunk resection.

In 1924 preoperative and postoperative calorimetric studies were made by Brown¹⁷ of patients on whose sympathetic apparatus I operated for spastic conditions. The report showed that following operation elimination of heat had increased on an average of 400 per cent, and that this increase had remained permanent. These data suggested

the practicability of applying surgical procedures in vasospastic diseases, and I performed such an operation with success on March 19, 1925, in a case of Raynaud's disease of the lower extremities. Subsequent study of this patient and of others has shown that vasodilatation has remained, and that the patients have been free from all symptoms. I first carried out cervicothoracic ganglionectomy and trunk resection by the posterior approach on July 31, 1928. Following success in the treatment of Raynaud's disease patients with other diseases in which vasospastic phenomena were manifested were likewise subjected to the operation. It was necessary, however, before such operations could be undertaken that some method be provided of determining preoperatively the degree of vasomotor spasm present and whether sufficient relaxation of this spasm was possible to justify the employment of surgical procedures to secure such relaxation.

Brown¹⁴ found that some aid in answering these questions could be obtained from the study of capillary behavior in the affected extremities but that a more reliable *vasomotor index* resulted from determination of the possible variations in blood flow to the extremity as indicated by variations in the skin temperature under standard conditions. Therefore, Brown¹⁵ introduced studies of cutaneous temperature as a vasomotor index, arguing that unless the peripheral cutaneous temperature could be increased 3°C. by regional or spinal anesthesia or increased two or more times the increase of the mouth temperature following intravenous administration of a foreign protein, operation on the sympathetic nerves was not indicated. These deductions were based on postoperative results obtained during the investigative study since it was noted that the increases in temperature observed before operation could be reproduced by sympathetic ganglionectomy and trunk resection. This result indicated that the actual flow of blood to the extremity had been increased by the operation. Utilizing this method of selection cases of thromboangiitis obliterans, with vasospasm of the collaterals, acral scleroderma, and atrophic arthritis, have thus been treated by the neurosurgical staff members of The Mayo Clinic.

Wade, and Wade and Royle in 1927 advocated ramisection for congenital megacolon. Their technic, slightly modified, was employed with complete success in three cases by Judd and the author, and subsequently was modified again and employed with success by Rankin and Learmonth. In 1930 Learmonth developed a surgical procedure for sectioning the presacral nerve in selected cases of incontinence of urine and trophic lesions of the bladder. C. H. Mayo and Devine have suggested and carried out sections of nerves to the stomach and pylorus for duodenal ulcer and pylorospasm, and Pieri has sectioned splanchnic nerves for gastric disorders.

RAYNAUD'S DISEASE

Raynaud's contributions, in 1862 and 1874, demonstrated that gangrene could develop in the digits without occlusion or demonstrable organic disease of the principal arteries. Bernard Schrader, in 1629, described a symmetric, recurring form of gangrene in the extremities of a young girl. The disease was not considered to be a vasomotor phenomenon until Raynaud called attention to the local asphyxia and cyanosis which preceded gangrene. Two schools of thought prevail concerning the underlying causes of Raynaud's disease. One holds that phenomena of vasomotor spasm involve small arteries, arterioles, and probably capillaries and venules; that the vasoconstrictor impulses are of central origin; and that the local responses to heat and cold are normal reflexes carried by vasomotor fibers, and are imposed on arteries and arterioles, producing pathologic states of contraction. The other school, the chief exponents of which are Krogh, and Lewis¹⁷ in collaboration with Kerr, holds that the defective circulation is due to fault of the digital arteries and vessels of smaller caliber, without

spasm of the veins, and that the phenomena are produced by cool temperatures and are relieved by heat. Lewis stated that these phenomena are the results of abnormality of the arteries, that this abnormality displays itself in hypersensitivity to reflexes initiated by relatively low temperature, and that the effects of cold are not produced through the intervention of the nervous system.

Etiology. The etiology is unknown. The influence of heredity, according to Monroe, may be made out in approximately 8 per cent of the cases. Persons of subnormal vasomotor type and of asthenic tendency are those who develop symptoms of true Raynaud's disease. The condition occurs more frequently in females than in males. Of Brown's patients 80 per cent were females and in Monroe's review of cases 62.6 per cent were females. The average age incidence according to Monroe's report was 30.9 years for both sexes.

Substantiating the argument that Raynaud's disease is primarily of central origin is the fact that Brown and I have seen it afflict patients who have lived in extremely hot regions, and have failed to see the symptoms subside when patients have moved from cold to hot climates. We have seen the changes in color of the skin take place in patients who have been subjected to severe emotional strain and in those who have become excited while in a hot room. We have also noted the failure of color changes to occur when patients have been exposed to cold and at the same time have been subjected to induced fever. The results of interruption of vasomotor

fibers constitute even more conclusive evidence that Raynaud's disease is of central origin and that the local changes in the extremities are controlled by vasomotor fibers. Horton and Craig have been able to produce these results experimentally. Following a successful operation the affected extremity becomes warm and pink and remains so permanently. The changes in color characteristic of asphyxia and cyanosis permanently disappear and cannot be brought on by exposure to cold or to emotional stimuli. Wagener has demonstrated that after cervicothoracic ganglionectomy and trunk resection in Raynaud's disease the retinal arteries and veins dilate from one and a third to one and a half their preoperative size. This dilatation is permanent. At the clinic we have had occasion to re-examine many of our patients, months and years subsequent to operation. In addition we have had the opportunity to measure and to compare the retinal arteries and veins of a man who underwent resection of the stellate ganglion on one side for anginoid pain eighteen years before, and we found that the arteries and veins on the side on which operation had been performed were one and a half times as large as those on the side on which operation had not been performed.

In partial support of Lewis' position may be cited the observation by Simpson, Brown, and Adson in a case of Raynaud's disease of the recurrence of cyanosis in the distal end of a digit on which there had been an ulcer, in spite of previous thorough operative interruption of the vasomotor fibers. This recurrence may have resulted from hypersensitivity of the arterioles

and capillaries, but I am more inclined to believe that it was due to faulty arterial circulation resulting from the capillary and arteriolar thrombosis, which gave rise to the primary ulcer. Recurrence of symptoms and of changes in color of the upper extremities were seen to occur when vasomotor fibers were missed, and considerable difficulty has been encountered in perfecting a surgical procedure that would thoroughly interrupt all of the vasomotor fibers to the arteries of the fingers and hand. The operative results following resection of the second, third, and fourth lumbar sympathetic ganglia, and of the intervening trunks have, however, always been successful. It is true that ulcers are much less common on the toes than they are on the finger tips; the toes are exposed less than the fingers to environmental temperature. It is apparent, however, that the surgical results depend directly on the thoroughness of the operation. This can be determined by the sweating test, since the sympathetic fibers to the sweat glands and pilomotor muscles are sectioned with the vasomotor fibers; they are closely associated, and cannot be separated at the time of operation. In the sweating test, dry heat must be employed and not pilocarpine, for pilocarpine is capable of stimulating the sweat glands directly and will produce secretions independent of the sympathetic innervation.

Pathologic Physiology. The underlying disturbances which produce the changes in color are easily studied by microscopy of the capillaries of the nailfold, and have been described by Muller, Parrisius, and Brown.¹⁴ In

the stage of pallor few capillaries are visible, filling of the loops with blood is incomplete, and the capillaries have a segmented or broken appearance. The blood contained in the capillaries is static²⁹; blood is not observed entering the capillary loops from the arterioles. The collecting venules are usually invisible, or contain small amounts of blood. In the stage of cyanosis blood is admitted into the capillaries both from the arterioles and by retrograde flow from the venules. The blood enters the capillaries in the form of small segments. The capillaries become dilated, an increased number of them is visible, and the blood in the loops is stationary, or flow occurs only after long intermissions. There is gradual deoxidation of the capillary blood, with increasing cyanosis. The capillaries may become greatly distended and may lose their characteristic shape. The collecting venules become dilated. With recovery, whether it is spontaneous or is induced by increasing the local or environmental temperature, the arterioles open, the flow of blood in the capillary loops becomes rapid, and the color of the blood changes to bright red. The stage of rubor, then, is due to a large number of open capillaries and venules containing red oxygenated blood. Many of these vessels remain to some degree dilated.

A summary of these studies corroborates in a striking manner the clinical deductions which were made by Raynaud on this mechanism. As he surmised, there is, in the stage of pallor or syncope, spasm of the arterioles, capillaries, and venules, the degree of pallor depending on the completeness of the spasm. The stage of

cyanosis is due to partial relaxation of the venules, with retrograde flow of blood in the capillary loops. Concomitant opening of the arterioles has been observed also, but the relaxation is not complete enough to allow the resumption of the usual flow. All gradations in behavior are noted in different cases; this amply explains the variations in color observed in certain subjects. Areas of moderate cyanosis may appear on one finger, and on another deep cyanosis may remain, or, in one area of skin there may be recovery, with return to normal pink or rubor, and the surrounding skin may be cyanotic.

Prognosis and Course. The prognosis of Raynaud's disease is subject to wide variations. As far as is known, it is never in itself a cause of death. In our experience, death has been due to the consecutive or the subsequent development of an entirely different disease. In mild cases, with local syncope or mild grades of cyanosis of the digits, there may not be any change over a long period of years. Many patients have been observed who have had vasomotor disturbance for more than ten years and yet have not suffered actual pain, trophic lesions, or progression of the disturbances of color. The previous course of the malady is probably of importance in considering the prognosis. In mild cases, in which the condition has remained unchanged for two or three years, the prognosis is usually good, and reassurance may be the only advice necessary. More usually there has been gradual progression from the stage of syncope; more digits have become involved, perhaps the entire

hand; and the condition has advanced into the stage of cyanosis, or syncope has alternated with cyanosis. Then, after variable periods of time, there may be gradual transition into a condition of chronic cyanosis of the extremities. Intermittent recovery of the parts is now less complete, and when recovery does take place it is accompanied by excessive sensations of heat and by excessive redness. Sensitivity to environmental temperature becomes more acute and the paroxysms are induced by slight variations in temperature, even during the summer months. Pain, numbness, or dull aching during the period of syncope and cyanosis are the rule. Small, dry ulcers of the skin of the digits may appear. In this primary type of case the prognosis is not good from the standpoint of spontaneous cure. The condition usually persists, and although it does not progress to the point of serious gangrene, yet it constitutes real disability to the patient. In the rarer forms, in which gangrene supervenes early in the course of the disease, the prognosis is most grave from the standpoint of preservation of the digits. In considering the prognosis, the important factor is the rate of progression of the disease in the first two or three years. Brown and I have observed that if at the end of this period trophic changes have not appeared, usually they will not appear later; and that long periods of remission may occur without known cause. This substantiates the argument that the disease is of central rather than of peripheral origin, and that its manifestations depend on the sympathetic reserve and the emotional stress of the patient.

Symptoms. Wide experience with various forms of vascular disease of the extremities allows separation of the cases presenting vasomotor disturbances of the spastic type into four groups.

First, there is a fairly large group of so-called normal persons, predominantly females, who have cold moist and clammy hands and feet associated with such disturbances as a mild degree of pallor in symmetric single digits, the so-called dead finger, or slight cyanosis. These persons are frequently of the asthenic type and suffer easily from cold. The surface temperature of the extremities is subject to wide fluctuations, depending on variations in environmental temperature. Such manifestations do not constitute a disease, and the physician is rarely consulted unless the changes in color are striking. These subjects are classified by Muller as having a "vasomotor constitution". At the clinic, we have designated them as suffering from subnormal vasomotor states.

Second, there are gradations from these so-called normal states to those in which the disturbances in color in the extremities are more profound, frequently paroxysmal, and occur even when the environmental temperature is not so low. Attacks of pallor may be followed in a period of months by more or less chronic states of cyanosis; or pallor and cyanosis may alternate for some time. The signs and symptoms are of sufficient intensity for the patient to seek advice from the physician. The symptoms usually consist of numbness and occasionally partial anesthesia during the period of local asphyxia, and of extreme coldness

during the stage of syncope. Dull aching distress is present during the periods of both syncope and cyanosis. With high environmental temperature, the hands become excessively warm and red, accompanied by sensations of burning.

Third, there is another group of persons who have further aggravation of the disturbance. The attacks of pallor become more intense and more painful, or a condition of chronic cyanosis or asphyxia supervenes; temporary recovery is much more difficult to effect. The changes in color are induced by emotional stimuli and by the least change in temperature. The hands and feet frequently become swollen and puffy. Trophic disturbances then appear, consisting of minute regions of gangrene in the tips of the digits, with symmetric distribution.

The fourth group consists of the more severe, but much rarer, type of case in which, without a prolonged antecedent history of vasomotor disturbance, gangrene may develop in the distal portions, rather than in the tips, of symmetric digits. Pain may be a marked feature.

All of these groups fulfill the criteria laid down by Raynaud; namely, symmetry of the disturbance, intermittency or paroxysmal nature of the disturbance, and pulsations in the arteries of the affected part. The groups seem to represent different degrees of the same underlying fault of the vasomotor mechanism, justifying the belief that the condition is a "vasomotor neurosis of the spastic type", and that the term Raynaud's disease should be reserved for the type of case included in the second, third, and fourth

groups. The cases in the first two groups probably represent an exaggeration of the vasomotor changes which affect the normal subject on exposure to cold. There is in the peripheral regions a transitory phase of pallor and of cyanosis; and with exposure to increased local or environmental temperature, redness and increased surface temperature result.

Clinical Considerations. The real problem is to select suitable cases for operation and to decide when operation is indicated. It is obvious that dilatation of an arteriosclerotic or occluded artery cannot be produced, and that surgical intervention is useless unless there is positive evidence that the disease has resulted from an inadequate supply of blood induced by vasospasm. The vasospastic phenomena may be intermittent or continuous. If they are intermittent and mild, disturbing symptoms or trophic changes do not occur, since complete recovery takes place between the attacks of vasomotor spasm.

Vasomotor Index. In a search for some means to determine the flow of blood to an extremity the capillaries were examined, and elimination of heat and surface temperature were measured. These procedures do not estimate exactly the volume of blood, but give relative estimates. One can observe the number of capillary loops to a given field and can determine the rate of flow of the corpuscles; and one can also measure the elimination of heat and the temperature of the skin, both of which are dependent on the flow of blood. By the Stewart-Kegerreis calorimeter the radiation of heat before and after operation could be determined, but it was not until Brown suggested recording the temperature of the skin before fever had been induced, and during its course, that there was any accurate knowledge concerning vasospasm. The electrodes of the elec-

trothermocouple are fastened to the various portions of the fingers, toes, hands, feet, and body, in preparation for readings of surface temperature. First, readings are recorded of the temperature of the room, and of the mouth and surface of the skin. Thus, corrections can be made for the environmental temperature, and the temperature of the mouth and skin can be compared with the corresponding temperatures of a normal person, and with the readings taken during the height of fever. The fever is produced by administering, intravenously, a foreign protein, for example, 5,000,000 to 75,000,000 dead bacilli in triple typhoid vaccine. The dose depends on the weight and sex of the patient. Hourly readings are made until the maximal rise of fever has been obtained. These readings are compared with the initial temperatures, to determine the ratios of increased temperature. General, regional, and spinal anesthesia produce vasodilator effects and can be employed instead of the administration of protein.

In studying the temperature of a normal person, it will be observed that the temperature of the mouth may have increased as much as an average of $2^{\circ}\text{C}.$, whereas the temperature of the skin over the digits will have increased 4° to $6^{\circ}\text{C}.$, or two to three times more than the mouth temperature, indicating that the peripheral arteries have been opened by inhibition of the vasomotor center and that more blood has been permitted to flow to the periphery. In cases of vasospastic disorder, the difference in temperatures is still greater, since the initial surface temperature of the digits is lower than that of a normal subject exposed to the same room temperature. In cases of general arterial sclerosis there may be little, if any, difference in the skin temperatures before and after administration of the foreign protein, indicating that the vessels are incapable of relaxing to allow increase of the flow of blood to the periphery. In cases of thromboangiitis obliterans it is possible to determine whether or not there exists an element of vasomotor spasm of the collateral vessels and unoccluded arteries; and it is possible, also, to determine, by individual readings, the condition of each digit. Therefore, the test serves as an index; and unless the rise

in temperature of the skin of the digits is two or more times greater than the rise of the oral temperature, the condition is considered inoperable. The test also permits determination of the degree of collateral circulation in different portions of the same digit.

Surgical Treatment. When medical treatment fails, surgical procedures have been instituted with the purpose of relieving vasomotor spasm. It has been proved that vasodilatation results from section of vasoconstrictor fibers, that the increase in temperature of the skin from injection of foreign protein can be reproduced by sympathetic ganglionectomy and trunk resection, and that the increased flow of blood in terms of increased elimination of heat continues and does not recede to the level at which it was before operation. Following interruption of all vasoconstrictor fibers, the pain disappears, swelling subsides, ulcers heal, nails grow, the characteristic changes in color disappear, arterial pulsations increase, and the skin appears normal, pale pink, and distinctly warmer and drier. The capillaries are found to be smaller in diameter than they were in the cyanotic phase but the stream of corpuscles is seen to flow much faster.

The surgical procedure which I have employed in interrupting the vasomotor fibers to the arteries of the lower extremities consists of an abdominal transperitoneal approach to the lumbar ganglia, and resection of the second, third, and fourth lumbar ganglia and the intervening trunks. The thorough interruption of the vasomotor fibers is thereby ensured. In this procedure, sympathetic trunks which give rise to the lateral branches of the presacral

nerves are severed; but inasmuch as clinical symptoms referable to the bladder or rectum do not develop from their inclusion, I see in this no contraindication. My purpose is to make sure that not only the lumbar rami are divided but also such truncal fibers and stray rami as might reënter the sacral nerves. In some instances the operation also serves as a treatment for constipation, since presacral fibers contribute to the innervation of the internal sphincters and to inhibition of the lower part of the large bowel and of the rectum. The sectioning of these presacral fibers has also reduced the inhibition of the detrusor muscles of the bladder, and has relaxed the internal sphincters, but since other presacral fibers remain undivided, symptoms are not manifest.

The problem of thoroughly interrupting all of the vasomotor fibers to the arteries of the upper extremities has been much more difficult to solve than that of interrupting the vasomotor fibers to the arteries of the lower extremities. The anatomic arrangement of the cervicothoracic ganglion is not constant. According to Kuntz¹⁰ and the author's experience, this ganglion has been found to be fused in only 40 to 50 per cent of cases. Kuntz¹⁰ has also demonstrated that postganglionic fibers may leave the thoracic trunk and ganglia as low as the second thoracic ganglion, and may pass directly to the lower trunk of the brachial plexus, without entering the so-called stellate ganglion. The anatomic arrangement, I believe, has been responsible for the partial successes and the failures in attempts to inter-

rupt all of the vasomotor fibers by the anterior-superior approaches to the cervicothoracic ganglion.^{18,21} The posterior approach, through the second rib, resulted in experiences similar to those noted in the superior-anterior approach^{25,26} except that the lower cervical ganglion was occasionally overlooked when it was not fused with the first thoracic, whereas in the anterior approach the first thoracic and the rami from the second thoracic ganglia were missed.

In the light of these experiences, I am employing a technic which consists of entering the mediastinum posteriorly through the first rib, an approach which gives exposure of the lower cervical and the first thoracic ganglia and allows of their resection.² Occasionally I am able to remove the second thoracic ganglion through the same operative field, but if it happens to lie low in the thoracic cavity, I proceed with thorough ramisection of the lower cervical and first thoracic nerves,

in addition to dividing all stray rami which may pass mesially to the thoracic trunk and accessory intercostal arteries. These measures insure against the entrance of stray postganglionic fibers into the brachial plexus. This procedure has been extremely satisfactory, but even yet an occasional fiber is overlooked and it may become necessary to follow this operation with further ramisection of the brachial plexus.

Results. In order to evaluate the results of sympathectomy in the treatment of Raynaud's disease in its various degrees of severity, cases have been classified in three groups. In the first group the cases are uncomplicated and the patients complain of asphyxia and cyanosis associated with paresthesia. In the second group are more advanced cases of active ulceration. In the third group are the most advanced cases in which ulcer or gangrene is associated with marked evidence of scleroderma and arthritis.

TABLE I
RAYNAUD'S DISEASE*

	CASES	AGE, YEARS	MALE	FEMALE	AVERAGE DURATION OF SYMPTOMS, MONTHS	AVERAGE DURATION OF SYMPTOMS SINCE SYMPATHECTOMY, MONTHS	CERVICOTHORACIC SYMPATHECTOMY	LUMBAR SYMPATHECTOMY
Group 1 (uncomplicated)	16	33.6	1	15	58.6	34.0	11	5
Group 2 (with ulcers)	6	25.7	0	6	71.0	40.7	3	3
Group 3 (with ulcers or gangrene with scleroderma and arthritis)	32	33.0	3	29	79.0	25.7	25	7
Total	54	30.7	4	50	69.5	33.2	39	15

*Illustrates the incidence of Raynaud's disease, sexes, average age, duration of disease previous to sympathectomy, the relation of the involvement to the upper and lower extremities, and the number of operations performed.

TABLE II
RAYNAUD'S DISEASE*

CERVICOTHORACIC SYMPATHECTOMY	CASES	AVERAGE RELIEF OF COLOR CHANGES, PER CENT	AVERAGE RELIEF OF PAIN, PER CENT	AVERAGE HEALING OF ULCERS, PER CENT	RECURRENT SIGNS	INCOMPLETE SYMPATHECTOMY
Group 1 (uncomplicated)	11	85	85	No ulcers	None	None
Group 2 (with ulcers)	3	60	60	100	1	1

Group 3 (with ulcers or gangrene with scleroderma and arthritis)	7	90	90	90	None	None
Total	15					

*Illustrates the results accompanied by either cervicothoracic or lumbar ganglionectomy and trunk resection.

A review of tables 1 and 2 will show that the disease affects the upper extremities more often than the lower, and that the results from lumbar sympathectomy are better than those from cervicothoracic sympathectomy. The incomplete results in the fingers are apparently due to failures to include all of the vasomotor fibers when using the second rib approach, or to the advanced stage of the disease which has produced permanent changes in the peripheral circulation that do not permit vasodilatation of the arterioles or return to normal of the tremendously dilated capillaries.

The postoperative sequelae of these surgical procedures result in dryness of the skin, which can be relieved by application of lanolin and cocoa butter.

The Horner's syndrome of apparent enophthalmus, contracted pupils, and lagging of the lids due to relaxation of the musculus tarsalis is not a serious disfigurement if it is bilateral, nor does it interfere seriously with vision at night. Resection of the upper portion of the thoracic sympathetic trunk, and of the corresponding ganglia, does not materially alter acceleration of the heart, and none of the patients who have been subjected to the procedure has complained of cardiac symptoms after operation.

THROMBOANGIITIS OBLITERANS

Thromboangiitis obliterans^{5,11,12} is characterized by vascular thrombosis of inflammatory causation, occurring in both arteries and veins but not at

the same levels in each. Arterial thrombosis usually occurs in the main peripheral arterial channels such as the dorsalis pedis, posterior tibial, radial and ulnar arteries. In the more severe cases, the arterial thrombosis ascends to include the popliteal and femoral arteries, and it may occur in the brachial arteries. Venous thrombosis is more of the recurring type, and may appear in any region of the foot, leg, thigh, or arm. Arterial thrombosis is likely to affect the arteries of one leg more than those of the other. But since the lesion has a tendency to progress and to spread, it may affect the opposite extremity, or the upper extremity, months or years after the onset. It has also been observed that when occlusion of the principal arteries of one extremity is present, the arteries of the other extremity, although still patent, may show diminished pulsation.

The disease has a predilection for young, asthenic males, but it does afflict robust males. It has been seen to occur in young, asthenic females. The vessels of two young females each of whom gave an antecedent history of having had symptoms simulating Raynaud's disease in all extremities, with accompanying sclerodermic and arthritic changes, were found to be thrombosed.

Symptoms. The initial symptoms usually consist of intermittent claudication on exertion in the muscles of the lower parts of the legs, but as the disease progresses pain is present even while the patient is at rest, and changes in color appear. The usual colors are those of rubor and cyanosis. They are

accompanied by the signs of passive congestion, of swelling, of localized phlebitis and of occluded arteries. The changes in color are more prominent when the extremity is held in a dependent position, and will disappear when the extremity is elevated. The degree of collateral circulation can be determined clinically by the time that is required for the color to return when the extremity is placed in a horizontal position. Ulcers and gangrene appear in the advanced stages of the disease.

Selection of Patients for Sympathetic Ganglionectomy and Trunk Resection. The rationale of carrying out lumbar ganglionectomy and trunk resection in cases of occlusive disease of the arteries affecting the extremities is based on the following clinical and physiologic observations: In many cases of thromboangiitis obliterans with closure of the main arteries, there are varying degrees of vasospastic disturbance. The changes in color due to lowered environmental temperature are in some cases so striking as to lead to an erroneous diagnosis of Raynaud's disease. This clinical observation suggests the conclusion that in some cases the collateral vessels, which maintain the circulation of the extremities, are subject to excessive vasospastic reactions. This is easily understood if the pathologic changes which occur in this disease are recalled; namely, marked inflammatory reaction in all coats of the arteries, especially in the adventitia or perivascular structures, and cellular thrombosis occluding segments of variable length. Further evidence of considerable vasomo-

tor spasm is obtained from the calorimetric and thermometric studies carried out on the extremities of these patients. The rate of elimination of heat, as determined in the hand or the foot calorimeter, and as measured in small calories eliminated for each unit of surface area for each unit of time, is subject to variations similar to, but less in degree than, those observed in normal subjects or in subjects with functional vasospastic disturbances. It may be assumed, therefore, that the diminished blood supply in some cases of thromboangiitis obliterans has a twofold basis; namely, occlusion of the main arterial channels, and superimposed vasoconstriction of the collateral circulation.

The medical treatment consists of rest in bed, application of dry heat, the use of contrast baths, and intravenous injection of protein. This is the treatment that should be employed in early and mild cases. The surgical treatment, until recently, has consisted of amputation, but in view of experience in the treatment of vasospastic disorders, such as Raynaud's disease, by sympathetic ganglionectomy and trunk resection, selected patients of this group have been subjected to similar operations. In our earlier experiences, before the introduction of the studies on induced fever, Brown and the author were compelled to operate without any particular method for the selection of patients, and had to judge from the results in previous cases whether or not a patient for whom the operation was contemplated would prove suitable. But with the advent of studies of cutaneous temperature, bet-

ter selection has been made possible. The same criteria have been employed as those adopted in the selection of cases of Raynaud's disease. However, selection should not be based on this method only, for it is unwise to operate on a patient during the period of extending arterial thrombosis; the danger is that the thrombosis may ascend to include the femoral artery and may result in gangrene in spite of the operation on the sympathetic system. Those patients who present themselves with acute processes are placed in bed, under medical treatment, until the lesion has become quiescent. This may require from three to six weeks. Patients with trophic ulcers, or gangrenous digits, are likewise treated medically, including administration of protein, until demarcation between healthy and diseased tissue appears and until healing of the ulcer begins; then operation is instituted. Occasionally it is wise to resect the thrombosed veins to hasten the convalescence.

Results. The results of sympathetic ganglionectomy in cases of thromboangiitis obliterans in properly selected cases are just as striking as those in cases of Raynaud's disease. The pain subsides, swelling disappears, and the ulcers heal with remarkable rapidity. Following the operation, spontaneous amputation of the gangrenous digits usually occurs at a level much lower than that at which surgical amputation would have been performed. The vasodilation and the improved circulation materially reduce the incidence of extending arterial thrombosis of the affected extremity, and they also reduce the incidence of its occurrence

in the opposite extremity. Intermittent claudication completely disappears in some cases, whereas in others it is only diminished. Pain disappears either entirely or when the part is at rest. The effect of interruption of vasomotor fibers to unoccluded and collateral arteries in thromboangiitis obliterans, is therefore to decrease the incidence of extension of thrombosis, to conserve extremities, to remove or lessen pain, to hasten the healing of ulcers, and to rehabilitate the patient for service within a period of months. The older type of treatment consisted of amputation, and maimed patients were the result.

In a carefully controlled series of 240 cases, 150 patients were treated medically and sympathectomy was performed on ninety. Brown and his collaborators have demonstrated repeatedly that preoperative increase in skin temperature from vaccine therapy has been reproduced and maintained by ganglionectomy and trunk resection, which proves that vasomotor spasm of the collateral vessels has been removed and that the circulation has been increased.

In reviewing the statistics of these cases it was observed that in 60 per cent of the cases the disease was confined to the lower extremities, and in only 2 per cent was it limited to the upper extremities. In 38 per cent both upper and lower extremities were involved. In 2 per cent massive gangrene was present, in 31 per cent gangrenous digits, in 36 per cent trophic ulcers, and in 31 per cent painful or swollen extremities. Ninety per cent of the patients complained of intermittent claudication, and 74 per cent

complained of rest pain. It was also observed in 98 per cent of these cases that when one extremity presented evidence of disease the corresponding extremity either showed or later developed occlusive arterial lesions with vasomotor spasm. It is this fact which has led the writer to perform bilateral sympathetic ganglionectomy.

The comparative results of treatment revealed that without adequate medical treatment the incidence of amputation was 25 per cent; with medical treatment it was reduced to 14 per cent, and with sympathectomy to 5 per cent. There were three deaths in the medical group and five in the surgical group. Fifty-six per cent of the patients treated medically were markedly improved, the remainder were subject to active recurrences. Eighty-three per cent of the patients treated surgically returned to gainful occupations with a cessation of the process in the less affected extremity.

SCLERODERMA

Adson, O'Leary and Brown, in 1929, stated that a third of the patients who consult a dermatologist for scleroderma give a history of vasospastic phenomena simulating Raynaud's disease. Scleroderma also may accompany thromboangiitis obliterans and certain types of arthritis. The vascular spasm in scleroderma is more or less continuous, and produces a constant reduction of the supply of blood to the extremities.¹⁷ Since the spasm and cyanosis can be temporarily relieved by application of heat, by the use of general, spinal, and regional anesthesia and by the administration of vaccine, this condition was studied in a

manner similar to that in which Raynaud's disease was studied. The changes in scleroderma simulate those that arise from a plaster cast that is too tight; namely, cyanosis, swelling, pain, atrophy, contracture, deformities, and disuse. The type of scleroderma under discussion differs from the amorphous type in that the disease affects chiefly the skin over the hands, forearms, face, neck, and scalp. The atrophy and contracting processes of the skin are associated with similar processes in the underlying structures, and it is not unusual for a patient to complain of weakness, inability to use muscles, and inability to open the mouth or to protrude the tongue. Arthritic changes often become manifest in the fingers; this condition is referred to as sclerodactylia. The changes associated with scleroderma are more pronounced in the skin of the uncovered parts, such as the hands, forearms, face, and neck, than they are in the covered parts, which suggests that reflex stimuli of cold accentuate existing vasomotor spasm. The fact that underlying tissues are subjected to atrophic changes suggests that vasospasm is not confined to the vessels of the skin, but that it interferes also with the circulation of all tissues.

Care should be exercised in selecting suitable cases, since the hide-binding process of scleroderma strangulates and destroys capillaries and arterioles which naturally cannot be opened by a vasodilating procedure. The vasomotor index again serves its purpose in the selection of operable cases. The postoperative results are dependent on the stage of the disease. The vascular phenomenon is corrected, as

in Raynaud's disease, and rehabilitation of skin and adjacent tissues will take place after operation if vasomotor spasm was present, and not too many capillaries and arterioles had been destroyed. If it is not possible to demonstrate the desired increase in surface temperature by administration of protein, little is to be expected from operation. Ankylosed joints are not made flexible by sympathetic ganglionectomy and trunk resection. It is wiser to choose the earlier cases for operation; improvement is more likely to occur in these cases than in advanced cases in which deformity has taken place.

Results. The cases were divided into three groups and classified on the basis of the relationship of the vasospastic phenomena to the development of the disease. In the first group were cases of primary scleroderma with vasomotor phenomena developing late in the disease. In the second group were cases in which scleroderma and vasomotor disturbances developed simultaneously. In the third group vasomotor disturbances preceded the development of scleroderma.

In the first group the vasomotor phenomena were improved, the skin temperature was increased, the skin became more flexible, and ulcers healed, but the results still were not as good as those observed in the third group. The outstanding accomplishment was the checking of the disease with an average improvement of 10 per cent.

In the second group the results were similar to those in the first group, but with a considerable restoration of function in addition and with an average improvement of 25 per cent.

In the third group the degree of recovery following lumbar sympathectomy averaged 85 per cent, whereas following cervicothoracic sympathectomy it averaged 45 per cent. In this group the skin not only became pink, warm, soft, and elastic but the muscles again became fusiform and flexible with a resultant improvement in strength. Patients who had been unable to open their mouths or to protrude their tongues were again able to masticate their food as formerly. The skin still remained very thick and bruised easily; ankylosed joints were unchanged.

CHRONIC ARTHRITIS

Because of the satisfactory results of lumbar sympathetic ganglionectomy and trunk resection for Raynaud's disease affecting the lower extremities, Rowntree suggested that the procedure be tried in a case of polyarthritis with vasospastic phenomena in which the condition was becoming progressively worse under medical treatment. The result was satisfactory, and since then numerous cases have been reported. However, the surgical procedure is limited to young persons who complain of cold, wet, pale, clammy skin and painful, swollen, tender joints with atrophy and contractures of the muscles. The procedure is of greatest value in the treatment of arthritic processes in the hands, wrists, feet, and ankles; it is less effective in arthritic lesions of the elbows, shoulders, knees, and cervical portion of the spinal column; it offers scarcely any relief in cases of lesions of the thoracic and lumbar portions of the spine.

Results. Immediately following operation, the skin over the extremities

becomes warm, pink, and dry giving evidence that the vasomotor fibers and those leading to the sweat glands have been interrupted. For five or six days the skin remains flushed; then it subsides to normal color, but if examination is made of the capillary loops after that period, and if their condition is compared with that before operation, it will be observed that the flow of blood, as indicated by movement of the corpuscles, has been distinctly increased. The pain and swelling become gradually less, and continue to decrease while the patient is in bed at rest; on movement of the joints or use of the extremity, the symptoms may temporarily reappear but subside again gradually. Very often, patients overdo during their convalescence because they feel so comfortable when at rest, and they are therefore prone to become discouraged in the first six months following operation. To obviate this feature, Rowntree urged graduated light exercise and physiotherapy, so as to avoid undue trauma during this period of restoration. Some patients do not experience as much discomfort as others and progress slowly from the onset. The usual course, however, is for a patient to experience marked relief immediately following operation, then for pain and soreness partially to return for three or four months, and finally for gradual and permanent recovery from pain, tenderness, and swelling of the extremities to supervene. The mobility and the return of function continue parallel with the reduction in pain and swelling and the development of muscular function.

Tables III and IV contain data on

TABLE III
CHRONIC ARTHRITIS: TYPES OF CASES IN WHICH OPERATION WAS PERFORMED

GROUP	CASES*	GENERAL RESULTS	AVERAGE			
			AGE AT ONSET, YEARS	DURATION OF SYMPTOMS, MONTHS	VASCULAR INDEX (G. E. BROWN)	INCREASE IN CUTANEOUS TEMPERATURE, DEGREES C.
1	6	Failure	28	92	6.9	9.0
2	11	Slight (30 per cent) improvement	29	76	4.4	7.0
3	20	Marked (70 per cent) improvement	21	58	4.9	7.6

*In four of the forty-one cases studied, operations were performed too recently to be included in the table; the patients were still in the hospital at the time this paper was written.

the types of cases in which operation was performed, and on the results obtained. Group 1 represents the cases in which the disease was most advanced and in which there were numerous ankylosed joints. In such cases sympathectomy is of no value. Group 2 represents the border-line cases, in which sympathetic ganglionectomy and trunk resection may be justified in the hope of reducing the pain and of checking the disease. Group 3 represents the cases in which sympathetic ganglionectomy and trunk resection has produced satisfactory results and in which it is indicated.³²

Hench, Henderson, Rowntree and the author believe that operation on the sympathetic system is not indicated in any arthritic condition until thorough investigation and intensive medical treatment have been employed; but if the lesion is progressive, that is, if it is inactive only when some form of heat which improves the circulation locally is being administered, operation is advisable. The studies to be made, and the indications to be ob-

served are similar to those requisite before operative treatment of any vasospastic disorder.

CONGENITAL MEGACOLON

The term "congenital megacolon" has come to mean a condition of dilated, hypertrophied colon resulting from interference with the normal peristaltic function, but it does not indicate whether the condition is of mechanical or of neurogenic origin. Since the advanced degrees of the mechanical type require different operative procedures from advanced degrees of the neurogenic type, a more accurate classification is necessary. Acute obstructions of the large bowel result in dilatation and distention, whereas chronic obstructions produce compensatory hypertrophy with dilatation. Bands, adhesions, chronic volvulus, and tumors are responsible for mechanical blockage. Neurogenic lesions produce symptoms similar to those of mechanical origin, but the condition is usually discovered in youth or is present at birth. Neurogenic lesions are

*Arthritis progressed, in extremities for condition of which operation was not done, in five cases and remained stationary in three, and did not develop in three.

**Arthritis progressed, in extremities for condition of which operation was not done, in six cases, remained stationary in two, and improved in two.

characterized by chronic obstipation which can be temporarily relieved by enemas, purging and dilatation of the anus, especially if these measures are supplemented by the use of a diet without residue. The symptoms vary in degree, but they are not permanently relieved by medical treatment. General surgeons have resorted to colostomy and colectomy. The results have been variable and the mortality high. Wade, at the suggestion of Royle, performed ramisection and trunk resection in a case of megacolon of neurogenic origin. This was the first attempt to cure the condition by operation on the nervous system.

Anatomy and Physiology of the Rectum and Bladder. Gaskell has pointed out that there are three sphincter muscles which terminate the different regions of the primitive gut: (a) the ileocolic sphincter at the end of

the small intestine; (b) the internal anal sphincter at the end of the coprodeum; (c) the internal vesical sphincter and the urethral muscles at the end of the urodeum. The motor nerve cells for the ileocolic sphincter are situated in the superior mesenteric ganglion, while the motor nerve cells for the internal anal sphincter and the internal vesical sphincter are in the inferior mesenteric ganglion.^{25,42,24} The inhibitory nerves to the internal sphincter ani and to the internal sphincter of the bladder, according to Elliott, travel through the pelvic nerve as a part of the sacral outflow. The motor nerves to the musculature of the large intestine, according to Bayliss and Starling,^{12,13} and also Langley and Anderson,⁴² are likewise a part of the sacral outflow and travel through the pelvic nerve. Elliott has confirmed this by the injection of adrenalin which

causes no contraction whatever of any part of the large intestine with the exception of the internal sphincter ani.²³ The inhibition of the musculature of the large intestine is mediated through inhibitory nerves whose cells are situated in the inferior mesenteric ganglion²⁴; stimulation of the lumbar splanchnics, or of the hypogastric nerves, causes relaxation of the musculature of the colon.

Limitation of space prevents the quoting in full of the detailed description of the anatomy of the innervation of the anal and vesical sphincter and of the colon, which has been given by Learmonth. This author favors section of the presacral and inferior mesenteric nerve in megacolon of urogenic origin. His views are well represented in the following quotation.

"The colon is dilated, and the dilation is most marked in its distal part, sometimes reaching the internal sphincter of the anus. Although the muscular coat is hypertrophied, it is unable to transmit the content of the intestine. Even if, in our ignorance of its ultimate cause, we cannot attack the disease directly, we may still carry out flanking attacks in three directions: (1) we may attempt to diminish the dilation of the colon; (2) we may try to leave its motor nerves in less disputed control; and (3) we may attempt to relieve any opposition to the expulsion of the content of the bowel offered by the internal sphincter of the anus. If our anatomic and physiologic reasoning is correct, we can accomplish the first and the second objects by division of the inferior mesenteric nerves and the third by division of the presacral nerve.

"Next it must be inquired if these operations can be performed without endangering the functions of any viscera, by interrupting important efferent or afferent fibers. In particular, it is essential to safeguard the afferent fibers from the ampulla of the rectum, so that the mechanism for defecation may be set in motion when fecal matter enters that part of the bowel. In the dog, division of the inferior mesenteric nerves results only in increase in the tonus of the distal part of the colon, and in the patients on whom we performed this operation, the only discernible effect on the colon was the desired one. With regard to the presacral nerve, there is abundant evidence of its functions in man; it is an important afferent path for painful impulses, particularly from the female genitalia and from the bladder; it probably contains inhibitory fibers for the musculature of the bladder, but only rarely, after its section, is transient frequency of micturition observed; and it supplies motor fibers to the internal sphincter of the anus. The afferent fibers concerned in reflex defecation pass to the spinal cord largely if not entirely by way of the pelvic nerves and the second, third, and fourth sacral posterior roots; they are preserved in the suggested operation, which may be performed without fear of producing undesirable results."

Wade's clinical results have convinced him that section of the white ramus to the first lumbar ganglion, and of the medially directed fibers from the sympathetic trunk, together with section of the sympathetic trunk below the fourth lumbar ganglion on the left side, is sufficient. Judd and

the author, before the suggestion of Rankin and Learmonth, resected the second, third, and fourth ganglia and intervening trunks on both sides, in order to interrupt postganglionic fibers composing lateral branches of the presacral nerves, in addition to interrupting fibers passing from the second lumbar ganglion and fibers descending in the lumbar sympathetic trunk to communicate with the intermesenteric plexus, which supplies the inferior mesenteric nerve.

Results. Sympathectomy has been performed without a fatality in eight cases of Hirschsprung's disease of children and in two cases of acquired megacolon of young women. The patients have recovered from their symptoms. The colon has been reduced in size but has not returned to normal.

Since either procedure appears to have accomplished the desired result the ultimate choice of operation will be determined by comparison of cases. The operation of Rankin and Learmonth has the advantage of not interrupting vasomotor fibers to the extremities. That interruption of these fibers is not a serious disadvantage of ramisection, trunk resection, or ganglionectomy, is shown by the fact that patients with spastic paralysis or with vasomotor disturbance on whom such operations have been performed do not complain of excessive heat in their feet.

CORD BLADDER

Learmonth, and Learmonth and Bransch have shown that urinary retention resulting from spina bifida, tumor of the spinal cord, inflammatory lesions and injuries which interfere

with the parasympathetic innervation to the bladder through the second, third, and fourth sacral nerves, can be partially or totally relieved by section of the presacral sympathetic fibers. This is possible because these fibers represent the reciprocal innervation of the detrusor muscle and of the internal sphincter. Section of the presacral fibers reduces the inhibitory impulses to the muscle of the bladder and relaxes the internal sphincter. Also, Learmonth has shown that trophic lesions can be improved by the same operative procedure, since the vasomotor fibers are intermingled with those which carry inhibitory and contractile impulses. Painful sensations are partially reduced also by section of the presacral nerves, since afferent fibers are found in these nerves, although the largest afferent element from the bladder returns to the spinal cord by way of the hypogastric plexus and sacral nerves.

Results. The following résumé was prepared by Learmonth who has permitted me to include it in this paper. He states that at The Mayo Clinic sympathetic neurectomy has been undertaken in disturbance in vesical function in three types of cases:

1. *Paresis of the Musculature of the Bladder.* When a bladder is incapable of emptying completely as a result of injury to any portion of the parasympathetic pathway, it has seemed reasonable to suppose that the intact sympathetic contribution to vesical innervation provided too effective a brake for the decreased parasympathetic innervation, and that after sympathetic neurectomy the diminished activity of the evacuant set of nerves would be unhampered by this brake. Operation has been carried out in eight cases of this type, one of which has

been reported in detail elsewhere.⁴⁵ One patient in this series cannot be traced, and one failed to receive benefit. Of the remainder, two are considered cured (for periods of two years and one and a half years, respectively), and the expulsive power of the bladder of the other four patients has been materially improved; the amount of residual urine has been reduced from 200 or 300 c.c. to 20 or 30 c.c. It is necessary to warn men that after the operation, although they will be able to perform the sexual act and to experience a normal orgasm, ejaculation will not occur; no detectable alteration in reproductive function follows the operation on women. It has been found that after two or three weeks the internal sphincter of male subjects recovers a portion of its tonus, although the trigone, bereft of its motor nerve supply, remains flaccid. A small quantity of residual urine may persist as a trigonal pool; in these cases a channel is made from the pool to the posterior urethra by the operating cystoscope, and this operation has often enabled the bladder to expel its contents completely.

2. *Spasm of the Neck of the Bladder.*

In two cases in which there was difficulty in starting the flow of urine, a diagnosis was made of spasm, or better, achalasia, of the internal vesical sphincter. In both cases, urologic and neurologic examinations were negative, and attempts had been made to rectify the condition by punch operations on the neck of the bladder. Because the sympathetic system provides motor nerves to the internal sphincter, it was thought that its overcontraction would be diminished by sympathetic neurectomy. The operation was immediately successful in both cases, and neither patient has had any subsequent difficulty in beginning or in completing the act of micturition.

3. *Inveterate Vesical Pain.* Since 1926, when Pieri first performed presacral neurectomy for the relief of vesical pain, a number of successful operations has been recorded. Pieri has devised a more complete procedure, which aims at interrupting all possible sympathetic paths from the bladder to the central nervous system; this he considered necessary, because one or two fine branches may connect the hypogastric

ganglia directly to the sacral paravertebral sympathetic ganglia. The complete operation interrupts impulses which, after reaching the hypogastric ganglia, might pass by fibers traversing the paravertebral chains either to the sacral nerves by way of the rami communicantes, and so to the spinal cord, or, after ascending in the paravertebral chain, by way of lumbar or thoracic rami communicantes to the spinal cord at a higher level.

Among the conditions in which this operation has been tested at The Mayo Clinic are interstitial cystitis, inoperable carcinoma of the bladder, chronic cystitis of unknown etiology, and the irritability of the bladder which may remain after nephrectomy for renal tuberculosis. The result has been satisfactory in six of eleven cases. There has not been any marked difference between the result after simple presacral neurectomy, and that after the more extensive operation. The relief from pain is due chiefly to mitigation of the spasmodic and uncoordinated contractions of the musculature.

SUMMARY

Sympathectomy has become a useful procedure. Physiologic data and clinical indications for operation are becoming gradually crystallized. Opinions may have to be altered and new ideas will arise, but the author feels confident that sympathectomy, in its various forms, is a surgical procedure that will continue as a means of treatment in conditions of dysfunction of blood vessels, smooth muscle, and glands.

It is obvious that progress in this field requires the coöperation of the anatomist, the physiologist, and the clinician and that it would be unwise for the surgeon to attempt operations on the sympathetic system unless he is thoroughly familiar with the anatomy of the fields concerned.

Pathologic Differentiations in Bright's Disease* †

By JEAN OLIVER, M.D., *Brooklyn, N. Y.*

ONE'S conception of a pathologic differentiation may vary greatly depending on the implications found in the term "pathology". For those to whom the word suggests "morbid anatomy" a pathologic differentiation would seem adequate when it has accurately described structural differences between disease processes. It is this manner of differentiation which has been applied in great detail to the renal lesion in Bright's disease by pathologists, for their differentiations in this condition have consisted mainly in contrasting inflammatory processes in the glomeruli with degenerative changes in the tubules or sclerotic lesions in the arteries. In this way various types of the disease have been established, and though such a method is perhaps the best available for purposes of classification, since it is based on that sound concept which recognizes the importance of structural change as the determining factor in disease, we must recognize the fact that, in such a form as has been used in the past, the method is woefully inadequate as a means of establishing any complete concept

of disease processes. This is so because such pathologic differentiation does not include within its scope an objective demonstration of both the structural and functional aspects of the abnormality.

Now it is obvious that what causes man to suffer is altered or arrested function, not the presence or absence of this or that mass of tissue cells. And so in his differentiations in Bright's disease the pathologist has been forced to supply for his structural abnormalities suitable functional significances. But in many instances, in fact in the great majority, his objective endeavor has ceased when he has completed only the first half of his differentiation, that is the demonstration of structural abnormality, and the second half which concerns the essential functional aspect of the damage, is supplied by recourse to a subjective process, namely his scientific imagination. Angiospasm is assumed to occur in a diseased arteriole, an inflamed glomerulus to be less competent as a filter. You can think of many analogous combinations of structural and functional damage, where the pathologist has suggested that tissues which appear different are acting differently, but it is the rare case indeed where he can give you any objective evidence that his assumption is correct. There

*Read before the American College of Physicians, San Francisco, California, April 4, 1932.

†From the Department of Pathology of the Long Island College of Medicine, Brooklyn, N. Y.

always remains, therefore, the disturbing possibility that it is not the queer looking cell which is incompetent but rather the pathologist.

I would like to describe, therefore, a pathologic differentiation in which,

epithelium of the convoluted tubules and though this cell destruction varies in intensity in the various types of the disease it is always sufficient to require repair. Under the simplest conditions, such as in the degenerative lesions fol-

FIG. 1. Active stage of hemorrhagic Bright's disease. Hyaline thrombosis and necrosis with nuclear debris are seen in the glomerular tufts. The original epithelium of all the convoluted tubules is replaced by an atypical irregular lining of immature regenerated cells.

due to the simplicity of conditions, it is possible to complete this essential correlation of structural and functional abnormality. The general problem may be stated as follows.

In all forms of Bright's disease there occur regressive changes in the

lowing corrosive sublimate, the repair takes a direct course and, if the individual survives, the destroyed tubular cells are replaced by new ones that are indistinguishable from those which originally lined the tubules. Since the function of such kidneys is entirely

normal, there is no reason to suppose that the new cells are inadequate in their particular function.

In other forms of Bright's disease, especially in the terminal stages of the hemorrhagic form, where all the structures and tissues of the kidney are af-

markedly atypical in their structure.¹ Since in the course of time, such atypical epithelium may replace the greater part of the tubular tissue and since the kidney ultimately fails, the question arises as to what part epithelial, that is tubular, dysfunction may

FIG. 2. Early immature regenerated epithelium of the convoluted tubules three days after sublimite poisoning.

ected, repair in the epithelial elements is complicated by the simultaneous occurrence of many other sorts of structural change. The more important of these are the growth of connective tissue and the development of arterial sclerosis. Under these conditions epithelial regeneration is abundant in its amount, but abnormal in nature, for the newly formed cells are

play in the production of the total organ's inadequacy. (Figure 1)

Here then is a problem for pathologic differentiation which demands more than the conventional answer that the pathologist often gives. The experiments which I shall describe illustrate an attempt at the more complete sort of answer.

Experimental nephritis was pro-

FIG. 3. Complete repair after sublimate poisoning. The convoluted tubules throughout the section are filled with dark staining mitochondria that are arranged in Heidenhain rods.

FIG. 4. Incomplete repair 146 days after uranium poisoning. Note irregularity in staining, caused by the patches of immature regenerated and atrophied epithelium which contains little or no electron staining. The dark tubules are lined by original cells that were not damaged by the toxic agent.

duced in guinea pigs by two toxic agents, corrosive sublimate and uranium nitrate.² That following sublimate poisoning is identical with the lesion found in man, and the regenerating epithelium, though at first irregular in size and shape (Figure 2), ultimately resembles exactly the original epithelium. After uranium administration, however, a development of connective tissue complicates the repair, so that a structural change in part at least analogous to the fibrosis of chronic Bright's disease in man is produced. The regenerated epithelium in such kidneys remains immature and morphologically atypical and so resembles that seen in the human kidney. Since the animal dies of renal

failure we have available for our examination under controllable experimental conditions the original problem I previously described.

Starting from the probably reasonable hypothesis that abnormal structure will result in abnormal activity, the pathologist assumes that these atypical regenerated cells cannot function properly and in his search for facts to bring forward in support of his assumption it occurs to him that, since there is considerable evidence that connects mitochondrial alterations with functional activity, it might be well to examine these cell structures.

This was done in our experimental lesions and it was found that in both forms of renal damage the early regen-

FIG. 5. Detail of immature regenerated cells from figure 4. The dark tubules are original undamaged ones filled with Heidenhain's rodlets. A is a normal collecting tubule in which mitochondria are normally scanty and the remaining irregularly lined tubules, B, are lined with the immature rodlet-free regenerated cells. (2)

—Courtesy of *Jr. Exper. Med.*

erated epithelium had only a small amount of mitochondrial substance and this not arranged in such definite cell organs as the rods of Heidenhain. In the mature regenerated cells of the completely repaired sublimate kidney, whose function was normal, all the characteristics of the normal mitochondria were ultimately devel-

tant part in cell activity, evidence has therefore been obtained that the atypical regenerated epithelial cell is functionally abnormal, and that this abnormality may play a part in the production of renal failure.

It is at this point that the pathologist often rests from his labors, either content with their fruits, or seeing no

—Courtesy of *Jr. Exper. Med.*

FIG. 6. Urea in normal convoluted tubules. All details are obscured by the dense black deposits. (2)

oped (Figure 3). But the atypical regenerated cells in uranium nephritis, where renal failure developed, remained immature in regard to their mitochondrial elements permanently, and never showed the presence of the Heidenhain rods, which characterize the normal original renal epithelial cell. (Figures 4 and 5) By the assumption that the mitochondria play an impor-

immediate way to proceed. An exact analysis of his contribution so far will show, however, that he has in fact added nothing to the evidence in the case, except detail and refinement of method; and the problem must still be stated as a hypothesis, namely that mitochondrial, i.e., structural, abnormality determines functional disturbance.

The final step in our search for an answer that completes the pathologic differentiation by correlating structure and function is, however, possible in the particular problem I am describing and this by means of direct objective evidence, where hypothesis plays no part.

Urea may be stained in situ in tis-

drial substance contained little or no urea. (Figures 6 and 7)

We need not be concerned with whether this means that the cells are failing to secrete or to absorb urea, but we can state definitely that, in a kidney which is failing to eliminate urea, the cells do not handle this sub-

—Courtesy of *Jr. Exper. Med.*

FIG. 7. Kidney after uranium poisoning stained for urea. Three original persisting convoluted tubules contain urea deposits. At A and B immature regenerated cells are seen almost free of this substance. For correlation of the structure and function of these cells compare figures 5 and 7. (2)

sues by its reaction with mercurous nitrate and, though like most micro-chemical reactions the procedure is not entirely specific, practical tests have shown that it is sufficiently so to demonstrate any considerable amount of urea in the kidney cells. Applied to the kidneys of uranium nephritis, it was found that the atypical regenerated cells that were poor in mitochon-

stance as do the original cells which possess a complex mitochondrial apparatus. And so this objective observation completes our pathologic differentiation by its demonstration of a correlation of structural and functional abnormality.

The first and specific conclusion of these findings, which is by analogy and must therefore be tentative, is that

tubular dysfunction plays a not unimportant part in the development of renal failure in terminal hemorrhagic Bright's disease, a statement which perhaps sounds more remarkable if the term "chronic glomerular nephritis" is used to designate the condition.

The second and general conclusion

suggests that the pathologist direct his efforts at differentiation towards a completion of his chains of evidence, for these must remain inadequate until his pathologic differentiation includes within its limits an objective correlation of both the structural and functional aspects of damage.

Science and Practice in Bright's Disease*†

By T. ADDIS, M.D., F.A.C.P., *San Francisco, California*

THERE are in the main two sorts of men interested in Bright's disease. We may call them the clinical scientists and the clinical practitioners. They are separated by a difference in their aims. The ultimate aim of the clinical scientist is to disentangle from the chaos of the accidental and nonessential the general laws which govern the course of the disease. He searches for what is constant and measurable and turns aside from anything individual and concrete since such things are variable and cannot be measured. He reduces his observations on the living patient to something so cold, neutral, and generalized that it can be expressed in numbers, for his desire is to describe Bright's disease in abstract quantitative terms.

On the other hand, the purpose of the practitioner is to help the patient who has Bright's disease. He has to try to understand each patient and the special form which the disease takes in him, and so the individual and the variable, the very things which cannot be measured or expressed in numbers, are matters for his particular interest and attention, and since what he is

trying to do has no relation to absolute quantity it is sufficient for his purpose to recognize the presence and degree of abnormalities without defining them in precise numerical terms.

Now if we grant that there is this profound divergence in the respective purposes of the clinical scientist and the clinical practitioner the fact is worth considering that those who have the reputation of being the most up-to-date practitioners in Bright's disease are notoriously those who make a large use of the methods not of practice but of science. For are not their records full of all sorts of quantitative data, of figures which purport to represent precisely the quantities of various substances present in their patients' blood and urine? I think that an unbiased observer, analyzing this paradoxical situation, might come in the end to suspect that these figures were not present in the records because they were necessary for the work of the practitioner, but that they represented something really extraneous to his purpose which had been forced upon him. For such an observer would note that the practitioners who embellish their records with these quantitative facts do not value them so highly that they themselves are willing to take the trouble to make the measurements, for that sort of work is done by those who

*Read before the American College of Physicians, San Francisco, California, April 4, 1932.

†From the Department of Medicine, Stanford University Medical School, San Francisco, California.

are neither clinical scientists nor practitioners. On reviewing the figures he would come on many instances of contradiction and palpable error and he would note that the revelation of such mistakes fails to disturb the calm of the practitioner. He would take into account how widespread is the popular worship of science in medicine and how general is the delusion that all medicine is scientific medicine, so that an ever-increasing number of patients believe that they cannot be comprehended or helped until they have been subjected to an elaborate and expensive system of physical and chemical measurement, and he would note also the persistent efforts of non-clinical scientists to reform the practitioner by making the introduction of the quantitative method into medicine relatively easy. So in summing up all such considerations he would have good grounds for the suspicion that these figures in the practitioner's records are really symbols of defeat, signs that the practitioner has been deviated from his purpose by a fashion in popular opinion. And, whatever may be thought of this, there is little doubt that such records are indications of the defeat of the clinical scientist, for here we find his methods, designed for abstract and general purposes, prostituted for the sake of what is transient and individual.

The majority of both clinical scientists and practitioners will probably revolt from this conclusion. They will attack the premise on which it rests by pointing out that there is no such person as the pure scientist or the pure practitioner and that each one of us has within him something of the scien-

tist and something of the practitioner. But can they argue that because we are thus compounded we should manifest something of the spirit of science while we are doing our practical work and be somewhat practical in our scientific endeavor? I do not think so. For the paths of practice and of science lead in opposite directions and they are straight and narrow ways on which only he makes progress whose mind is single and who for the time being is wholly scientific, with no thought for anything but quantity and generalization, or is wholly practical and attending only to what is qualitative and individual. My thesis is that the union of science and practice gives origin to an emasculated bastard lacking in the proper virtues of both its parents.

Having thus, in theory, divorced clinical science and practice, something may be said about the nature of the technical procedures peculiar to practice. For nothing of any but historical interest is to be said about the methods of clinical science. They are designed to answer some special question and when they have done that they are thrown away. All the methods we are now hearing about are already discarded and will never be used again, for in clinical science there is no standardization, no efficiency, no organization. Still less have such business virtues anything to do with practice in Bright's disease which, while it lives, is always new and individual and infinitely variable. But it can be said that the methods used in practice are in general of the "look and see" variety and that they usually present a vivid and concrete picture which has

color and body. Let us, for example, consider the sort of method which is useful to the practitioner in examining the blood of a patient with Bright's disease. He draws some blood from his patient's arm vein into a syringe which contains an anti-coagulant. After spinning it down in a centrifuge all he does is to look at it and in that glance, without thought or effort, he takes in the color and degree of turbidity of the plasma and the depth of the leukocytic layer and sees as in a colored graph that the red cells occupy half, or a third, or a fifth of the total volume. Then he takes some of the plasma, and on the addition of a reagent the depth of a color tells him whether there is little or much retention of urinary constituents. And all the while these vivid details are passing before him the living patient is still beside him, and his mind travels from the blood pictures to the patient and back again, subconsciously striving to create a larger and more inclusive picture, until at last, perhaps, it all falls together in a complete composition of the patient and the disease, and he may be able to see how he must act if he is to avoid doing harm or be able to do any good. That is the pure practice and art of medicine. Let no such practitioner feel any embarrassment because he is unable to tell some half-scientist half-practitioner consultant the exact number of red and white blood cells or the number of milligrams of creatinine and uric acid nitrogen in 100 c.c. of his patient's blood.

This warfare between the clinical scientist and the practitioner, both within and without us, goes on for-

ever, and neither side will finally prevail, for in this conflict only what is weak and superfluous on either side can be defeated while those things that remain stand firm. But it is a fruitful conflict only when the battle lines are clearly drawn. While we are practising medicine we must be only artists and while we are investigating disease we must be altogether scientists, for when we try to fight simultaneously under both flags we are double traitors. And so no practitioner need be deluded by the present uncomprehending worship of the scientific method into supposing that he can directly further his purpose by hiring someone else to provide him with numerical data on his patients. All he needs is to see with his own eyes his own clear pictures. One glance at a urine is worth more to him than a page of figures. Only let him make sure that the conditions under which he looks are not such as will blur and distort his picture. It is true that the microscopic examination of the urinary sediment can do for Bright's disease what the X-rays have done for diseases of the chest, but we can never see the renal lesion in the urinary sediment of our patients until we get them to abstain from fluids and give us timed collections of urine in order that the very elements of the picture may not dissolve and that we may see it undistorted by the accidental variations of time. The artist must understand the properties of the material with which he works but the composition is all his own and when it is completed it is seen at a glance, as a whole, and as a picture, not as an array of lifeless, disconnected, and abstract numbers.

Etiology and Pathogenesis of Hepatic Cirrhosis*†

By T. L. ALTHAUSEN, M.D., *San Francisco, California*

EXPERIMENTAL CIRRHOSIS OF THE LIVER

IMPROVED methods of microscopic technic permitting the study of finer changes in the structure of the liver, especially mitochondrial and reticulum stains, are responsible for recent additions to our knowledge regarding the pathogenesis of cirrhosis of this organ.

Fiessinger and Albot,¹ as well as Martin,² in studying in animals early stages of experimental lesions that eventually lead to cirrhosis of the liver, have shown that the first detectable changes invariably take place in the hepatic parenchyma and consist of mitochondriolysis and hyaline degeneration. This was found to be true regardless of the toxic agent used. Even colloidal silica, which according to Gye and Purdy³ initiates primary hypertrophy in the hepatic framework, was proven to cause lesions first in the parenchyma.⁴

The microscopic evidence of the uniform character of hepatic injury is supported by physiological observations on the metabolic activity of the

liver following the administration of various hepatic toxins. By following the blood sugar curves of rabbits after the administration of glucose, of glucose plus insulin, and of epinephrine, it has been shown in the author's laboratory that identical disturbances in hepatic metabolism were produced by phosphorus, chloroform,⁵ manganese, bacterial toxins, and even by India ink.⁶ Moreover, the changes in function were similar in kind, regardless of whether one large dose or many small doses of hepatic toxins were given.

The first effect of these substances is to produce an irritation of hepatic tissue resulting in hyperfunction which later changes into hypofunction. This finding is substantiated by Fiessinger's⁷ histological evidence that the hepatic cells in early poisoning are in a state of hyperfunction.

In human beings with various hepatic diseases the same disturbances of carbohydrate metabolism were demonstrated after insulin plus glucose and after epinephrine as those described in experimental animals.^{8,9,10}

The essential factor in the production of experimental cirrhosis is the repeated administration of hepatic toxins in sufficient doses to produce necrosis of some of the parenchymatous cells without causing death of the ani-

*Presented at the Clinical Section of the San Francisco Meeting of the American College of Physicians, April 6, 1932.
†From the Department of Medicine, University of California, School of Medicine, San Francisco, California.

mal. Agents causing fatty infiltration alone do not produce cirrhosis. The localization of lesions within the hepatic lobule depends upon the nature of the toxic agent employed. The extent of necrosis depends upon the dose of the toxin and upon the susceptibility of the individual animal at the time of administration.

Following necrosis of hepatic parenchyma two types of response to the injury can be observed. One is regeneration of hepatic cells from similar preëxisting cells. The other is sclerosis or a replacement proliferation on the part of the framework of the liver. The second process is ushered in by the appearance of islands of round-cell infiltration at the site of necrosis. Later these islands are succeeded by accumulations of fibroblasts in a thickened portion of the reticulum. From these foci, after repeated episodes of necrosis, strands of fibrous tissue extend into the parenchyma of the liver and may eventually join similar strands coming from other foci, giving a nodular appearance to the cut surface of the organ. At the same time the reticulum of the liver, in unaffected portions of the lobules also increases in density.

It is curious that even under the controlled conditions of an animal experiment with equal daily doses of a poison given by injection, the metabolic function of the liver undergoes periodic fluctuations for many months, testifying to the alternating predominance of necrosis and regeneration.⁶

HEPATOTOXINS

The list of substances which are known or suspected to cause cirrhosis

of the liver in man is a long one. The list of toxic agents which have been used to produce cirrhosis in animals is even longer, including over fifty different compounds. The necessary condition for the production of cirrhosis with any of them is long repeated exposure in doses sufficient to induce necrosis.

Among substances injurious to the liver, two classes deserve special mention. The first of these comprises alcoholic beverages to which unusual interest is attached because of their significance in the etiology of human cirrhosis and also because of their status in experimental cirrhosis. The connection between abuse of alcohol and cirrhosis of the liver is well established. Regarding the acute phase of the action of alcohol, Beckmann¹¹ showed that a single large indulgence results in a temporarily reduced capacity of the liver to metabolize lactic acid injected intravenously in the form of sodium lactate. Similar results were obtained by him¹² in animals subjected to poisoning by a variety of toxic agents including phosphorus and chloroform. Wallace,¹³ working with two tests of liver function, the quantitative van den Bergh test and the quantitative determination of urobilinogen in the urine, found definite evidence of hepatic injury following acute alcoholic intoxication. Von Bergmann¹⁴ and Eilbott¹⁵ were able to demonstrate under similar conditions that the power of the liver to excrete injected bilirubin is also impaired.

Turning to statistical evidence showing the effects of chronic alcoholism we see that in England and in Ger-

many, cirrhosis of the liver is more prevalent in urban than in rural populations, corresponding to the relative consumption of alcoholic beverages.¹⁶ For the same reason the disease is more common in men than in women, the only exception applying to prostitutes. The parallelism existing between deaths from cirrhosis and from alcoholism speaks for itself.¹⁷ The marked decline of cirrhosis in the United States during the first years of prohibition¹⁸ and in Germany during the war,¹⁹ due to difficulties in procuring alcohol, constitutes additional evidence linking alcohol with this disease. Finally the alcoholic history of a large majority of patients with cirrhosis cannot be disregarded. On the other hand the absence of this disease in most chronic drinkers can no more be used as evidence against the alcoholic etiology of cirrhosis than the absence of delirium tremens in a majority of alcoholics can be urged against the alcoholic origin of the latter affliction. The individual susceptibility of organs plays a large part in both conditions.

In the laboratory the majority of observers were unable to produce cirrhosis of the liver by alcohol alone. On the other hand when alcohol is given in combination with other toxic substances, (carbon tetrachloride,²⁰ bacterial toxins,²¹ phosphorus²²), the damage to the liver is augmented. The dose of either that alcohol in itself or the other hepatic toxin producing cirrhosis, only in conjunction with alcoholism in the body and brought to a focus, is so small that it is difficult to see how the disease is specific to

the action of other toxic agents. In either case the result is the same.

The second group of substances, to which in contrast to alcohol little attention has been paid in connection with cirrhosis of the liver, is the group of inert colloids. Such substances as India ink, colloidal silica, Trypan blue, etc. are being used in biological experiments to impair the function of the reticulo-endothelial system. The changes produced by injections of these substances, such as diminution in the titre of antibodies, etc., are ascribed to a so-called "block" of this system on the assumption that chemically inert bodies in colloidal suspension are powerless to injure parenchymatous organs. However, in some recent experiments,⁶ the author found with surprise that after three injections of India ink the tolerance for sugar and the response of rabbits to epinephrine were affected as markedly as after any of the "specific" hepatic poisons. In agreement with this finding is the description by Albot¹ of hyaline degeneration in the liver of animals following as few as two injections of India ink.

A plausible explanation of the mechanism of such an injury is that particles of India ink, by filling the Küpfer cells and other units of the reticulo-endothelial system, are exposing the hepatic parenchyma to the influence of poisons circulating in the blood. If such is the true mechanism it would be comparable to the action of alcohol in rendering the liver more susceptible to the effect of toxins. It is also of interest that in individuals with pulmonary tuberculosis and allied, etc.

hosis of the liver has been described due to the probable action of particles of coal and quartz on this organ.^{22,23,24,25} That pigmentary cirrhosis of the liver probably also belongs to this group is suggested by the experimental production of cirrhosis by injections of hemoglobin and a number of hemolytic substances.

THE UNITARY CONCEPTION OF HEPATIC CIRRHOSIS IN MAN

Knowing that cirrhosis of the liver is the result of an interplay of necrosis, regeneration, and sclerosis, it is not difficult to see that the relative prominence of these processes accounts for the terminal picture seen by the clinician and by the pathologist. Experimentally this can be demonstrated by the example of chloroform which, depending on the mode of administration, will produce either a picture

closely simulating acute yellow atrophy or cirrhosis.

In the clinic we have at one extreme the toxic cirrhosis of Mallory caused by repeated attacks of subacute yellow atrophy of the liver, the end-result, that is, of massive necrosis and extremely vigorous regeneration of hepatic parenchyma with little interstitial fibrosis. (Figure 1) At the other end of the scale we see the atrophic type of portal cirrhosis, resulting from several decades of steady drinking in susceptible persons and characterized by extensive penetration of fibrous tissue into the hepatic lobules. (Figure 2) The occurrence of all possible grades of transition between these outstanding types of cirrhoses* is of fundamental significance. If further proof is desired, a perusal of the more elaborate systems

*"Luetic cirrhosis" or, more correctly, lues of the liver is not considered here.

FIG. 1. Toxic cirrhosis of the liver showing great loss of hepatic substance and adenomatoid nodules of regenerated cells.

of classification will show how blurred the distinctions really are between the various types of cirrhosis. Especially misleading are the classifications taking into account the size of the liver since an enlargement of this organ can be brought about by active regeneration, fatty infiltration, or hyperemia, regardless of the other features of any given case. Also, as shown by Bollman and Mann,²⁶ in experimental cirrhosis of the dog some lobes of the liver may be atrophied while adjacent lobes in the same animal are hypertrophied.

The unitary conception of the genesis of cirrhosis of the liver is important because it focuses attention on the necrotizing agent instead of on the anatomical diagnosis and, in the individual case, is conducive to earlier

recognition and treatment of this disease.

PROSPECTS OF THERAPY IN CIRRHOSIS OF THE LIVER

In conclusion a few words may be said regarding therapeutic possibilities in cirrhosis of the liver. In animal experiments even extensive cirrhosis with ascites and jaundice recedes soon after the administration of the poison is stopped. The same improvement has been reported in individuals who developed cirrhosis with ascites from prolonged medication with arsenicals.²⁷ Such observations, taken together with other suggestive facts from the clinic and the autopsy table, make it probable that many patients with this disease, especially in the alcoholic groups, recover when the advice of a physician

Fig. 2. Photomicrograph of the liver characterized by extensive diffuse fibrosis.

or an attack of jaundice has influenced them to stop the abuse of alcohol.

The intractability of the easily recognizable stages of cirrhosis depends upon the fact that the "classical" symptoms of this disease are really signs of grave decompensation which supervenes only after regeneration has been for some time falling behind necrosis. The main factors responsible for the slowing down of regenerative processes in the liver are diminution in blood supply and extensive fibrosis. The tendency which becomes manifest in middle age, to replace parenchyma by connective tissue, probably favors the usual appearance of cirrhosis during this time of life.²⁸

SUMMARY

The earliest lesions leading to experimental cirrhosis of the liver are

always found in the hepatic parenchyma. Any toxic agent causing necrosis of the parenchymatous cells of the liver will on repeated administration produce cirrhosis of this organ. Alcohol and inert colloids are discussed as etiological factors in cirrhosis.

Following necrosis of hepatic tissue, regeneration of parenchyma and proliferation of the framework of the liver take place. The relative prominence of these two processes, as well as the dose of the toxin and its chemical nature, determine the clinical and pathological end-picture of cirrhosis.

The unitary conception of the genesis of the various types of cirrhosis of the liver furthers earlier recognition and treatment of this disease by focusing attention on the toxin involved.

Aleukemic Myelosis with Osteosclerosis*†

By D. J. STEPHENS, M.D., and J. F. BREDECK, M.D., F.A.C.P.,
St. Louis, Missouri

IN 1904 Albers-Schönberg¹ first described the roentgenologic picture of a disease of the skeletal system characterized by transformation of the medullary canal and spongy portions into compact bone. The condition has since been described under various names: Albers-Schönberg disease, osteosclerosis, osteopetrosis, marble bones, Marmorknochen, Marmorskellett, etc. According to Karshner,² who has recently reviewed the subject, osteosclerosis is hereditary and is due to a primary dyscrasia of the mesenchyme, resulting in abnormal and excessive bone formation. The essential lesion is an increase in thickness of the hard, cortical bone, with condensation and broadening of trabeculae and crowding of the marrow elements, which are often replaced by fibrous tissue. There is no apparent relation to syphilis or vitamin deficiency. Commonly found in infancy and childhood, the primary changes are known to persist without symptoms well into adult life. Of cases reported in the literature, about one-third have shown

blood dyscrasias which may be classified as aleukemic myeloses; the remainder have been accompanied either by an anemia or by no change in the circulating blood.

From the literature, we have been able to collect twenty-four cases of generalized osteosclerosis with aleukemic myelosis. Of these, nineteen are described in sufficient detail to be included in the summary of table 1. In addition, incomplete reports of cases which fall into this group are given by Baumgarten²¹ and Schmorl.²² Of the twenty-one cases, that of Goodall appeared in the English literature, the remainder in the German. The postmortem observations of still another case are described in the Italian literature by Pastore.²³

From table 1 it is seen that the association of osteosclerosis with a leukemoid blood picture has been observed with about equal frequency in the two sexes and is not limited to any particular age group: the age of patients has varied from ten weeks to seventy-six years, with each decade represented by one or more cases. In adults at least, the condition has been chronic. Most of the patients give a long history of splenomegaly, and cases followed for a number of years show but little change in the clinical

*An abstract of this paper was read before the Central Society for Clinical Research at Chicago on November 20, 1931.

†From the Department of Medicine, Washington University, and the Barnes Hospital, St. Louis, Mo.

picture other than a slowly progressive anemia. Jores' patient was observed over a period of twelve years; the patient described by Albers-Schönberg in 1904 was reported by Reiche¹⁷ in 1915 and again by Lorey and Reye²⁵ in 1923.

The requirements for the diagnosis of aleukemic myelosis in these patients are fulfilled by extramedullary proliferation of the myelogenous apparatus in the spleen and other organs, with young cells in the peripheral blood in the presence of a normal or but slightly elevated total white blood cell count. It may be seen that six of the patients described in the literature exhibited total counts of over 20,000 per cu. mm. It should be noted, however, that three of these patients were very young, and in all three the leuk counts were

apparently terminal. Splenomegaly is probably the most striking clinical manifestation of the syndrome, and in our cases, as in others, it was the presence of splenic tumor that led the patients to seek medical advice. In autopsied cases the spleen has been found to weigh from 1400 to 2700 grams; histologically the enlargement is seen to be due to infiltration and proliferation of myelogenous cells. The less marked enlargement of liver and lymph nodes is due to a similar myelometaplasia. In contrast to chronic myelogenous leukemia the percentage of myelocytes and myeloblasts in the peripheral blood is not high, in most cases not over 20 per cent. A case recently reported by Zypkin²¹ is unusual in that the leukemic disturbance was of the lymphoid type. The

patient was a man of 42 years, who exhibited generalized enlargement of lymph nodes, splenomegaly and hepatomegaly, moderate anemia and white blood cell counts from 4,700 to 87,000 with 65 to 70 per cent lymphocytes. At autopsy the lymph nodes throughout the body were found to be enlarged and there were lymphoid infiltrations of the spleen, liver, and bone marrow; the bones showed a generalized osteosclerosis similar to that observed in other cases.

The anemia, which varies greatly in severity from case to case, is always of a highly regenerative type. The increased activity of the remaining marrow and the severity of the strain on the impoverished erythropoietic system is reflected in the peripheral blood by the presence of normoblasts, punctate basophilia, polychromatophilia, and changes in the size and shape of the red blood cells. We have no evidence of ectopic, extramedullary red blood cell formation in these cases, but, as Doan²⁷ has pointed out, it is entirely possible that this may occur when unusual demands are made on the blood forming system.

The case reports which follow are apparently the first of this type to appear in the American literature.

CASE I

W. McC., a white carpenter 51 years old, was admitted to Barnes Hospital May 12, 1930, complaining of a mass in the left side of the abdomen. His attention had first been called to this mass seven years before by a dull aching pain in the upper abdomen. Two years later he was admitted to his local hospital because of gradual loss of weight and strength; he was told that he had a disturbance of the white blood cells, and on exploratory laparotomy a huge

spleen was found. At that time he received six exposures to X-ray and eight arsenical injections; he gained weight and strength, was able to return to work, and remained in fair health for almost five years. During the four months before admission to the hospital, however, he had again been losing weight and strength and had had constant pain in the left side of the abdomen. In the past his health had always been good and the family history revealed nothing of significance.

On examination the patient appeared chronically ill; the complexion was sallow, the skin and mucous membranes pale. The inguinal lymph nodes were slightly enlarged but there was no general lymphadenopathy. Examination of the head showed nothing abnormal. The lungs were clear, the heart normal. Blood pressure was 100 mm. Hg systolic, 60 diastolic. The peripheral arteries were markedly thickened. A greatly enlarged, hard spleen was found, extending past the midline and downwards to the iliac crest. The liver was slightly enlarged to percussion. The prostate was normal. The extremities showed nothing unusual.

Blood hemoglobin was 65 per cent (Sahli), red blood cells numbered 3,240,000 per cubic millimeter, white blood cells 10,300. The smear showed variation in size and shape of erythrocytes, many normoblasts and stippled cells. Differential white blood cell count revealed the presence of myelocytes and young granular cells. The blood findings are shown in detail in table 2. The urine on several occasions showed nothing unusual; in particular it contained no Bence-Jones protein. Stool examinations were negative. The blood Kahn was negative. Roentgen examinations of the skeletal system showed extensive changes, with general increase in density and multiple small areas of *relative* rarefaction. Figure 1 shows these changes in the bones of the pelvis. The areas of relative rarefaction were considered by the roentgenologist to be representative of bone of normal density, with darker areas representing bone of increased density. Striking changes of similar character were observed in the clavicles and ribs and in the vertebrae. The films also showed marked calcification of arteries. Blood calcium was 10.5 mg. per cent, uric acid 8 mg. per cent.

TABLE II
Blood findings in Case 1.

non-protein-nitrogen 40 mg. per cent. Gastric analysis showed a normal acid curve. Phenolsulphonephthalein excretion was 50 per cent in two hours. The basal metabolic rate was plus 19 per cent. Material obtained on splenic puncture showed many myelocytes.

The patient's course in the hospital was afebrile and uneventful except for diagnostic procedures. He received one exposure to deep X-ray therapy without apparent benefit.

Six months later he reentered the hospital because of dull pains in the back and legs. Findings on examination were similar in all respects to those on the previous admission. After a biopsy of a rib the patient was again discharged; he has since moved from the vicinity of St. Louis and the authors have not been able to trace him.

Pathological report by Dr. Howard McCordock revealed the following: "The gross specimen consisted of a piece of rib about

Fig. 1. Roentgenogram of rib cage in Case 1, showing nodules presumably due to metastatic disease. (X-ray taken for chest tumor at St. Louis.)

one inch in length. On cross section there was no definite marrow cavity. The medullary cavity appeared to have been replaced by newly formed bone tissue. In this, however, there were small red flecks representing the remains of marrow spaces. The increased hardness of the rib was evident when it was cut, for it offered as much resistance to the

bone which stained red with the eosin. Alongside of this new bone formation there could be seen evidences of bone destruction with large numbers of multinucleated osteoclasts resting in excavations situated along the edge of the bone trabeculae. The bone marrow spaces almost everywhere were filled with a loose cellular connective tissue. In

FIG. 2. *Left:* Photomicrograph of rib of Case 1, showing osteosclerotic invasion of the medullary cavity. *Right:* Normal rib, showing relatively wide cortex and normal medullary cavity without obvious trabeculation.

saw as the outer table of the skull usually does. The cut surface was of ivory-like density.

"After decalcification sections were made and stained with hematoxylin and eosin and Giemsa stain. The thin bone trabeculae that normally traverse the marrow cavity were greatly increased in number and thickened. This produced a dense bony structure in which there were only tiny remnants of the marrow spaces. All this newly formed bone was well calcified. One could often make out the original bone trabeculae by their deeper blue stain, and surrounding these there was a thick layer of newly formed

places in the meshes of this connective tissue there might be seen small nests of blood forming cells among which one could recognize myelocytes, polynuclear leukocytes, normoblasts, red blood cells, and a few megakaryocytes. On the whole, however, the fibrous marrow predominated and the islands of hematopoietic tissue were few and far between. *Diagnosis:* Osteosclerosis with fibrosis of bone marrow."

CASE II

J. J., a farmer 48 years old, was admitted to Barnes Hospital August 7, 1930, complaining of a mass in the left side of the

40 years. This mass had been first noted two years previously, had increased somewhat in size but had not been painful or tender. There were no gastrointestinal symptoms other than a sense of fullness after eating. He had noted a slowly progressive weakness and his weight had dropped from 170 to 145 pounds. His general health in the past had been good; the

table 3. The urine showed small amounts of albumin but no Bence-Jones protein. The blood Kahn was negative. Stools were normal. Blood non-protein-nitrogen was 30 per cent, calcium 10.7, phosphorus 4.5, acid 10.6. Gastric analysis was normal. Phenolsulphonephthalein excretion was per cent in two hours. The basal metabolic rate was plus 13 per cent. Cystosc-

Fig. 1. Photomicrograph of trabecular cavity of osteosclerotic rib, showing fibrosis of connective tissue.

metastases were of the most important type, namely, poorly circumscribed, rather extensive, and diffusely infiltrative. There was no evidence of extramedullary involvement. The primary site of the tumor was not identified. The patient died of complications of the disease. The autopsy showed a large, firm, and hard, white, lobulated mass, 10 cm. in diameter, in the right lung, which was the primary site of the tumor. The mass was surrounded by a thin layer of connective tissue and was infiltrated by numerous small, dark, round cells, which were the tumor cells. The tumor cells were arranged in nests and cords, and were surrounded by a thin layer of connective tissue. The tumor cells were stained with hematoxylin and eosin, and showed a high degree of cellular atypia and mitotic activity. The tumor cells were also stained with special stains, which showed that they were of the same type as the tumor cells found in the bone metastases.

The tumor cells were also stained with special stains, which showed that they were of the same type as the tumor cells found in the bone metastases. The tumor cells were also stained with special stains, which showed that they were of the same type as the tumor cells found in the bone metastases.

examination and pyelograms were negative except for evidence of extra-renal pressure on the left. Roentgen-ray examination of the gastrointestinal tract showed displacement of the splenic flexure of the colon by an extraluminary tumor, but nothing else abnormal. Roentgen-ray examination showed an extensive involvement of the skeletal system, similar to that seen in Case 1, with generalized increase in density and multiple small areas of relative rarefaction. Figure 4 is a reproduction of an X-ray negative which is based on the roentgen markings of the trabecular system of the heads of the femora, especially proximal. It was previously shown that the trabecular system

the ribs and clavicles similar to those observed in the pelvic bones. Material from splenic puncture showed many myelocytes.

A small therapeutic dose of X-ray was followed by a drop in the white blood cell count from 14,000 to 10,000 per cubic millimeter; this was considered a contraindication to further radiotherapy. The patient returned three months later with but little change except for the presence of ascites; there was no dependent edema. Paracentesis abdominalis was performed and five liters of yellowish green fluid obtained. The fluid contained 1200 cells per cubic millimeter and had a specific gravity of 1.020. Differential count of the cells in the ascitic fluid showed 20 per cent myelocytes, 15 per cent segmented polymorphonuclear leukocytes, 6 per cent lymphocytes and 59 per cent unclassified cells.

After discharge from the hospital it was necessary to perform a paracentesis about every ten days. In a recent letter from the patient's physician it was learned that a blood examination in July, 1931, showed practically the same picture as that observed by the authors and that the patient died in August, 1931, of a gastric hemorrhage.

DISCUSSION

These two patients exhibit a striking similarity in history and in physical and laboratory findings. Both presented the complaint of a mass of long duration in the left side of the abdomen. Although the history was of but

two years' duration in Case 2, it is not unlikely that the splenomegaly was of much longer standing. In view of the fact that the spleen was quite large when first noted and increased but little in size during the following two years, it is reasonable to suppose that the spleen had been enlarged for some time, but that in the absence of other symptoms this enlargement had not been discovered. The splenomegaly overshadowed all other physical findings, and splenic puncture indicated that the marked enlargement was due to myelogenous infiltration. The presence of myelocytes in the ascitic fluid in the second patient suggested the presence of myeloid metaplasia in the peritoneum and probably in the liver. In both cases the roentgenologic findings were considered most suggestive of metastatic carcinomatosis of bone with reactive sclerosis, but detailed investigation in each case failed to demonstrate any evidence of a primary carcinoma. In the first patient rib biopsy revealed the true nature of the bone disturbance and definitely established the diagnosis. The second patient refused to submit to biopsy of bone, and, although unlikely, the pos-

sibility of metastatic miliary carcinomatosis of bone cannot be definitely excluded. It is of interest that both patients showed clinical evidence of rather marked peripheral arteriosclerosis.

In consideration of the pathogenesis

with the cortex of the long bones partially replaced by cancellous tissue of dirty brick red color, so that the bone on section showed only a narrow cortical border. Similar cases have been described by others. A reactive sclerosis of bone secondary to true

FIG. 4. Roentgenogram of pelvic bones in Case 2, showing marked trabeculation and changes almost identical to those of figure 1.

of this syndrome, there is a difference of opinion as to whether this is primarily a disease of blood and blood forming organs or of bone. Bone changes have been described in true leukemia, but here the marrow cavity is usually increased in extent at the expense of the cortical bone in direct contrast to the obliteration of marrow in osteosclerosis. For example, in 1900 Mott²⁴ described a case of leukemia with ear changes in which the petrous bone showed rarefaction; the bones throughout the body showed changes,

leukemia has been said to occur, but we have been unable to find case reports in which this relationship has been established.

The studies of Karshner² indicate that the type of bone disturbance seen in osteosclerosis is hereditary; apparently the character and degree of change in the erythropoietic and leukopoietic systems depend on the extent and severity of marrow involvement. The myelogenous deposits in spleen, liver, and lymph nodes may well be regarded as a compensatory mechanism.

ism. Donhauser²⁹ has considered that the spleen may act as a hematopoietic organ as exemplified in the autopsy observations of a 58-year-old man who showed splenomegaly considered secondary to a primary sclerosis of bone marrow. The marrow was replaced by lymphoid cells and fibroblasts but the bone changes of osteosclerosis were not present. The spleen contained cells normally found in the bone marrow, and the author concluded that the spleen had reacted to the destruction of marrow by resuming its hematopoietic function.

Osteosclerosis may be compared to metastatic carcinomatosis of bone as a primary factor in the pathogenesis of leukemoid disturbances. Weber³⁰ described under the title, "A Case of Osteosclerotic Anemia or Leukemia", a man of fifty-eight in whose bones the cancellous tissue was solid and rocklike with the medullary canals partially filled with hard bone and fibrous tissue. This was first regarded as true osteosclerosis but further microscopic study of autopsy material showed that the osteosclerosis was in reality a reactive change to metastatic generalized miliary carcinomatosis of bone, secondary to a small primary carcinoma of the prostate.³¹ In many cases described in the literature as unqualified aleukemic myelosis, aleukemic leukemia, or pseudoleukemia, there is no mention made of clinical or pathological examination of the skeletal system. It is possible that aleukemic myelosis is not a clinical entity but is a secondary and sympto-

matic result of another disease localized in the bone marrow.

In the differential diagnosis of these cases leukemia is usually considered. However, the long duration of symptoms and of splenomegaly, the low total count, and the relatively small percentage of young cells in the differential formula should make one wary of diagnosing a true leukemia. Roentgenologic study of the skeletal system is indicated in all patients with this type of blood dyscrasia. As we have seen, the roentgenologic picture of osteosclerosis may simulate that of metastatic carcinomatosis. Here again the long duration and chronicity of the disease, together with the lack of evidence of primary tumor or of metastasis to other regions, indicate that the bone change is not a metastatic one. The diagnosis may be definitely established by biopsy of bone, or, as has been done in some instances, by sternal puncture.

There is no known type of therapy which influences the course of osteosclerosis. If, as we believe, the leukemoid changes are in the nature of a compensatory mechanism, it is best not to attempt to influence the leukopoietic apparatus by means of deep X-ray therapy or by other measures commonly used in the treatment of leukemia. Treatment, in the light of our present conception of the etiology of the disease, should be symptomatic and directed at the improvement of the general health of the patient.

Some Unusual Cardiac Complications of Hyperthyroidism*†

A Report of Four Cases

By CARTER SMITH, M.D., and H. CLIFF SAULS, M.D., F.A.C.P.,
Atlanta, Georgia

OCCASIONALLY we encounter patients with heart disease who have none of the usual etiological or associated diseases, viz., hypertension, the rheumatic syndrome, or lues. Obscure hyperthyroidism must be excluded in these cases. Since 1924 there have been numerous publications on hyperthyroidism masked as heart disease. Levine and Walker¹ recently reviewed the literature and reported eleven such cases.

Thyrotoxicosis imposes a tremendous burden on the heart. Even with the patient at rest the work of the heart in an individual with hyperthyroidism is comparable to that of the normal heart when undergoing the most strenuous exercise.² If this overactivity is continued for any great length of time, widespread myocardial damage may result. Following thyroidectomy the work and volume output of the heart returns to normal³ and there is a striking increase in myocardial reserve. Thyroidectomy should be attempted even in patients

with advanced myocardial failure after proper medical preparation.

DIAGNOSIS

To suspect thyrotoxicosis in the absence of physical signs is essential in making a diagnosis in these obscure cases. Attempts should be made to elicit a history of nervousness, palpitation of the heart, loss of weight, diarrhea of inexplicable origin, excessive sweating, premature gray hair, the preference of cold to hot weather, and the familial occurrence of hyperthyroidism. On close questioning a history of hyperthyroidism with a spontaneous remission many years before may be obtained.

On examination a slight general increase in excitability of the patient may be encountered. The skin often assumes a "salmon-like" hue and is warm, moist, and velvety. The hair may be prematurely gray. The thyroid gland may or may not be palpable. The heart is usually enlarged. The apical first sound is usually accentuated. There is often a systolic murmur at the apex. On one occasion the authors found a diastolic murmur over the aortic area with all the accompany-

*Received for publication February 9, 1932.

†From the Medical Services of Emory University and Piedmont Hospital.

ing signs of aortic insufficiency, which disappeared following operation. There is usually an elevation of the systolic pressure and an increase of pulse pressures. The heart rate is usually rapid and the rhythm is often irregular. In one patient, in the series reported below, an electrocardiogram showed the arrhythmia to be due to auricular fibrillation and in another to auricular premature beats.

Occasionally thyrotoxicosis may manifest itself principally as precordial pain, and we may find coexisting coronary disease and hyperthyroidism. Lev and Hamburger³ have reported such a case. Unusually severe and frequent attacks of precordial pain in patients without the usual signs of accompanying vascular disease should arouse the suspicion of thyrotoxicosis as an etiological or contributing factor.

When suspected, the diagnosis can be confirmed or ruled out by basal metabolism tests. Elevated metabolic rates are sometimes associated with cardiac failure, but this increase is usually not more than 20 per cent.⁴ Repeated tests should be made on those patients in whom hyperthyroidism is suspected and if these are not conclusive the therapeutic iodine test may be done. In the cases reported below the metabolic readings were quite conclusive as they were \pm 40 per cent or more on repeated determinations. The finding of a relative lymphocytosis, which has been observed in a large percentage of patients with hyperthyroidism, may be of some diagnostic aid.^{5,6}

After corroboration of the diagnosis a very careful examination of the

heart and a teleoroentgenogram and electrocardiogram should be made to determine the extent of the cardiac damage.

MANAGEMENT

Since the introduction of iodine for the preoperative preparation of patients with hyperthyroidism its misuse has increased yearly in spite of frequent publications on this subject. Iodine should almost never be given unless plans for operation have been made. The administration of iodine is generally followed by a period of improvement lasting several weeks. If operation is not performed during this period of improvement the iodine effect is lost and a relapse will occur. Relapses are often accompanied by violent "thyroid storms". If a "storm" occurs in a patient with an already seriously damaged myocardium, death may result. If the patient survives the "storm" and operation is attempted, the surgeon is at a great disadvantage since the patient is usually refractory to iodine for several weeks. Operation without the use of iodine, especially in a patient with heart disease, is a hazardous undertaking.

It is sometimes difficult to find a surgeon who will agree to operate on a patient with cardiac failure even though he is convinced that the etiology is hyperthyroidism. When the diagnosis has been based upon a careful study, and when adequate preoperative preparation can be carried out, we feel that internists should strongly urge the performance of thyroidectomy.

The use of digitalis is frequently discouraging in patients with hyper-

thyroidism. It is a well-known fact that this drug will often fail to slow the heart rate in a patient with auricular fibrillation when the auricular fibrillation is associated with thyrotoxicosis. Probably the only indication for digitalis in thyroid heart disease is the presence of congestive heart failure. It is usually unnecessary to treat auricular fibrillation with quinidine as the majority will revert to normal rhythm after thyroidectomy.

Preoperative preparation should consist of complete bed rest, forced feedings, and large doses of sedatives. After consent for operation has been obtained, iodine may be begun. Basal metabolic rates should be determined at intervals of four or five days. After ten to fourteen days of iodine administration the patient's general condition will usually be much improved and the metabolic rate greatly reduced. Operation can then be performed without difficulty.

Instances arise in which patients with hyperthyroidism have to be treated without operation. This is at present a long and often disappointing procedure. Absolute bed rest with forced feedings and large doses of sedatives must be insisted upon. Marine⁷ has suggested the use of iodine in very minute doses, 1 milligram (or 1/60 grain) three times daily over an extended period of time. This produces a more gradual reduction in thyroid overactivity, and "iodine escape" with its attendant evils is less likely to occur. The use of ergotamine tartrate has been advocated by some⁸ as an aid in reducing the metabolic rate because of its depressive action on the

sympathetic nerve system. The recent work of Youmans and Trimble⁹ seems to indicate, however, that this drug is without value in the treatment of hyperthyroidism.

Radiation of the thyroid gland was used rather extensively in the medical treatment of hyperthyroidism a few years ago. This procedure also has proved unsatisfactory; it has the added disadvantage of making the gland quite difficult to remove if surgery is attempted at some later date.

CASE I

Mrs. D. H. W., a Caucasian housewife of 46 years, was first admitted to the hospital June 20, 1931, complaining of nervousness, palpitation of the heart, shortness of breath and loss of weight.

Five months before admission she consulted her family physician because of occipital headaches. She was referred to a dentist who found several abscessed teeth. These were removed and the headaches disappeared. A short time later she first noticed a rapid and forceful heart action with shortness of breath on slight exertion. She was extremely nervous and easily fatigued. She was also losing weight in spite of a very good appetite. Three months after the onset of the present illness the shortness of breath had become quite marked and she first noticed swelling of the feet and ankles. Upon the advice of her family physician she went to a hospital. There she was given Lugol's solution for about two weeks and showed marked improvement. She was then discharged from the hospital but remained in bed at home. There was a return of symptoms in about six weeks and she was seen by us at that time.

Her past history was unimportant except for occasional attacks of diarrhea all of her life. She admitted a preference for cold weather; and she had noted an increase in nervousness during the past three years.

On examination she was an emaciated, anemic, dyspneic, generally overactive, middle-aged woman lying propped up in bed.

The skin was warm, velvety, and had a "salmon yellow" tint. The hair was gray. The eyes were blue. There was well marked lid-lag and exophthalmos. The conjunctivae and the mucous membranes of the mouth were quite pale. The small papillae of the tongue were atrophied. The thyroid gland was soft and symmetrically enlarged. There was a definite thrill and bruit present. There was marked over-filling of the jugular veins and the carotid pulsations were vigorous. A moderate number of medium moist râles was found at the bases of both lungs. The apex impulse of the heart was diffuse and forceful. There was a moderate cardiac hypertrophy; the left border of dullness was 11.5 cm. from the midline, the right border 5 cm., and the supracardiac dullness in the second interspace was 7 cm. in width. The first sound at the apex was greatly accentuated and there was a loud systolic murmur. At the left sternal border in the fourth intercostal space there was a long high-pitched diastolic murmur. This was also heard over the second right interspace. The aortic second sound was audible but muffled. The heart rhythm was fundamentally regular but there were frequent premature beats. The rate was 100 per minute. The entire vascular bed was shaken with each systole. All peripheral veins pulsated. There was a Corrigan pulse, and pistol shot sounds were heard over the femoral vessels. The blood pressure was 160 mm. Hg systolic and 0 mm. diastolic. There was a moderate pitting edema of the ankles and slight edema in the sacral region.

The blood count showed 3,000,000 red cells and the hemoglobin was 50 per cent (Dare). There was 39 per cent of lymphocytes in the blood smear. The reticulocyte count was 2.8 per cent. The blood chemical tests performed gave normal results and the Wassermann reaction was negative. The urine examination was negative, and there was a phthalein excretion of 82 per cent in two hours. The basal metabolic rate on admission was \pm 58 per cent. The electrocardiogram showed a biphasic "T" wave and slight notching and slurring of the "Q-R-S" complex in lead I. There were numerous auricular premature beats. The gastric analysis

showed a total acidity of 67 degrees with 28 degrees of free hydrochloric acid.

The patient was given her calculated dose of digitalis, heavy doses of bromides, and 5 drops three times daily of Lugol's solution. The secondary anemia was treated with preparations of liver and of iron. Two transfusions were given. Two weeks after admission the cardiac failure had largely subsided, the blood pressure was 140 mm. Hg systolic and 40 mm. diastolic. The peripheral signs of aortic insufficiency and the diastolic murmur were still present.

Three weeks after admission the blood count was practically normal and all signs of cardiac failure had disappeared. The basal metabolic rate was \pm 38 per cent. A subtotal thyroidectomy was done at this time. The postoperative course was not unusually severe but probably more so than if iodine had not been given previous to her preoperative preparation. There was a moderate tracheitis. The temperature was 100 degrees for two or three days. Convalescence was uneventful and she was discharged ten days after operation.

One month after operation the patient had gained 16 pounds in weight and felt quite well. Her only symptoms were occasional palpitation of the heart and easy fatigue. There were no signs of cardiac failure. The over-activity of the heart had completely disappeared and the diastolic murmur and peripheral signs of aortic insufficiency were no longer present. The blood pressure was 145 mm. Hg systolic and 70 mm. diastolic. There was a moderate systolic murmur at the apex, the heart rate was 66 per minute and the rhythm completely regular. The basal metabolic rate was \pm 3 per cent. The blood count and urinalysis were normal.

DISCUSSION

This patient illustrates the importance of making an early diagnosis and removing the thyroid gland before cardiac damage has become so advanced. The necessity of operating, even though there is advanced heart failure, is also well demonstrated. This patient had a striking return of circulatory competence in spite of the fact that her degree of congestive heart failure was advanced. It was with some difficulty that the

surgeon was convinced that she did not have primary heart disease with aortic insufficiency. There is nearly always an increase in pulse pressure with thyrotoxicosis because of the increased amount of blood that is discharged from the ventricles with each systole. Only very rarely, however, will it produce the peripheral signs of an aortic insufficiency. These signs, associated with the diastolic murmur, made the picture quite confusing. The cause of the diastolic murmur was uncertain. A combination of the anemia and hyperthyroidism may have been responsible.

Anemia is a very unusual complication of hyperthyroidism. There is often an increase in the red cell count. This patient's anemia was of a secondary type but its cause remained obscure, as her diet had been unusually adequate and there was no history of blood loss or of chronic infection.

CASE II

L. S., a colored male cook of 51 years, was admitted to the hospital April 6, 1931, operated on June 6, 1931, and died twenty-four hours later.

Seven months before admission the patient began to have diarrhea. There were no abdominal cramps and no blood or mucus in the stools. At first there were two to four stools daily; these later increased to six or eight and he became quite weak. Associated with the diarrhea there was occasional epigastric fullness, palpitation of the heart, and shortness of breath. He lost 27 pounds during the seven months prior to admission to the hospital. The appetite was fair during this time and his diet was not particularly lacking in any of the essential foods. He had noticed very little increase in nervousness.

The past history was unimportant except for a period of diarrhea twenty-six years before. He had gray hair at the age of thirty and premature grayness was a paternal hereditary trait.

On examination he was lying quietly in bed, without apparent nervousness or overactivity. The skin was warm, moist and velvety. There was no lid-lag, exophthalmos or loss of convergence. There was moderate retinal sclerosis. The tongue

showed an unusual redness, and there was some atrophy of the small papillae. The thyroid was not felt but there was some fixation of the trachea. The lungs were normal. The apex impulse of the heart was rather forceful in the fifth interspace just outside the midclavicular line. The heart was moderately enlarged to percussion. The left border of dullness measured 10 cm. from the midline, the right border 3 cm., and the supracardiac dullness in the second interspace was 5 cm. in width. Over the apex there was some accentuation of the first sound and a soft systolic murmur. The aortic second sound was of fair quality and greater than the pulmonic second sound. No diastolic murmurs were heard at this time. The heart rate was 120 per minute and the rhythm regular. The blood pressure was 135 mm. Hg systolic and 70 mm. diastolic. There was slight sclerosis of the radial vessels. The abdomen was emaciated but there was no tenderness or enlargement of organs. There was no edema of the feet and ankles. The extended fingers showed a moderate fine tremor. There was some pallor of the nails and of the mucous membranes. The reflexes were normal.

Examination of the blood showed 3,000,000 red blood cells with a hemoglobin of 55 per cent. There was a lymphocytosis of 59 per cent. The reticulocyte count was .7 per cent. The urine examination was entirely normal. The Wassermann test was negative. Repeated blood cultures were negative. Examination and culture of the stool revealed nothing unusual. The gastric analysis showed no free hydrochloric acid and a combined acidity of only two degrees. The duodenal contents were normal. Roentgenographic examination of the gastrointestinal tract showed only some spasticity of the descending colon.

During the early part of his stay in the hospital efforts were directed largely towards finding an explanation for the diarrhea, the achlorhydria, the anemia, the papillary atrophy of the tongue and the premature gray hair. The vascular findings were regarded as secondary to the long-standing diarrhea and anemia. The diagnostic possibilities were numerous and included

pellagra, sprue, primary anemia, and chronic ulcerative colitis.

Eleven days after admission the heart rhythm became grossly irregular and the electrocardiogram showed the presence of auricular fibrillation. A pulse deficit of twenty per minute was associated with the arrhythmia. After the onset of auricular fibrillation the possibility of hyperthyroidism as an explanation for the entire clinical picture was considered. The basal metabolic rate was determined on three successive occasions and found successively to be +47, +32, and +36 per cent.

During the next month the treatment consisted of forced feeding and the administration of sedatives and preparations of liver and iron. He continued to lose weight and there was no increase in the red blood cells or hemoglobin. Auricular fibrillation continued and a diastolic murmur developed over the second right interspace at the sternal border. There was no decrease in the diastolic pressure. The patient was advised to have the thyroid removed and he finally consented. Lugol's solution was begun and the metabolic rate dropped to +10 per cent during the next two weeks but with very little improvement in his general condition.

Two months after admission, and two weeks after beginning iodine, a subtotal thyroidectomy was performed. A few hours later the patient's temperature rose to 106 degrees F. The heart rate was 150 per minute, and the rhythm grossly irregular. He was treated with oxygen and the usual supportive measures but failed to rally, and died thirty-six hours after operation.

Discussion

This patient presented a most difficult diagnostic and therapeutic problem. The thyroid overactivity may have been primarily responsible for the entire picture, but the course of events makes one suspect that it was associated with a "pellagra-like" deficiency disease. We believe that this case affords a striking example of the close association of these diseases with hyperthyroidism. The symptoms of cardiovascular disease were not permanent and it was only after the development of auricular fibrillation that attention

was focused on them. The lack of improvement after the administration of Lugol's solution, in spite of a drop in the metabolic rate, further emphasizes the probability of an association of diseases rather than just an unusual and obscure hyperthyroidism.

CASE III

L. B. S., a colored maid of 56 years, was first admitted to the hospital September 15, 1930, operated on January 28, 1931, and discharged February 5, 1931.

About the time of puberty this patient first noticed a slight enlargement of the thyroid gland. This enlargement persisted but without symptoms or change in size throughout the years that followed. Two months before admission to the hospital she first noticed slight palpitation of the heart and shortness of breath on exertion. She also noticed a fullness beneath the sternum but no pain. There was no nervousness, no increase in appetite and no loss in weight.

On examination at this time there was no general overactivity nor any signs to suggest thyrotoxicosis. There was a small nodular enlargement of the thyroid without thrill or bruit. The eye signs of hyperthyroidism were absent. The skin, while moist and velvety, was cooler than normal. There was no significant tremor.

The heart was moderately enlarged and there was a palpable thrill over the base. The apical first sound was somewhat accentuated and there was a long, harsh systolic murmur in this area. Over the second right intercostal space there was a long, high-pitched systolic murmur which was transmitted into the vessels of the neck, and a shorter and lower pitched diastolic murmur. This was better heard in the left intercostal spaces at the sternal border. The aortic second sound was not heard. The rhythm was regular. The rate was 80 per minute. There was a moderate sclerosis of the radial and retinal vessels. Moist râles were present at the bases of both lungs. The blood pressure was 240 mm. Hg systolic and 130 mm. diastolic. The abdomen was essentially negative. There was slight pitting edema over the tibiae. The height was 5 feet, 4 inches, and the weight 138 pounds.

Examination of the urine showed nothing unusual. The phthalein excretion was 55 per cent in two hours. The blood count was normal except for a lymphocytosis of 50 per cent. The Wassermann test was negative. The blood chemical tests gave normal results. A teleoroentgenogram of the heart showed the aortic shadow to be 5.5 cm. in width; the right margin 5 cm., and the left margin 10.5 cm. from the midline. The electrocardiogram showed only a left axis deviation. The vital capacity was 3 liters.

From this study it was concluded that the patient had hypertensive heart disease and early congestive heart failure. The auscultatory findings over the aortic area were difficult to explain on a rheumatic or luetic basis and it was thought that they might be due to calcareous deposits on the aortic cusps.

The patient was treated by bed rest, digitalis, and sedatives but with very little evidence of improvement. It was then decided to determine the basal metabolic rate because of the nodule in the thyroid gland. The rate was found to be + 51 per cent in the first test and + 55 per cent in a second test a few days later. The patient was advised to enter the hospital for thyroidectomy but refused. She remained in bed at home and was given digitalis, bromides, and forced feedings. Even with the above treatment she lost weight and showed no improvement except for the disappearance of the symptoms of cardiac failure.

Three months later she consented to operation. After two weeks of preparation with iodine she was generally improved; a subtotal thyroidectomy was done without difficulty. The postoperative course was uneventful except for a drop in blood pressure to 140 mm. Hg systolic and 80 mm. diastolic. One month after operation the patient had gained 20 pounds in weight and felt quite well. The blood pressure had increased to 170 mm. Hg systolic and 90 mm. diastolic. She has been seen at regular intervals for about one year. There has been no return of congestive heart failure. She has gained 25 pounds. The basal metabolism is normal. The blood pressure has gradually increased to 190 mm. Hg systolic and 90 mm. diastolic. The auscultatory signs of the heart are unchanged.

DISCUSSION

The relation of the nodular thyroid gland to the hypertensive heart disease is of interest in this patient. The thyrotoxicosis may have been a longstanding, recurring one without symptoms but with the gradual production of vascular damage. The hypertensive vascular disease may have developed without relation to the goiter. The nodular thyroid, after years of latency, may have recently become toxic, and, superimposed on an already damaged vascular system, may have caused cardiac failure. The diastolic murmur did not disappear following operation. Its etiology still remains obscure.

In the absence of the usual signs thyrotoxicosis would not have been even suspected if the nodular thyroid had not suggested this possibility. The removal of the burden of an increased metabolism has considerably increased the patient's cardiac reserve so that she may, with proper care, live for several years.

CASE IV

Mrs. I. Q., a housewife of 47 years, was admitted to the hospital July 3, 1931, complaining only of weakness and occasional palpitation of the heart. This was first noticed about two weeks before admission. Previous to this time there had never been any complaints referable to the heart except for occasional "fluttering" on going up stairs. She had never been excessively nervous. There was no history of digestive disturbance and her appetite had been good until recently. There had been no recent loss in weight.

On physical examination she was a well developed and well nourished Jewish woman lying quietly in bed. There was no general overactivity. The skin was moist but not particularly warm or soft. There was a beginning arcus senilis. There was no lid-lag, no exophthalmus and no failure of convergence. Fundus examination showed slight sclerosis of the retinal arteries. All teeth had been removed. The tongue protruded normally. The thyroid was not enlarged. There were no thrills, no bruits, and no unusual pulsations in the neck. The chest was symmetrical, expansion fair, and the lungs were clear throughout. The apex

impulse of the heart was felt in the fifth intercostal space 9 cm. from the midsternal line. By percussion the heart was found slightly enlarged, measuring 3 cm. to the right of the midline and 9.5 cm. to the left. The supracardiac dullness was 5 cm. in width. The first sound at the apex was a little distant and of inferior quality. There was a soft systolic murmur. The aortic and pulmonic second sounds were equal, and both were of fair quality. No diastolic murmurs were heard. The heart rate was 80 per minute. The rhythm was grossly irregular but there was no pulse deficit. There was a slight sclerosis of the radial vessels. The blood pressure was 110 mm. Hg systolic and 80 mm. diastolic. The abdomen was not unusual. The extremities showed slight pitting edema. There was no tremor of the extended fingers.

The blood count was normal. The urine examination was negative. The electrocardiogram showed auricular fibrillation with normal ventricular complexes. A basal metabolic rate was determined and found to be + 50 per cent. A second test was similar to the first.

After the metabolic rates were determined the patient was told that she had hyperthyroidism and operation was advised. She elected to defer removal of the gland and to take a period of bed rest with sedatives and forced feedings. The basal metabolic rate had decreased to + 19 per cent after five weeks of this treatment but there was some increase in the heart rate, and a pulse deficit of 10 to 15 per minute had developed. This could be eliminated by the use of digitalis.

DISCUSSION

Auricular fibrillation is usually associated either with hypertensive heart disease, with mitral stenosis or with hyperthyroidism. In

this patient there was very little evidence of vascular disease. The blood pressure was normal and there was only slight sclerosis of the vessels. There were no signs of mitral stenosis. In the absence of these two most frequent coexisting diseases (mitral stenosis and hypertensive vascular disease), hyperthyroidism was suspected as the etiological factor of her auricular fibrillation even though there were no clinical signs of its presence.

This patient's prognosis depends entirely on whether or not the thyroid overactivity will subside without operation. There is already considerable myocardial damage and she will probably develop an advanced congestive heart failure if the cardiac burden persists. As digitalis controls the pulse deficit and the heart rate, it was deemed unnecessary to attempt to obtain a normal rhythm through the use of quinidine.

This patient illustrates the importance of suspecting thyrotoxicosis in individuals who have an obscure type of auricular fibrillation even in the absence of any physical signs.

SUMMARY

1. Four patients with hyperthyroidism and unusual cardiac complications are presented and discussed.
2. The necessity of suspecting hyperthyroidism in some patients with heart disease, even though there are none of the usual signs of thyrotoxicosis, has been illustrated.
3. The diagnosis and treatment of patients with hyperthyroidism and unusual cardiac complications have been outlined.

Pneumosilicosis and Amyloidosis*†

Report of a Case of Asymptomatic Pulmonary Silicosis and Amyloid Kidney; Death from Uremia.

By J. B. CAREY, M.D., F.A.C.P., *Minneapolis, Minnesota*

THE condition of pneumosilicosis is in itself of interest only as an occupational disease. Its gradual production by intermittent rather than by constant exposure to silica-bearing dust, without apparent symptoms and with no accompanying infection, may perhaps be unusual. The deposition of silica-bearing particles of foreign material in the lung, causes much fibrosis. That this fibrosis is the direct result of irritation by the silica itself, and not of simple mechanical traumatization of pulmonary tissue by a foreign agent as such, is conceded. In individuals in whose lungs silica has been deposited, symptoms apparently result from the secondary infections which occur in such irritated organs. That the silica or any compounds derived from it may cause systemic symptoms or metastatic effects is not apparent from our present knowledge.

The association, in the same individual, of a condition of pulmonary silicosis and renal and splenic amyloidosis has not, to the author's knowledge, been reported. Because of such

a bizarre coincidence—one hesitates to call it a relationship—the following case is detailed. There is the further unusual circumstance that the amyloidosis of the kidney resulted in a renal impairment, progressive to the point of causing the death of the patient in uremia.

CASE REPORT

A white male, 49 years of age, was brought into the clinic December 9, 1931, complaining of weakness and diarrhea. In addition to his regular occupation as a farmer, the patient, for the past 21 years, had occasionally worked in granite yards and quarries for considerable periods at a time. The intermittent periodicity of this labor seems important. He was an only child. His father had died at the age of 82, but his mother was still living at 88. He was married and had six children, all living and well.

The patient had never had any illness or disability which interfered with his work until the onset of the present symptoms. The only illness of note in his past history was an attack of "bronchitis" in the fall of 1930 which did not incapacitate him.

On October 22, 1931, a large block of granite, on which the patient was working in a stone-cutting yard, slipped from its supports and fell over against him, striking him across the abdomen and knocking him down. He was thus thrown upon a smaller block, so as to be struck across his left back. He was not rendered unconscious by

*Read before the Minnesota Society of Internal Medicine, June 4, 1932.

†From the Department of Medicine, The Newell Clinic, Minneapolis, Minnesota.

this injury nor did he show signs of shock or hemorrhage at that time. He was placed in a hospital in St. Cloud, Minnesota, and remained there until November 14, 1931. During his stay in the hospital he suffered from backache, became very weak and lost weight. Diarrhea developed and persisted. When he finally went home the backache was less troublesome but the other symptoms continued. He was finally brought to the clinic by his daughter on the date mentioned.

There was no further history elicited. His complaints were weakness, diarrhea, weight loss, anorexia, and pain in the left back and side. The man seemed quite ill and unable to move about comfortably. He was therefore immediately placed in the hospital.

A résumé of the pertinent findings discovered in the subsequent examination is tabulated as follows:

Skin: pale, sweaty.

Pulse: 100.

Blood pressure: 100/60 mm. Hg.

Eye-grounds: negative.

Heart: normal.

Lungs: negative on physical examination.

Abdomen: slight tenderness deep in left upper quadrant (spleen not palpable).

Back: tenderness of lumbar muscles of left side, but no abnormality of spine itself, discovered; no edema.

Extremities: no edema.

Neurological examination: negative.

Blood: Hgb. 72 (Sahli).

R.B.C. 4,010,000.

W.B.C. 8,700—P.M.N.'s 72, lymphocytes 25, eosinophiles 3.

N.P.N. 50.8 mg. per 100 c.c.

Urine: Sp. gr. 1.018.

Albumin 2+.

Sugar 0.

Hyaline and granular casts, occasional R.B.C. and 8-12 pus cells per high power field.

Dilution and concentration test: fixation of sp. gr. 1.009-1.012.

Fixation of amount 50-70 c.e. per hour.

Phthalein: 20% first hour, 25% second hour.

Gastric Contents (45 min. after Ewald meal): Free HCl 0.

Combined acid 12.

Roentgenological studies:

Kidney, ureter and bladder regions: negative.

Spine: moderate hypertrophic changes.

Lungs: pneumosilicosis (Figure 1).

Stomach and bowel: negative.

Cystoscopic examination with pyelograms: opinion, bilateral pyelonephritis with

anatomical narrowing of ends of both ureters.

Urine obtained from ureteral catheterization:

Right: 20-30 pus cells per high power field, and a few r.b.c.

Left: 10-15 pus cells per high power field, and a few r.b.c.

Blood Wassermann: negative.

Clinical diagnosis:

Hypertrophic spinal arthritis (occupational).

Pneumosilicosis (occupational).

Sprain of back, traumatic, recovering.

Chronic nephritis, with moderate kidney insufficiency.

Chronic pyelitis, with moderate kidney insufficiency.

Achylia gastrica.

The patient remained in the hospital until December 24, 1931. Throughout his stay his pulse varied from 60 to 100, his temperature remained normal, and his blood pressure varied from 100 to 110 systolic and from 60 to 70 diastolic. Repeated examinations of urine specimens were made and always revealed variable amounts of albumin and numbers of pus cells, red blood cells, and hyaline and granular casts. He became quite comfortable while resting in bed. The diarrhea stopped, and the pain in the back was considerably improved. He was given dilute hydrochloric acid by mouth as this seemed to control his gastrointestinal symptoms. While in the hospital he was on a diet containing 60 gm. of protein.

After his discharge from the hospital he remained in the city, at the home of his daughter, where he continued the restricted diet and the use of dilute HCl, and reported for lavage of kidney pelvis and bladder at intervals. On January 26, 1932 he reported a recurrence of the diarrhea, possibly because he had stopped the use of the acid. He seemed somewhat paler on this date. A blood examination showed Hgb. 50 (Dare) R.B.C. 3,370,000. The urine showed albumin 4+ but no pus or blood cells.

Soon after this visit the patient went to his farm at Hinekley, Minnesota and remained there until he was brought into the hospital, on March 4, 1932, in a comatose condition. His wife said that he had contracted an upper respiratory tract infection about February 15 and that he had been bedridden since that time. There was not

versity of Minnesota. From his report the following facts were obtained:

The right lung weighed 1150 gm., the left 890 gm. The outer surfaces were of a greenish black mottled color. There was marked retraction by fibrosis toward the hilus in such a way as to produce lobulation. By palpation there was very little aerated tissue felt, except in the upper portion and periphery of the lung, most of the tissue being quite hard. The mediastinal nodes attached to the hilus were dark grayish in color and very hard. All of these findings were more marked in the right lung than in the left. The resistance to the cutting knife was harsh and gritty in character. On cut section the lung was found to be almost solid around the hilus, the normal tissue appearing

Fig. 2. Gross appearance of cut section of pneumosis.

Blood pressure: 100/60 mm. Hg.
 Heart: negative except for rapidity of rate.
 Lungs: negative on physical examination.
 Bladder was catheterized and 200 c.c. of
 concentrated urine obtained showing a
 heavy trace of albumin, 1-2 hyaline
 casts, occasional r.b.c. and 4-5 pus cells.
 Blood: Hgb. 50 (Sahl).
 R.B.C. 3,600,000.
 Urea N. 95 mg. per 100 c.c.
 Creatinine 4.5 mg. per 100 c.c.
 CO_2 62 vol. %

Intravenous fluids were given which
 seemed to bring about a slight improvement
 in the general condition late in the after-
 noon. However, about 8:00 o'clock he sank
 into a deep coma from which he could not
 be aroused and died at 10:00 p.m.

An autopsy was performed the following
 morning at 9:30 o'clock by Dr. B. J. Pear-
 son of the Department of Pathology, Uni-

much cough with this attack, but headache,
 malaise, fever, and a recurrence of the
 diarrhea had been noted. On February 20,
 without preceding symptoms, the right ear
 began to discharge. On March 2 the patient
 became stuporous and remained so until he
 was brought into the hospital two days later.
 During these two days he took no food and
 very little fluid and passed no urine.
 The pertinent findings of an examination
 on March 4 were as follows:

Stuporous, semicomatose condition from
 which the patient could barely be

aroused.
 Skin: dry and pale.

No edema or ascites.

Reflexes: sluggish.

Eye-grounds: negative.

Respirations: rapid, but regular and of good

amplitude.

Pulse: rapid, small volume, regular.

FIG. 4. Amyloid infiltration of spleen.

FIG. 5. Amyloid infiltration of glomerulus of kidney.

ently being almost completely replaced by the silica deposit. The resemblance of this substance to carborundum was striking. The hilus nodes cut like sandstone. This gritty material was present in other parts of the lung to a lesser extent than around the hilus, and in the left lung to a lesser degree than in the right. The extreme periphery was free from the substance. (Figure 2) Microscopic sections of lung tissue showed

showed amyloid infiltration replacing normal tissue to some extent. Otherwise nothing noteworthy was seen. (Figure 4)

The right *kidney* weighed 200 gm. and the left 225 gm. The capsules stripped easily and revealed smooth, pale, mottled surfaces of both kidneys. On cut section pale mottled areas were seen scattered throughout, predominating in the cortex. Although the texture was not typically that

FIG. 3. Microscopic section of pneumosilicosis with fibrosis.

extensive deposit of silica and very marked fibrotic changes. There was no evidence of infection, tuberculous or otherwise. Figure 3 shows clearly the microscopic appearance of a typical area of pulmonary tissue.

The *heart* weighed 390 gm. There was very possibly a slight hypertrophy of the left ventricle. Slight coronary sclerosis was present and a few patches of sclerosis at the root of the aorta and near the aortic leaf of the mitral valve.

The *spleen* weighed 250 gm. It had a grayish, slightly wrinkled capsule. On cut section it was firm and presented a lardaceous texture interpreted as being due to amyloid infiltration. Tested grossly with iodine solution, amyloid stain was abundant and ample. Microscopic section of the spleen

of amyloid infiltration, staining with iodine showed this to be present abundantly. The kidneys showed no evidence of infection of the parenchyma or of the pelvis. Microscopic sections showed amyloid infiltration of the glomeruli with little or no amyloid in the tubular portion (figure 5), and none in the interstitial tissue.

The other organs were essentially negative. The *liver* weighed 2250 gm. and was grossly normal. On cut section it showed a moderate amount of cloudy swelling. There was no evidence of chronic passive congestion. The *gall-bladder* was quite distended with bile; but on careful dissection no obstruction was found.

The *stomach* was found to be normal. The *small and large intestines* showed no patho-

logical lesions. The *mesenteric glands* were normal in size and did not contain any silica deposit or amyloid. The abdominal glands were normal, except a few which were rather soft and dark. Microscopic examination of these glands was negative. The *pancreas* weighed 100 gm. and was normal grossly and on cut section. The *adrenals* seemed somewhat larger than normal, especially the left one. On cut section the proportion of cortex to medulla was normal and nothing unusual was noted. The *bladder* contained about 250 c.c. of cloudy urine. There was some hemorrhagic congestion of the mucosa. The *prostate* was of normal size. The *bones* of the thorax and spine were inspected and no evidence of injury was seen.

As before mentioned, all organs were tested for amyloid, and none was found except in the kidneys and spleen.

The complete anatomical diagnosis was:

- (1) Pneumoconiosis (silicosis),
- (2) Amyloid kidney,
- (3) Amyloid spleen,
- (4) Hydrothorax,
- (5) Pleural adhesions (right),
- (6) Diaphragmatic adhesions (left),
- (7) Cloudy swelling of liver,
- (8) Dilated gall-bladder,
- (9) Multiple puncture wounds,
- (10) Slight cystitis.

COMMENTS

The most striking points in the case are:

1. The association of silicosis of the lung with amyloidosis of the kidneys and the spleen.

2. The absence of any chronic infection of pulmonary structures accompanying the silicosis; and the absence of any other focus of chronic suppuration or of infection to explain the amyloidosis. The pyelitis clinically was of a transient character and no evidence of its presence was found post mortem.

3. The uremic death was due apparently to amyloidosis. In this connection it was thought clinically that the pye-

litis might account for the kidney insufficiency (nephritis), but since the pyelitis cleared up and no evidence of it was found post mortem, it is probable that the renal insufficiency was on an amyloid basis originally and that the pyelitis was a secondary and transient factor only. Nephritis with renal insufficiency of glomerular type resulting from a pyelitis is in itself a rarity and is only occasionally found in a few cases of very persistent low grade chronic pyelitis.

The question which naturally arises is whether the silicosis (pulmonary) was responsible for the amyloid change in the kidneys and spleen. No record of such an association could be found in the literature. Amyloidosis has been produced experimentally in mice and rabbits by injection of sodium silicate solutions, but inasmuch as amyloidosis can be produced in these animals by almost any chemical or infectious material such results cannot well be applied to man.^{1,2,3}

The possibility that the amyloid change was initiated by trauma must be considered. There is little evidence to be derived from the literature on this matter. Some German reports indicate that an attempt has been made in that country to connect nephritis with trauma, but since German compensation medicine is so highly organized such an opinion is hard to evaluate. No reports of any such connection are found in the American, English or French literature. More pertinent to our case is the report of von Schnitzer,⁴ but such evidence as he presents seems quite insufficient to prove a relationship between trauma

and the production of amyloid. Perhaps more cases presenting the association of silicosis and amyloidosis or trauma and kidney lesions may be reported in the future, therewith

bringing enlightenment; but until more such data is collected it seems best to report simply an association or coincidence rather than a probably explicable relationship.

At a meeting of the Board of Regents of the American College of Physicians at San Francisco, California, April 8, 1932, the following appreciation was ordered spread upon the Minutes:

An Appreciation

DR. CARL VERNON WELLER

ANN ARBOR, MICHIGAN

BY THE

BOARD OF REGENTS

OF THE

AMERICAN COLLEGE OF PHYSICIANS

"The Board of Regents of the American College of Physicians desires at this time to record its highest appreciation of the valuable services of Dr. Carl Vernon Weller, as Editor of the ANNALS OF INTERNAL MEDICINE during the years 1931 and 1932.

"Accepting the mantle of his great chief, Dr. Aldred Scott Warthin, he carried on in the same spirit of enthusiasm and devotion to scientific ideals that had brought the Annals to its high place in the field of medical journalism.

"It is a further privilege to accord to Dr. Weller the fullest recognition for giving so freely of his scholarly talents. By his constant endeavor to maintain the high standards of the Annals, he has extended the influence of the College and has contributed in no small measure to the advancement of Internal Medicine in America."

WALTER L. BIERRING

JOHN H. MUSSEY

DAVID PRESWICK BARR

Committee

Editorial

The Editorship of the ANNALS OF INTERNAL MEDICINE is accepted as a trust from the College and from the former Editors. Into the building of this journal have gone the thought, the faithful work, something of the ideals, and indeed a part of the lives of those who have previously held this position. The service which the Annals now renders the College and the medical profession and its standing among medical publications are the results of their labors. Tribute is due especially to Aldred Scott Warthin, who took over the task at a stage when to obtain contributors to ensure a monthly appearance was still a struggle, and who for seven years, by personal effort, by stimulating contributors and often assisting them, by judgment in selection, by endless patient care with the copy and the proof, brought the Annals through the difficulties of this formative period to the established position it now holds. When death suddenly cut short his achievements in this and many other fields, his colleague and successor in the Chair of Pathology at the University of Michigan, Dr. Carl Vernon Weller, in answer to the appeal of the College, became also his successor in the Editorship of this journal. It has grown stronger in his capable hands. The group of contributors has become constantly larger and the quality of the papers selected for publication has steadily risen. The increasing circula-

tion of the Annals at home and abroad is the best evidence of the importance of its contents. In appearance and in uniformity of typographical style, great gains have been made through Dr. Weller's conscientious and time-consuming labors in the technical aspects of the editor's task. The results of all these accomplishments are now placed in the hands of the new Editor. It is for him to attempt to guide this publication so that it may show still further progress along the path first broken and then marked out by his predecessors. What success his untried capacities may enable him to achieve he feels will be due largely to the example that has been set him of devotion to the task.

Among the functions of the Annals is that of publishing the most noteworthy of the addresses and of the clinics delivered at the annual meeting of the College. In this respect it takes the place held by the "transactions" of other societies. These articles in the Annals will serve more and more as a yearly summary of the important advances in the field of internal medicine and its allied sciences. To the Fellow who has been unable to attend the meeting, the Annals brings some compensation in the form of the published articles; to him who has been aroused and stimulated by the speakers at the Sessions, there is even greater value in having the addresses in permanent form.

In addition to the material derived from the annual meeting, the *Annals* contains each month a number of articles which have been submitted directly to the Editor. There are at present several times as many manuscripts submitted as can be printed in a journal of the *Annals'* size. The Editor is therefore forced to adopt certain principles of selection. Naturally the first selection will be based on quality. The completeness of data, the reliability of methods, the consideration given to the work of others, the proof offered in support of assertions should all be weighed before a manuscript is accepted. Papers may be free from defects of quality, however, and yet fail in competition with others when judged as to relative importance. The Editor realizes his inability to predict the possible future importance of all facts: his standard will have to be the present interest and significance of the data offered. The formal and elaborately documented study of minor or trivial phenomena should find no place in the pages of the *ANNALS OF INTERNAL MEDICINE*.

The results of thorough investigations of real significance may sometimes have to be rejected by the Editor in favor of a paper of equal merit but on a subject more directly within the scope of internal medicine. This field certainly should not be defined too nar-

rowly: it blends indeed without sharp boundary into all the medical sciences and all the clinical specialties. Nothing in science or practice is truly foreign to its interests. The Editor, however, is of those who believe that the essence of internal medicine consists of careful clinical observation of disease and its response to treatment.

It is hoped that many of the articles eventually selected will have been written by members of the College, so that the *Annals* may serve the members of the College both in bringing advances in medicine to their notice and by facilitating the publication of their own work.

The editorial sheet of the journal offers to the reader brief analyses of interesting topics in the field of medical science or practice. The Editor will frequently solicit editorials from authorities in special fields. It is a further function of the editorial sheet to serve as a voice for the College. It will be open to receive such statements as from time to time our Officers, Boards of Regents and Governors, or the Committee on Public Relations may wish to make. Such comment as the Editor may utter upon educational, economic, or ethical problems of internal medicine will have no official character and for such views he in advance accepts personal responsibility.

Reviews

Hypnotism—Suggestion and Faith-Healing.

By ALEXANDER CANNON, M.D. William Heinemann Ltd., London, 1932. 43 pages. Price, 2s 6d net.

It is difficult to believe that this book is addressed to physicians, because lay people with a reasonable degree of critical judgment would refute the over-simplification and extravagant claims made by the author. Hypnotism, to the author, is a cure-all for many disorders and his faith in it is unbounding. The only value to the book is the brief presentation of others' methods of hypnotic technic. The discussion of suggestion is limited and highly colored by the author's dubious notions, and there is nothing informative about faith-healing. None of the dangers of hypnotism are mentioned and there are many. In the history of Medicine the story of the use of hypnotism and suggestion has been colored with an atmosphere of charlatanism. It is especially unfortunate, under these circumstances, that in this book a more critical attitude should not have been maintained. Most psychotherapists would probably admit that hypnosis is a helpful adjunct in their work but that its use is limited to certain well selected material and for special purposes. Actually, it is difficult to see a reason for the publication of this particular book.

R. P. T.

The Child and the Tuberculosis Problem.

By J. ARTHUR MYERS, Ph.D., M.D., F.A.C.P., with an introduction by WILLIAM P. SHEPARD, M.D., F.A.P.H.A. xvi + 230 pages, with 21 illustrations. Charles C. Thomas, Springfield, Illinois. 1932. Price, \$3.00.

With his experience as head of the Lymanhurst School for Tuberculous Children, the author has been exceptionally able to produce a book that general practitioners, pediatricians, school physicians, health officers, public health nurses, social workers, school

administrators, and executives of local tuberculosis associations, especially, should find of value. This monograph contains a clear and concise discussion of diagnostic measures, particularly those most valuable in diagnosing tuberculosis in children, viz., tuberculin skin tests and roentgen examination. In it also are the newer ideas concerning the etiology, pathogenesis, and diagnosis of the disease. The chapters on the finding of tuberculous children and the disposal of cases examined for the disease are well treated and should be studied by those interested in childhood tuberculosis. One of the most worthwhile parts of the book is that dealing with concrete suggestions for organizing a plan of work for the prevention of tuberculosis in the future. Emphasis is placed on the control of the disease among domestic animals and the contributions of veterinarians commended. Attention is called to the need of controlling tuberculosis among members of families and of outlining a method for the reduction in its occurrence among nurses. Each chapter is followed by a helpful summary; at the end of the book there is a bibliography of well chosen and recently published material.

A. H. F.

Diagnosis and Treatment of Diseases of the Thyroid Gland.

By GEORGE CRILE and Associates, 508 pages with 164 illustrations. W. B. Saunders Company, Philadelphia, 1932. Price, \$6.50 net.

This book cannot fail to be of great interest to all those concerned with the clinical aspects of the goiter problem. It presents very clearly the experience and point of view of one of the largest and most successful thyroid clinics. A large part of the book is devoted to chapters on special topics such as those on the cardiac symptoms, the ocular changes, the cutaneous manifestations, the laryngeal disturbances, the

alterations in carbohydrate metabolism, the relationship to joint lesions and to infections, and the association with syphilis and tuberculosis. These topical discussions are of great interest to the internist. Preoperative and postoperative management are well presented and there is an interesting account of postoperative complications.

The chapters on more general subjects, such as those on diagnosis of hyperthyroidism and on hypothyroidism, are clearly written but rather elementary in character and often omit mention of interesting work in other clinics. The surgical chapters are of interest even to the medical man. The bold treatment of postoperative lung complications by tracheotomy and suction is thought-provoking. A more detailed analysis of the results obtained would be helpful.

This book is by no means a complete consideration of goiter, but it is a very readable account of present day practical aspects of the goiter problem.

M. C. P.

The Differential Diagnosis of Endocrine Disorders. By ALLAN WINTER ROWE. 220 pages. The Williams & Wilkins Company, Baltimore, 1932. Price \$4.00.

The author of the book is the President of the Association for the Study of Internal Secretions, and Director of Research, Evans Memorial, Massachusetts Memorial Hospitals, in Boston. The prominence of the writer gives the contents of the book an authoritative stamp.

The material presented is based upon an elaborate study of over 5000 cases during the past twenty years. The author believes that a diagnosis should be based upon a thorough routine study supplemented at times by further special examinations, and the reader will get the impression that the "material represents the accurate, sincere, interested labor of a large group of highly trained individuals." Emphasis is placed upon the importance of differentiating between endocrinopathies and conditions simulating them but due to an underlying etiology not associated with the ductless glands. With this in mind the author has inserted in the text a table correlating with a large series of cases and the endocrine glands in some cases. The book is a valuable reference work.

The contents are divided into three sections: SECTION I, Clinical Considerations; SECTION II, Laboratory Measurements; SECTION III, Special Examinations. They are based entirely on the work of the one clinic, the rarer endocrinopathies are not considered, and reference to animal experimentation is purposely omitted. In the beginning the cases are divided into five groups: pituitary, thyroid, gonad, adrenal, and pancreas, without reference to phases of over- or underactivity, and analyzed according to symptoms, physical signs, and laboratory tests. The last two groups (adrenal and pancreas) contain only fifteen cases each and many of the data connected with them were considered not significant. They were nevertheless included in the tables.

The title of the book is somewhat misleading. The cases have already been diagnosed and pigeonholed in the different groups which are now subjected to minute analysis. The author mentions the necessity of the proper integration of a diagnostic study but of this important factor in diagnosis the monograph contains hardly a trace. Chapter XIV on "Differential Diagnostic Illustrations", consisting of less than four pages, might well have been considerably amplified.

The work should be welcomed by those especially interested in this field by reason of the valuable data it contains, but the busy physician may be disappointed if he expects a clear and concise aid in the differential diagnosis of endocrine disorders. The material is there but he must dig it out for himself. The index will be of some aid in the task.

Statistics, like those in Section I especially, do not constitute a pleasant diet for the practitioner and an unusual diction, combined with a somewhat involved style, will not whet his appetite. The contents of Section II flow more freely and more successfully hold the reader's interest.

T. P. S.

Outline of Preventive Medicine for Medical Practitioners and Students. Prepared under the auspices of the Committee on Public Health Relations, New York Academy of Medicine. 24 contributors. 2nd Edition.

tion revised and enlarged. Paul H. Hoeber, Inc., New York, 1932. Price, \$5.00. The second and enlarged edition of this book testifies to its usefulness. It is an outline of preventive medicine summarizing those opportunities which present themselves in daily practice for the institution of preventive measures. An orienting chapter on the incidence of disease presents briefly and clearly the nature of the problem of preventing disability and avoidable deaths. The prevention of specific diseases or complications of diseases in the fields of general medicine, surgery, obstetrics, pediatrics, and other specialties is dealt with in separate chapters. Venereal diseases and tuberculosis

are discussed as special topics. There is a rather brief chapter on occupational diseases. The field is such a large one that in the brief space allotted to each topic it is sometimes not possible to furnish more than general therapeutic principles instead of the specific instructions which the practitioner might desire. For the most part, however, the recommendations are definite and practical. The general tone of the book is conservative; it deals with the preventive measures which are feasible today. It will stimulate any physician to realize how much he may accomplish in this field and how real and undivided is his responsibility.

M. C. P.

College News Notes

Announcement is made of the following gifts to the College Library of publications by members:

- Dr. C. F. Morsman (Fellow), Hot Springs, S. D.—6 reprints;
- Dr. Henry M. Moses (Fellow), Brooklyn, N. Y.—3 reprints;
- Dr. Oliver T. Osborne (Fellow), New Haven, Conn.—1 reprint;
- Dr. George W. Parker (Fellow), Peoria, Ill.—1 reprint;
- Dr. Audley O. Sanders (Fellow), Palo Alto, Calif.—2 reprints;
- Dr. John F. Kenney (Associate), Pawtucket, R. I.—2 reprints;
- Dr. Curran Pope (Associate), Louisville, Ky.—1 reprint.

Dr. V. C. Rowland (Fellow), Cleveland, addressed the State Conference of Ohio Health Commissioners at Columbus, November 17, on "Preventive Medicine and Periodic Health Examinations."

Dr. E. J. G. Beardsley (Fellow), Philadelphia, was a guest of the Guthrie Clinic of Sayre, Pa., on November 2, 1932. He was the guest speaker at a joint meeting of the Bradford and Tioga County Medical Societies at Troy, Pa., that evening, his

subject being "The Cardiovascular Disorders of Everyday Medicine."

Dr. Stewart DeWitt Conklin (Fellow), Sayre, Pa., is Associate in Medicine at the Robert Packer Clinic and Hospital and Secretary of the Bradford County Medical Society.

Dr. Charles H. DeWan (Fellow) and Dr. Ronald L. Hamilton (Fellow) are the Pathologist and Cardiologist, respectively, at the Robert Packer Clinic and Hospital.

Dr. Edwin Henes, Jr. (Fellow), Milwaukee, retired as the Executive Secretary of the Inter-State Postgraduate Medical Association of North America following their October Meeting at Indianapolis. Dr. Henes had completed a decade of service to the Association, during which time he assisted in the arrangement for, and presentation of, ten International Assemblies. Dr. Henes retired due to the condition of his health. He will spend several months abroad.

Dr. Albert H. Rowe (Fellow), Oakland, Calif., delivered a paper entitled, "The Present Status of Food Allergy as Related to Bronchial Asthma," before the Kings

County Medical Society at Seattle, Wash., on October 24.

Dr. Albert S. Hyman (Fellow), New York City, Director of the Witkin Foundation for the Study and Prevention of Heart Disease, addressed the Yorkville Medical Society November 21, 1932, upon "Recent Advances in the Study and Treatment of Angina Pectoris."

On November 16, 1932, Dr. Hyman addressed the New York Physicians Association on "Heart Pain."

Dr. Howard T. Phillips (Fellow), Wheeling, W. Va., read a paper before the Raleigh County (West Virginia) Medical Society December 1, 1932, on "Diagnosis and Treatment of Some Common Skin Diseases."

At the November 21, 1932, Meeting of The Medical Association of the Greater City of New York, the following Fellows participated as indicated:

Dr. Edward E. Cornwall, "The Treatment of Pneumonia by Physiological Support."

Dr. LeGrand Kerr, "Pneumonia in Children."

Dr. Henry M. Moses, discussion of the above papers.

Dr. Samuel A. Brown (Fellow) is now Dean Emeritus of New York University Medical College. Dr. Warren Coleman (Fellow) has been appointed Professor of Clinical Medicine at this institution.

Dr. Howard T. Karsner (Fellow), Professor of Pathology at Western Reserve University School of Medicine, Cleveland, has been elected the member for the United States of the Comité Directeur of the International Society for Geographic Pathology.

Dr. Harold Swanberg (Fellow), Quincy, Ill., spoke at the Jackson County Medical Society, Jackson, Tenn., December 6, on "Radiation Therapy in General Practice."

Dr. Arthur C. Morgan (Fellow), Philadelphia, was a member of the Committee

on the Costs of Medical Care during its five-year study. Dr. Morgan has recently given talks on "Public Health Consciousness" in Philipsburg, Erie, Clearfield, St. Mary's and Conshohocken, Pa.

Dr. Henry O. Colomb (Associate) has recently assumed the position of Clinical Director of the Springfield State Hospital, Sykesville, Md.

Dr. Louis Faugeres Bishop, Jr. (Fellow), New York City, was elected to Fellowship in the New York Academy of Medicine at a stated meeting, November 3, 1932.

Dr. Hyman I. Goldstein (Associate), Camden, N. J., recently addressed the Monmouth County (New Jersey) Medical Society at the Monmouth Memorial Hospital, Long Branch, on "Recent Advances in the Treatment of Anemias" and discussed "A New Antispasmodic Remedy—'Perparin'."

The following are recent additions to the valued list of advertisers in the ANNALS OF INTERNAL MEDICINE:

Burrough Brothers Manufacturing Company, Baltimore;

S. M. A. Corporation, Cleveland;

Schering Corporation, New York City;

Curdolac Food Company, Waukesha, Wis.

Acknowledgment is made of the following gifts to the College Library of publications by members:

Dr. Bernard L. Wyatt (Fellow), Tucson, Arizona—1 book, "Chronic Arthritis and Fibrositis";

Dr. J. G. Archer (Fellow), Greenville, Miss.—1 reprint;

Dr. H. L. Arnold (Fellow), Honolulu, Hawaii—1 reprint;

Dr. Roy W. Benton (Fellow), Milwaukee, Wis.—1 reprint;

Dr. I. D. Bronfin (Fellow), Denver, Colo.—1 reprint;

Dr. William R. Brooksher, Jr. (Fellow), Fort Smith, Ark.—2 reprints;

Dr. Grafton Tyler Brown (Fellow), Washington, D. C.—1 reprint;

Dr. Harold N. Davidson (Fellow), Atlantic City, N. J.—4 reprints;

Dr. Hyman I. Goldstein (Associate), Camden, N. J.—2 reprints;
 Major C. C. Hillman (Fellow), Manila, P. I.—1 reprint;
 Dr. John F. Kenney (Associate), Pawtucket, R. I.—1 reprint;
 Dr. Allen K. Krause (Fellow), Tucson, Arizona—2 reprints;
 Dr. W. Paul Holbrook (Fellow), Tucson, Arizona—2 reprints;
 Dr. Max Pinner (Fellow), Tucson, Arizona—4 reprints;
 Dr. Roy D. Metz (Associate), Detroit, Mich.—1 reprint;
 Dr. B. S. Pollak (Fellow), Secaucus, N. J.—1 reprint;
 Dr. Wm. C. Pollock (Fellow), Denver, Colo.—1 reprint;
 Dr. Willard H. Squires (Associate), New York City, N. Y.—1 reprint;
 Dr. M. J. Synnott (Fellow), Montclair, N. J.—1 reprint.

The Southern California Members of the American College of Physicians gave a dinner in honor of Dr. F. M. Pottenger, then President of the College, at the California Club, Los Angeles, January 12. Dr. David P. Barr (Regent), Professor of Medicine at Washington University, St. Louis, the guest speaker, delivered the address of the evening.

Dr. James S. McLester (Fellow) and Dr. Charles M. Nice (Fellow) were recently elected Physicians-in-chief to Section A and Section B of the Medical Staff of the Hillman Hospital, Birmingham, Alabama. At the same time, they were appointed Chairman and Secretary, respectively, of the Advisory Board of the Hospital.

Dr. George R. Minot (Fellow), and Dr. Chester S. Keefer (Fellow), both of Boston, Mass., addressed the Boston Orthopedic Club at their symposium on arthritis.

Dr. Minot in November addressed the Toronto Academy of Medicine on the Treatment of Anemia. He was also one of the speakers at the celebration held at the Harvard Medical School December 20, 1932 to commemorate the 150th anniversary of the founding of the "Professorship of the Theory and Practice of Physic" at Harvard.

Dr. Albert F. R. Andresen (Fellow), Brooklyn, New York, addressed a meeting of the Atlantic County Medical Society, Atlantic City, N. J., November 18, 1932, on "Gastrointestinal Manifestations of Food Allergy". He lectured again on the same subject at one of a series of Friday Afternoon Practical Lectures, at the Jersey City Medical Center on January 13, 1933.

On January 6, Dr. Andresen gave a lecture on "The Diagnosis and Treatment of Biliary Tract Diseases" before the Cortland County Medical Society, Cortland, N. Y., one of a series of postgraduate lectures to county medical societies fostered by the Medical Society of the State of New York.

Dr. Max Einhorn (Fellow), New York City, N. Y., addressed a clinical conference of the Madison Park Hospital, Brooklyn, New York, January 13 on "Indications for Operations in Gall-Bladder Diseases", which was discussed by Dr. Albert F. R. Andresen (Fellow), of Brooklyn.

At the recent meeting of the American Association for the Advancement of Science at Atlantic City, N. J., Dr. Walter M. Simpson (Fellow), Dayton, Ohio, was elected Secretary of Section N (Medical Sciences) for a period of three years.

Dr. Edward J. Engberg (Fellow), St. Paul, Minn., was the guest speaker at a joint meeting of the Eastern Montana Medical Society and the Southwestern District Medical Society of North Dakota at Dickinson during the past autumn. His subject was "Treatment of Psychiatric Patients in Private Practice".

Dr. W. H. Kraemer (Fellow), Wilmington, Delaware, delivered an address on "A Discussion on the Clinical Application of Lead Therapy as a Research Feature of the Tumor Clinic" before the Post Graduate Clinic at the Lankenau Hospital, Philadelphia.

Major Edgar Erskine Hume (Fellow), formerly attached to the Adjutant General's Office, Boston, Mass., was transferred to Washington, D. C., at the end of September,

1932, when he became Librarian of the Army Medical Library.

Major C. C. Hillman (Fellow), since November, has been on duty at the Sternberg General Hospital, Manila, P. I.

Dr. P. P. McCain (Fellow), Sanatorium, N. C., recently read a paper on "Childhood Tuberculosis" before the Seaboard Medical Association at Rocky Mount, N. C. He also delivered a public address on the subject "Prevention of Tuberculosis" with the child as the important point of contact.

Dr. McCain addressed the State Radiological Society at Asheville recently on the subject of "Radiograms in the Diagnosis of Childhood Tuberculosis", and he has been selected as the guest speaker at the meeting of the South Carolina Medical Association at Greenville.

A testimonial dinner was recently tendered Dr. J. P. Munroe (Fellow), Charlotte, N. C., at the Charlotte Country Club. Addresses in appreciation of Dr. Munroe's work both within and without the State, but particularly in Charlotte, were made by several members of the local County Medical Society. Addresses were also delivered by Dr. J. T. Burrus, President of the State Board of Health and by Dr. L. B. McBrayer (Fellow), Secretary-Treasurer of the Medical Society of the State of North Carolina.

Dr. W. B. Kinlaw (Fellow), Rocky Mount, N. C., was elected Secretary of the Seaboard Medical Association at its recent meeting.

On January 1, Dr. Henry S. Houghton (Fellow), formerly Dean of the University of Iowa College of Medicine, assumed his duties as Associate Dean of the Division of Biological Sciences, University of Chicago, and as Director of the University Clinics. Dr. Houghton served as Dean of the Harvard Medical School of China, located at Shanghai from 1911 to 1917, and as Acting Director and Director of the Peking Union Medical College from 1918 until 1924, where-

upon he became Dean of the University of Iowa College of Medicine.

Dr. Peter T. Bohan (Fellow), Kansas City, Mo., was recently elected President of the Kansas City Southwest Clinical Society.

Dr. Benjamin W. Black (Fellow), Oakland, California, and Dr. Joseph C. Doane (Fellow), Philadelphia, are members of the Council on Community Relations and Administrative Practice recently appointed by the American Hospital Association to make an immediate study of the recommendations of the Committee on the Costs of Medical Care.

Dr. Augustus W. Crane (Fellow), Kalamazoo, Mich., was elected President of the Michigan Association of Radiologists recently organized.

Dr. C. Brewster Brainard (Fellow), Hartford, Conn., was recently elected President of the Hartford Medical Society. Dr. Robert S. Starr (Associate), was elected Vice-President.

Dr. Charles W. Burr (Fellow), Philadelphia, Pa., recently presented 19,000 books to the University of Pennsylvania Library. In 1928 Dr. Burr presented this library with a valuable collection of autographs and has on previous occasions donated about 700 other volumes.

Dr. Francis H. Smith (Fellow), Abingdon, Va., was recently elected one of the Vice-Presidents of the Medical Society of Virginia.

Dr. J. Gurney Taylor (Fellow), Milwaukee, Wis., is President of the Wisconsin Anti-Tuberculosis Association.

Dr. William S. Middleton (Fellow), Madison, Wis., was elected Vice-President of the Central Society for Clinical Research at its recent annual meeting in Chicago. Dr. William H. Bunn (Fellow), Youngstown, Ohio, was reflected Treasurer.

OBITUARY

DR. WILLIAM ENGELBACH died November 22, in St. John's Hospital, Springfield, Illinois, of heart disease after an illness of three months. As a Fellow of the College since January 14, 1920, he always took an active interest in its affairs.

Dr. Engelbach was born in Arenzville, Illinois, in 1877. He obtained the degrees of Bachelor and Master of Science from Illinois College in 1899. Northwestern University Medical School awarded him the degree of Doctor of Medicine in 1902, following which he spent several years in post-graduate study in Berlin, Paris, and Vienna. Returning to the United States he decided to affiliate with the St. Louis University School of Medicine where he served as an Instructor in Medicine from 1909-1911, and Professor of Medicine from 1911-1924.

His Hospital connections were as varied as his interests in Internal Medicine. He served as Chief of Staff of St. John's Hospital (St. Louis) from 1909-1924, and was a member of the Staffs of the City Hospital, Missouri Baptist Sanatorium, Maternity Hospital, and New Jewish Hospital for many years. During the War, service to his country was rendered as Chief Physician of Examining Board No. 1 in St. Louis.

Dr. Engelbach's interest was always with organized medicine in its broadest sense. His executive ability was an outstanding quality and his services were ever in demand when matters concerning the general profession were discussed. He was characterized by an untiring energy in the affairs of medicine. This was evidenced as a

member of the local and state medical societies in Missouri and as President of the St. Louis Medical Society in 1918. After removing to New York in 1931, where he opened an office at 897 Park Avenue for the practice of Internal Medicine, he became a member of the New York State Medical Association. He was a Fellow of the American Medical Association and a member and ex-President (1922-1923) of the Association for the study of Internal Secretions.

As a clinician in the truest sense of the word he contributed greatly to medical literature by his many writings. He was the author of numerous articles published in various medical journals and was a contributor to Tice's *Practice of Medicine*. While his interest lay in all fields related to Internal Medicine perhaps his greatest interest was in the disorders of the ductless glands. Bringing to the subject a broad general knowledge of medicine, the keenness of observation of the seasoned clinician, the breadth of view that is not restricted by prejudice and preconception, he was able to clarify the subject and reduce chaos to something simulating order. His clinical observations served as a basis for classification of the various phases of a most difficult subject. He was unquestionably one of the foremost clinical investigators in the field and time alone will determine the ultimate value of his contributions.

To achieve what was considered the most important work of his life, the summation and publication of his knowledge obtained from years of ob-

servation of the endocrine dyscrasias, he retired from active practice in 1929 and devoted nearly two years to the preparation of a three volume series entitled "Endocrine Medicine." The resumption of his practice in 1931 in New York was curtailed by his final illness.

Medicine has lost in the demise of Dr. Engelbach one of its most stalwart sons. Eager, enthusiastic, earnest, kindly and considerate, a scholar, scientist, teacher and gentleman, he

gave to the practice of medicine his entire personality, his interests, and an untiring devotion and sympathy. He received from his practice a knowledge of work well done, of effort rewarded by the appreciation on the part of all patients, students, associates and colleagues who were fortunate enough to come under his influence.

NUMBER 9

The Senile Patient*

By LEWELLYS F. BARKER, M.D., F.A.C.P., *Baltimore, Maryland*

SOME of you may be wondering how anyone connected with the Johns Hopkins Hospital dare say anything in public about the later life of man in view of the commotion aroused by our great internist, the late Dr. Osler, some years ago through his semi-serious, semi-jocular remarks upon the ages of forty and sixty; but the chairman of our Program Committee, Dr. George W. Crile, whose word is law, has assigned to me as a topic "The Senile Patient", and I must take the risk!

PHYSIOLOGICAL AND PATHOLOGICAL SENILITY

With your permission, I shall interpret the term "senile patient" as meaning simply "a patient advanced in years", avoiding by this definition any necessary connotation of preternatural mental or physical infirmity due directly to old age. For there is, you will grant, an old age that is, relatively speaking, "physiological" as well as a "pathological" old age.

Though a unicellular organism may live on indefinitely, every multicellular

organism grows old and ultimately dies. Though its constituent cells may, in cultures in vitro, seem to be potentially immortal, the aggregate of cells of a metazoan animal is definitely mortal. Old age and death are the price paid for the differentiation and specialization of function, characteristic of organisms made up of many cells and tissues that are reciprocally interdependent.

Though there are great differences in the length of life of the individual members of the human species, and though the average duration of human life has been steadily increasing for centuries and more rapidly during recent years (from thirty-five in 1880 to fifty-five in 1920), it is the expectation of life of children at birth and of people in the earlier decades of life that has been most markedly increased; the gain in the expectation of life of persons fifty years old has been only 1.35 in eighty years, whereas the expectation of life for older groups has been growing less, owing to the prolongation of the lives of weaker persons by means of our modern methods of curative and preventive medicine. Many human beings still reach

*Address to the Interstate Postgraduate Assembly, Indianapolis, Ind., Oct. 25, 1932.

the age of ninety or one hundred, but there is, as yet at least, but little if any scientific evidence that the maximal span of human life can be materially increased by any measures that are likely to be devised for the improvement either of man's environment or his heredity. It may not be possible to extend average longevity beyond the age of sixty—almost certainly not if the euthenic practices of the present are not to be supplemented by eugenic practices, to which many are antipathetic.

Biostatistical studies have thrown much light upon the factors that determine the span of life for the human individual. Though longevity depends partly upon inherited constitution, partly upon environment, the evidence strongly favors the view that, on the whole, factors of inheritance are of greater importance than environmental factors. Many years ago, in one fairly large aggregate of persons studied (the Hyde family), it was found that a group that had both fathers and mothers who lived to eighty or more years had an average duration of life of 52.7 years, whereas in the same aggregate, another group in which both parents died before sixty had an average duration of life of only 32.8 years, a difference of practically twenty years. From this and other evidence available the well-known aphorism "To live long, select long-lived parents" would seem to be justified!

In "physiological" old age, there is a gradual process of cell atrophy and a relative increase in the interstitial tissues at the expense of the parenchyma of the organ-system—an involution of the organism as a whole comparable in process to the involution

of single parts of the organism (such as the branchial clefts, the placenta, and the ovaries) occurring at different stages of life. The late Dr. A. S. Warthin spoke of this aging of the whole organism as "the major involution" and of the aging of single parts as "minor involutions"; and he thought that involution was as important as evolution in the great procession of life, minor involutions occurring when parts are no longer of use to the organism, the major involution taking place after the organism as a whole has passed through the periods in which ordinarily the fundamental biological functions have been fulfilled. Theoretically, then, senescence is as physiological as growth; both are inherent in the quality of the germ-plasm inherited. With the best germ-plasms and favorable environments the duration of life of higher organisms is rarely greater than five times the number of years of development to maturity and if the latter for man be taken to be twenty-one, the maximal span of human life cannot much exceed one hundred years, though through preventive medicine and hygiene we may increase average longevity a little more and may swell the numbers of human beings that enjoy a "physiological" old age. But it is better for the race that human individuals live not too long. Thoughtful men must agree with Goethe's statement, "Death is Nature's device for securing abundant life".

THE CAUSES OF DEATH AMONG THE OLD

The very old die from causes very different from those that are responsible for the death of younger persons.

By virtue of their inborn qualities of resistance, their good nutritive and reparative powers, the harmonious activity of their several organ-systems, their habits, and their good fortune in the avoidance of lethal exogenous influences (traumata; infections), they have reached advanced years of life, but they ultimately die either from the break-down of some important organ system or from trauma or suicide. The recent statistical studies of Pearl and Raenkham show that with advancing adult age there is a steady decrease of the percentage of total mortality due to diseases of organ-systems normally directly exposed to and in contact with the external environment, whereas there is an increase of the percentage of total mortality due to diseases of organ-systems not exposed to direct contact with the external environment.

Nearly half of our old people die from diseases of the circulatory system (cardiac failure; arterial disease; cerebral hemorrhage); about one-eighth from diseases of the respiratory system (especially lobar and bronchopneumonia); about one-eighth from cancer; about one-twelfth from renal disease; about one-fifteenth from diseases of the digestive system; and the rest from diseases of other organ systems, traumata, or ill-defined diseases reported as "deaths from senility". The last mentioned cause of death should rarely, if ever, be reported; if a definite cause has not been made out, it is wiser to report "death from unknown cause". The majority of deaths among old people occur during the winter months of the year; and more die during the latter half of the night than during the day and the first half

of the night. If you have not read the excellent paper by Dr. Alfred Worcester entitled, "The Care of the Dying", let me urge you to do so.

THE SOMATIC AND PSYCHIC INFIRMITIES OF LATER LIFE

All normal people desire long life, but they usually add the proviso that they shall continue to enjoy both bodily and mental health. As Talleyrand wittily said years ago, "Everybody wants to live long; but nobody wants to be old." Very few people in early life would willingly look forward to a long period of senile decrepitude or chronic invalidism. In his description of the Struldbugs (who lived forever), Swift painted their plight as so pitiable, when they were observed by Gulliver at Laputa, that any form of death seemed preferable to the continuance of such a life.

The physical infirmities of old age have been much studied through the centuries; since the earlier descriptions of non-medical writers in the Ninetieth Psalm, in Ecclesiastes, and in the literature of the Greeks and the Romans, medical men at all times have been interested in the gradual physical deterioration of the structures and functions of the human body in those who live long. Beginning with failure of accommodation in the eyes, change in the color and abundance of the hair, gradual loss of the teeth, diminution of sex potency, and increased fatigability, a whole series of other changes are prone sooner or later to become evident, until, if life continue long enough, the fully developed picture of senility is presented. The height is slightly reduced, a stooping posture is assumed, the body-weight decreases,

the bony prominences become more marked, the joints stiff and the muscles flabby, the skin is wrinkled, and shows hyperkeratoses, the arcus senilis appears, the breasts and the abdominal wall become pendent, the thorax grows rigid with shallow respiration and tendency to bronchitis, the arteries thicken, become tortuous, and sometimes calcified, varicose veins and hemorrhoids are common, digestion is slowed with diminution of hydrochloric acid in the gastric secretion and tendency to flatulence and constipation. In men there is difficulty in starting the flow of urine and of complete emptying of the bladder owing to hypertrophy of the prostate, atony of the bladder or both; the genitalia atrophy, the endocrine glands become less active (as shown by the lowered basal metabolic rate, the sensitiveness to cold, the tendency to hyperglycemia and glycosuria, and the changes in libido and potentia), and the sensory functions, motility, and coördination become more or less impaired.

Of the psychic manifestations of later life, some are referable to cognitive, some to affective-conative domains. Among the earlier symptoms are forgetfulness of names, a diminution of the instinctive urges (sex, food, social life), and lack of receptivity of new ideas. Later on, there may be loss of memory for recent events, difficulties of attention, concentration and orientation, somnolence in the daytime and insomnia at night. If the cerebral arteries undergo marked changes, pseudobulbar and other paralyzes (with or without aphasia and apraxia) may result, or changes in the psyche (eccentricity, lack of re-

gard for the welfare of others, stubbornness, tendency to suspicion, fall of the ethical level, pathological irritability and emotionalism) may follow. Whether outspoken "senile dementia" (with confusion, illusions, and delusions) and "second childhood" are to be regarded as merely the expression of an intensification and rapid progress of physiological involution of the cerebral cortex, or are to be kept separate from the latter as something more specific, are matters still under discussion. The relations of senile dementia to cerebral atherosclerosis, to Alzheimer's disease, to Pick's disease, and to other organic and functional psychoses of the senium and presenium can scarcely be dealt with in a brief paper such as this, though there is a large and growing bibliography of the subject.

GENERAL COMMENTS UPON DISEASES IN PERSONS ADVANCED IN YEARS

Students of geriatrics or presbyiatrics (the branch of medicine that deals with diseases of the old) have distinguished between the maladies that are largely restricted to the aged and the diseases that occur in both the young and the old.

Among the former are Paget's deforming osteitis, senile osteoporosis and *mahum coxae senile*, senile anorexia, diverticula of the esophagus and intestine, coproliths, senile bronchial catarrh, senile emphysema, prostatic hypertrophy and its sequelae, cerebral atherosclerosis, senile dementia, *paralysis agitans* (non-encephalitic in origin), and hyperkeratosis. Carcinoma, too, is much more frequent in the second than in the first half of

life, though in extreme old age its incidence lessens.

Among the diseases that occur in both the young and the old, those of the circulatory and of the respiratory system predominate in the old, but the symptomatology may vary considerably from that observable in the young. In vigorous old people, it is true, the clinical phenomena may not be very different, but in older people in whom characteristic involutional changes have already occurred, we meet with many bizarre, atypical, and more or less confusing clinical pictures.

It has been especially emphasized by internists of experience that *acute infections in the old* exhibit certain peculiarities, including (1) tendency to early collapse because of cardiac failure or failure of the vasomotor or respiratory centers in the medulla, (2) frequency of respiratory complications like pneumonia or capillary bronchitis because of increased rigidity of the thorax, senile emphysema, or stasis in the pulmonary circulation, (3) early cerebral manifestations (delirium, disorientation, coma) because of cerebral atherosclerosis, of lessened resistance of nerve cells to toxins, and of low blood pressure, (4) often evidences of diminished reaction-capacity to infection as seen in low rather than high fever, slight leukocytosis, and prolongation of convalescence, and (5) frequently, absence of any acute splenic enlargement. The local symptoms of infections such as pneumonia and meningitis are often less marked, too, than in earlier life.

Since nearly half of all old people die as a result of some disorder of the circulatory system, the management of

myocardial insufficiency merits especial consideration in any discussion of the senile patient. The physician attending the old should be ever on the alert for symptoms like dyspnea, edema, and other evidences of circulatory enfeeblement; early recognition is important not only for the prevention of outspoken cardiac decompensation but for the avoidance of uremic intoxication and of cerebral softening so prone to occur in old people whose renal arterioles or cerebral arteries have suffered damage. Many writers warn against giving digitalis preparations to old people, and certainly caution should be observed in using them, particularly when symptoms of heart block, of angina pectoris, of aortic aneurysm, of retinal hemorrhage, of cerebral hemorrhage or embolism, or of severe gastrointestinal disturbances (especially diarrhea) have been present. Nevertheless, I still regard digitalis as a most valuable remedy in old age for the support of the heart muscle after it has begun to fail, especially if caffein sodium benzoate or caffein sodium salicylate be used with it. The particular preparation of digitalis administered is of less importance than the physician's experience in its application. In acute myocardial insufficiency, camphor is, also, a valuable drug. Recently, the combined use of insulin and glucose in the treatment of failing heart in both old and young patients has been coming into vogue. Rest should of course be increased, but, whenever possible, the older patient should be allowed to sit in a chair at intervals, for continuous bed rest has its special dangers for the aged. A few days of Karrell's milk diet, fol-

lowed by a simple cardiac diet of five small meals with restriction of the total fluid intake to 1500 c.c. or less, should be ordered. A daily bowel movement should be arranged for, either by means of mineral oil, psyllium seeds, compound licorice powder, a small dose of saline laxative in the early morning, or, if necessary, by the use of enemata or glycerine suppositories. Gentle general massage daily is advisable but the forms of hydrotherapy and of heart gymnastics resorted to for younger cardiac patients are best avoided in the treatment of the old. Provision should also be made for sound sleep at night by prescribing, where necessary, some barbitol derivative, but never chloral preparations; if there be marked nocturnal restlessness, codeine or a small hypodermic of morphine may be given at 9:00 p.m. though caution in the use of morphine in older people is, as everyone knows, important. If diarrhea should develop, it may be necessary, temporarily, to stop digitalis therapy and to administer calcium carbonate, salicylate of bismuth, or tannalbin until the diarrhea is checked. After the signs of circulatory insufficiency have been made to disappear it is well to keep up chronic digitalis therapy for a time. I usually give a half grain of powdered digitalis leaves with $7\frac{1}{2}$ grains of theobromine sodium salicylate thrice daily, after eating, for three weeks out of each month, provided gastrointestinal disturbances do not appear. When edema is marked, we dare not purge or sweat the patient, but rather make use of salt-poor diet and of diuretics like thecin by mouth or the enphylin by suppository in ad-

dition to digitalis, diet, and rest. Many use calomel to promote diuresis, but I prefer to do without it in the treatment of old people. When there is bradycardia with tendency to heart block (Stokes-Adams syndrome), digitalis and strophanthus preparations should be shunned, though atropine is indicated, and caffein and theobromine preparations may be used as vasodilators; in the syncopal attacks, a handkerchief upon which a few drops of amyl nitrite have been sprinkled may be placed over the face for inhalation in the hope of cutting short the attack. Old people who suffer from heart block or from angina pectoris should have with them a small vial of nitroglycerine tablets, placing one on the back of the tongue when needed.

Of the killing diseases of old age, *pneumonia* (lobar or lobular) ranks second to circulatory disease; Dr. Osler used to speak of it as "the old man's friend". Senile lobar pneumonia is often of asthenic type (without initial chill, herpes or pain), with relatively low temperature and without marked leukocytosis. The urine is usually diminished in quantity and in chloride-content. The physical signs are often indefinite and when the existence of pneumonia is suspected, roentgenograms of the chest are most helpful in diagnosis though difficult of application unless the patient happens to be in a hospital when the attack occurs. The mortality is notoriously high. If the patient recovers, the termination is more often by lysis than by crisis. In treating pneumonia in a senile patient, we have to rely chiefly upon general measures, supporting the heart and vasomotor center by cau-

tious administration of digitalis and caffein sodium salicylate, giving inhalations of oxygen, using luke-warm compresses or sponging with alcohol and water (taking great precautions against the chilling of the patient), and paying due attention to skilful nursing, diet, elimination, and provision of fresh air. Immune sera should not, in my opinion, be used intravenously in the treatment of pneumonia in old people.

THE HYGIENE OF LATER LIFE AND THE QUESTION OF REJUVENESCENCE

Relatively few persons have a "physiological" old age; what has been designated as "normal" or "biological" death at ninety or one hundred (attributed to the wearing out of the energy units of some essential organ, most often in the form of simple senile atrophy of the heart muscle, in the course of the "major involution") is only rarely observed, for most people succumb long before the end of the maximal span for the species, either because of harmful environmental influences, or of inherent pathological defects.

It is the task of our profession to search for both the extrinsic and intrinsic causes of "pathological" old age and to educate the public as to possibilities of preventing it, or of, at least, deferring it. In attempting to solve the problem, we should keep ourselves free from the illusion that we can transcend the limits of the possible. No human organism can live longer than the potential period set by the energy-charge of the fertilized egg-cell from which it starts. The human individual must die, if for no other

reason than that this energy-charge must, during life, gradually undergo exhaustion; the human race continues because its germ-plasms receive renewals of energy-charge from generation to generation. In how far the exhaustion of the energy-charge during individual life is related to specific growth stimuli, to specific growth inhibiting factors or to both we do not yet know. Many hypotheses have been advanced with regard to changes in the blood serum and in the physical-chemical equilibrium in the body, to the accumulation of toxic products, and to endocrine disturbances; but, thus far, no hypothesis has found enough support to gain full acceptance.

Medicine has made real progress in the control of the extrinsic factors that prevent "physiological" old age and lead to death before the end of the possible span of life. The average longevity of the human being has been practically doubled since 1800 through the discoveries of curative and preventive medicine and earnest attempts to apply them. Average longevity may, doubtless, be somewhat further increased by an extension of environmental control. We have not yet reached the limits of the possible in the protection of human beings from errors of diet, faulty elimination, insufficient fresh air, physical and mental over-activity and under-activity, and the manifold pathological influences of temperature, light, electricity, mechanical forces, chemical action, infection, and the economic, the psychic, and the social surroundings. This work of protection should be enthusiastically supported with the goal of the theoretically preventable ever in mind. But

we must not forget that it is life expectancy at birth and in the earlier decades that has been increased, whereas expectancy at fifty has been increased very little in the past 100 years and average expectancy for persons of sixty and seventy has, as I have said, been falling.

Progress in the prevention of the intrinsic factors of disease and of premature death due to faulty germ-plasms has been less marked. The world has been slow to recognize and apply the possibilities of a practical eugenics that could, by a breeding-out process, improve the qualities of the germ-plasms from which human beings start. Human nature is, in a way, in conflict with the rest of Nature, and our concern for the human individual is to a certain extent antagonistic to the interests of the human race and of human society as a whole. Our humanitarian impulses compel us to do all that we can to prolong the lives not only of the strong and the "fit" but also of the weaker and the "less fit", so that many of the latter who would otherwise have died early survive to the reproductive period and transmit their faulty germ-plasms to their offspring. It can scarcely be expected that heredo-familial diseases and constitutional defects can be lessened without genetic control. We know a host of these harmful genetic influences now. Any physician who has carefully studied the genealogical records of many families must have been impressed with the significance of both dominant and recessive Mendelian traits for the incidence of disease and for the shortening of life. It is well to add that early arterio-sclero-

sis, cancer, diabetes mellitus, cerebellar ataxia, manic-depressive psychoses, and dementia praecox are especially prevalent in certain families. Even tuberculosis is not wholly a matter of exposure to Koch's bacillus; the constitutional disposition to disease plays a great part in the incidence of and lack of resistance to this and other infections as well as in the occurrence of the more obviously heredo-familial diseases and the mortality due to them. Longevity itself is undoubtedly dependent in part upon exquisitely inheritable components. From what I have said it will be sufficiently obvious that hygienic measures directed toward the increase of the number of old persons that are healthy must, of necessity, give due attention to both genetic and environmental factors.

In the few minutes that remain, may I make brief reference to the special hygiene of later life and also say a word with regard to "rejuvenescence".

Periodic health examinations are valuable for persons over fifty-five or sixty as well as for those who are younger, in order that habits that are faulty for the time of life may be corrected, that any infectious processes present may be brought under control, and that the mind as well as the body may become adjusted to the march of the years. Persons over sixty and especially over sixty-five should sedulously avoid over-exertion, either bodily or mental. More physical rest and fewer hours of mental work may be indicated. Though the body should be regularly exercised, this exercise should be gentle and if any new form be taken up training in it should be grad-

ual. Doubles at tennis are then better than singles and nine holes of golf probably better than tennis. Gardening is a source of joy for many older people. Violent exertion of any kind and undue haste should be forbidden. When the time approaches for the lessening of the strain of occupation, it should be foreseen and the reduction should be made by degrees rather than suddenly. All too often an abrupt retirement from business or professional life has disastrous effects. The rate of progress of the reduction of activities should be individualized, for the rate that is wholesome may vary greatly in different persons. The main thing is "to take in sail" at the right time and gradually. The use of tobacco in reasonable amounts may be permissible, though patients who are developing arterial diseases (hypertension, angina pectoris, or intermittent claudication) may do well to abandon the use of it entirely.

In countries in which the use of alcohol is not prohibited, a little wine or beer or an occasional cocktail, a glass of whisky and water, or a liqueur may be much appreciated by older persons and be beneficial rather than harmful, though any excessive use should be discouraged.

Water-drinking should be regulated; a glass or two a half hour before eating will suffice, whereas an excessive intake of water throws unnecessary strain upon the heart.

A much smaller intake of food than in earlier life is desirable for older persons; after fifty-five, one should each year eat a little less. The meals should be small and should consist of simple, easily digestible foods, the

caloric intake being adjusted to the caloric needs. In general, less meat and fats should be eaten than in youth, and foods that cause gaseous indigestion, as well as rich and highly spiced foods of all sorts, should be taboo. Meals should be eaten slowly; the food should be thoroughly masticated but "Fletcherism" is unnecessary. Five small meals are better than three large ones. Breakfast may consist of milk, cereal, a soft boiled egg, coffee or tea, and a little marmalade with toast or a roll; if fish be taken at breakfast, it should be fresh, not salt or smoked. In the mid-forenoon, a glass of milk, an egg, or a cup of soup or a cracker may be eaten. The principal meal should be taken near the middle of the day and may be composed of soup, a small portion of boiled or roast meat, chicken, fish or oysters, two delicate green vegetables, and a little stewed fruit or some cottage cheese and a demitasse of coffee; if the patient be not too heavy, a little mashed or baked potato, or rice, or macaroni may be added. In the afternoon, a cup of tea with a cracker or a little toast may be eaten. The evening meal should be small and devoid of meat; eggs in some form with bread and butter or toast and fresh salad, or (instead of eggs) milk, may be followed by a little stewed fruit or a simple pudding. A small cup of decaffeinated coffee will do no harm.

Older patients should weigh themselves weekly and keep a record of the weight in order that the physician may form a right judgment regarding the optimal caloric intake.

Regular bathing habits should be maintained, but caution should be ob-

served regarding excessively cold or hot water for the bath. Gentle calisthenic exercises in the morning are often advantageous; J. P. Müller's system in which part of the exercises are taken before the bath, and part (with skin rubbing) after the bath, are found helpful by many.

Constipation should be carefully avoided; when it is marked, one must make sure that no enterostenosis is developing. The fruits and green vegetables of the diet recommended together with regular exercise will usually suffice for regular bowel movements, though some persons may require acidophilus milk or a little mineral oil or psyllium seeds in addition. If laxatives are used, they should be mild and should be changed from time to time. An occasional enema may be desirable but I am opposed to the enema habit that so many adopt.

Summer vacations should be spent at the sea or, if preferred, at medium altitudes, where there are forests or shaded walks; very hot and very dry places are best avoided. Winter vacations may be spent in the South or Southwest, especially if there be any tendency to bronchial catarrh.

The dying down of sexual desire and potency in later life seems to be one of Nature's safeguards for older men, especially for those who have had bradycardia, dyspnea, or symptoms of angina pectoris. In any case, great moderation in sexual indulgence is advisable, remembering Wordsworth's saying that "Love in old folk a great damage is!" Much has been written of late of "rejuvenescence" by means of Stiehmach's operation or by administration of endocrine products.

The evidence favors the view that any rejuvenating effects obtainable are but transitory; there may be a temporary "re-erotization", but this is of doubtful value and not devoid of danger to the older man.

The mental state of older persons should be carefully watched. The physician who undervalues psychotherapy in the management of patients over sixty makes a great mistake. All too many persons, when they first become conscious of the fact that they are growing old become pessimistic, complain that the world is going to the "bow-wows", declare that "life is over" for them, become negligent of personal appearance, tidiness, and social duties, yield to their apathy and diminished interests and become hypochondriacal—attitudes that undoubtedly hasten the aging process. A few go to the other extreme, vehemently deny any change in their physical or mental powers, and, as a sort of overcompensation for the flagging of their powers that they have really felt, tend to become overactive and to outvie even younger people in their lust for pleasures and their enthusiasms. But when the shrewd physician who has observed many older persons detects the premonitory involutional symptoms, he will do all that he can to guide his patients along the right paths, discouraging undue "let-up" on the one hand and excessive epicurean "let-loose" on the other. The older person who is wise will frankly recognize that there are unpleasant features of age that cannot be abrogated; but he will cultivate a philosophy that is based upon the realities of the life of the human individual and of the human species.

He will cling to the fact that every age of life has its own blessings and is good for its own sake, though he will hope that he may be lucky enough to escape from life before "second childhood". As Longcope has recently emphasized, the mere extension of life for "helpless doddering wrecks of humanity" is of but little value; he approves of Stevenson's attitude when he asked the question, "Does not life go down with better grace, foaming in full body over a precipice, than miserably straggling to an end in sandy deltas?" Older persons ought to meet the restrictions that age imposes with

courage and common sense and should enjoy to the full the compensations that later life brings—"honor, love, obedience, troops of friends". Like Macbeth, they will determine that "the mind I sway by and the heart I bear shall never sag with doubt nor shake with fear". And as long as possible, they will cultivate their hobbies and continue to participate in the intellectual pleasures of music, art, literature, and science. Thus living, one may, it is true, become old, but he will at least have gone far in the art of bearing age aright.

The Rôle of Bacteria in Allergy, with Special Reference to Asthma*

By R. L. BENSON, A.M., M.D., F.A.C.P., *Portland, Oregon*

AS early as the beginning of the present century the late Victor C. Vaughan¹ already had an adequate understanding of the problems of bacterial sensitization. This eminent biochemist maintained that bacteria, although morphologically simple in structure, are correspondingly complicated in their chemistry and comprise in particular a group of highly complex proteins. His insight into the minute chemistry of bacteria is further evidenced by his account of one or more carbohydrate components which he regarded as intimately linked with the large nucleoprotein molecules. He concluded that these constituents could readily be split apart by dilute acid or alkali, but better by 2 per cent solution of caustic soda in absolute alcohol. The resulting protein nucleus set free was found to be non-specific and poisonous, while the other component, largely carbohydrate, was highly specific but non-toxic.

The further development of this important phase of bacteriology diverges along two general lines. One of these concerns bacterial variation from the smooth, or S-type, into the rough, or R-type, with relative loss of virulence.²

The other includes the advances in knowledge of the bacterial antigens found in the brilliant and detailed reports of Avery and his colleagues, Zinsser and his colleagues, Lancefield and others, who, working with various pathogenic organisms, have isolated two distinct fractions—a nucleoprotein which is antigenic but not highly specific and a carbohydrate which lacks antigenic power but is definitely specific.

Dochez and Avery³ in 1917 described a type-specific soluble substance which they had isolated from broth cultures of pneumococcus, and which they decided was a secretory product of the bacterial capsule. Zinsser and Parker⁴ in 1923 corroborated Dochez and Avery's result with pneumococcus and reported similar soluble specific substances obtained from cultures of tubercle bacillus, *Staphylococcus aureus*, influenza bacillus, and typhoid bacillus. The same type of specific soluble substance has been isolated from cultures of Friedlander's bacillus,⁵ yeasts,⁶ *Streptococcus viridans*,⁷ hemolytic streptococcus,⁸ *Meningococcus*,⁹ and members of the coli-typhoid group.² These various substances are admittedly of the same nature and apparently resemble that obtained by Pick¹⁰ as early as 1902. It is not necessary to recount in detail the prop-

*Read before the Sixteenth Annual Clinical Conference of the American College of Physicians, San Francisco, April 1, 1932.

erties of these soluble bacterial products. Full descriptions are to be found in the reports of Avery and Zinsser and their co-workers.

Mention should be made of other soluble antigens and corresponding antibodies recently attributed to the pneumococcus. Sabin¹¹ found that Type I antipneumococcus serum, after the total precipitation of the antihydrate precipitins, retained a definite amount of its type-specific protective action which was not neutralized by additional SSS ("specific soluble substance"). It could be absorbed, but only by the homologous virulent pneumococci. Enders¹² reported in the autolytic products of pneumococcus Type I a substance distinct from SSS but reacting specifically with its homologous antiserum. In weakly alkaline solution this is destroyed by boiling but not in acid solution. It resists peptic digestion and appears to belong, like SSS, to the group of haptenes. Such findings suggest the possibility that bacteria contain in their infinitesimal makeup an indefinite variety of specific protein compounds which are capable of acting as antigens and of inciting the formation of antibodies in the animal host.

It may not be out of place here to attempt a tabulation of various bacterial effects which have been described.

1. Foreign non-specific protein action has been reported by Miller¹³ and others, and may be regarded as having some importance. Coca and his collaborators,¹⁴ in their comprehensive text on allergy, conclude on inadequate premises that the idea has been "relinquished that vaccine treatment is a specific form of therapy". In this

presentation I shall admit the existence of such a procedure as protein shock therapy but at the same time draw a distinction between this type of treatment and the highly specific vaccine therapy employed by the Dicks and Dochez in scarlatina and by various workers in bacterial asthma. Topley and Wilson¹⁵ presented at length the experimental evidence against the reputed importance of the non-specific factors. They concluded that there is no evidence that any non-specific stimulus can cause the appearance of any of the known serum antibodies. While there is some evidence that such non-specific stimuli may cause an increase in any of the normal antibodies or a secondary rise in titre when administered after the effect of the preliminary specific immunization has reached its zenith or begun to decline, the responses falling within this category are irregular or trivial and never comparable to those following the reinjection of the specific antigen. Pilot¹⁶ and others, working with the skin reactions in man with staphylococci, found that of fifty-six patients suffering from staphylococcus infection 89 per cent reacted positively and often more violently than normal persons. From this it might be inferred that mere infection is identical with sensitization. On the other hand, Pottenger,¹⁷ referring to infection with another organism, calls attention to the important conception that a relatively greater hypersensitivity of the cells is likely to be present in the earlier and more active stages of the infection than later. Others¹⁸ have reported anaphylactic and even asthma-like symptoms in guinea pigs from repeated intravenous and intratracheal

injections of green-producing streptococci. The results, while not very striking, were said to resemble in many respects the corresponding human respiratory phenomena.

2. The Vaughan and Friedberger¹⁹ split products must be considered as possible toxic factors in any infectious disease but accentuated in their importance in hypersensitive states.

3. Production of histamine-like substances with resulting bronchospasm by bacteria of the *B. Friedlander* group has been reported by Knott and Oriel and is described in the Report of Research at the Asthma Clinic of Guy's Hospital for 1928-1930. Harkavy²⁰ had found a spasm-producing substance in the sputum during asthmatic attacks which was absent during the free interval. These findings are of interest in comparison with the observation of Koessler, Hanke and Sheppard²¹ that histamine could be produced in the intestinal tract by various members of the coli-typhoid group.

4. The nucleoprotein and SSS fractions of Avery and others have already been mentioned and the research of Salin and of Enders suggests the probability of a multiplicity of specific soluble products of bacteria.

5. The Arthus²² phenomenon is a special type of accelerated allergic response in rabbits and other animals. After several daily inoculations of a foreign protein without noteworthy effect, subsequent inoculations of the same type produce a hard aseptic infiltration which persists for days or even weeks.

6. The Schwartzman²³ phenomenon is an unexplained skin response to bac-

terial filtrates and is elicited as follows: The sterile filtrate of the broth culture is injected into the skin of rabbits and after twenty-four hours a suitable amount of the same filtrate is injected intravenously. This results within four or five hours in a hemorrhagic necrotic swelling of the originally injected skin sites. This phenomenon has been produced with cultures of several different bacteria even if filtrates from entirely unrelated bacteria were used for the skin-preparatory and injury-producing factors respectively. The skin-preparatory substance is, however, of a specific antigenic nature and neutralization of either the skin-preparatory or injury-producing factors is possible only through the use of homologous sera.

7. The Dick²⁴ toxin differs from the SSS of Avery in that, although heat resistant, it gives rise to a specific antiserum.

8. The observations of Touart²⁵ and others that old quiescent vaccine inoculation sites are relighted by subsequent inoculations of the same vaccine in a different location deserve comment. Patients have repeatedly called my attention to this phenomenon.

These various manifestations of bacterial action have been listed to call attention to the multiplicity of antigens and effects coming from bacterial metabolism and the corresponding complexity of reactions on the part of the host. It is entirely conceivable that some of these specific and non-specific bacterial agencies enact an appreciable part in the pathogenesis of infectious asthma and other hypersensitive clinical states attributable to bacteria.

SENSITIZATION TO BACTERIA

It is a matter of common observation that certain cases of asthma, rhinitis, migraine, urticaria and other allergic conditions are unexplainable on the basis of reaction to the ordinary foods and inhalants. It is equally evident that the causes of most of these must be sought in the infectious processes within the body. In general, the workers in this specialty of medicine have divided their cases into bacterial and non-bacterial, or categories which are equivalent. The only matter of disagreement concerns the question of specificity or non-specificity in the bacterial causes.

There can be no reasonable doubt that bacterial infection may, by its mere presence in the bronchial tree, cause irritation of the vagus nerve endings or bronchial musculature directly and thus furnish the *modus operandi* of the bronchospasm and attendant exudation and edema of asthma. In accordance with this many authorities maintain that vaccine treatment in asthma is nothing more than foreign protein shock therapy. This same line of reasoning applies also to the protein split product theories of Vaughan and of Friedlander, or to the bacterial histamine-like bodies of the Guy's Hospital Staff. It is entirely possible that any one or more of these non-specific chemical factors may be operative in certain instances. The pioneer research of Vaughan has indicated that any bacteria, including the relatively avirulent *B. coli* group, have an inherent toxicity for the animal organism.

We are, however, equally concerned with the more specific effect of the pathogenic microorganisms on the hu-

man subject. I refer to those manifestations of bacterial action which are characterized by definite sensitization phenomena.

Several difficulties present themselves at once. The first of these is the supposed discrepancy between human allergy and animal anaphylaxis, owing to the frequent failure to obtain passive sensitization of animals by injections of allergic sera. I am inclined to agree in this regard with Zinsser²⁶ that we should not neglect the basic principles of hypersensitiveness in favor of discrepancies which represent gaps in our experimental knowledge rather than fundamental differences of principle. Another and more formidable obstacle lies in the extreme complexity of the bacterial antigens and antibodies as compared with those of the simpler coagulable proteins.

Bacterial anaphylaxis has been thoroughly established as a scientific fact. "Active and passive sensitization may be induced with bacterial antigens, as determined by the occurrence of anaphylactic shock (Rosenau and Anderson 1907, Kraus and Doerr 1908, Holobut 1909, Kraus and Admiridzibi 1910, Zinsser and Parker 1917, Tomcsik and Kurotchkin 1928), or by Dale's technic with the isolated uterus (Zinsser and Parker 1917, Zinsser and Mallory 1924, Tomcsik and Kurotchkin 1928). The reactions are specific and desensitization can be demonstrated.

"Sensitization to bacterial antigens cannot, however, be produced with the same ease and certainty, as in the case of horse serum or egg-white. A single injection of bacteria, or bacterial extract, frequently fails to produce any

demonstrable sensitization, and the most successful results have been obtained by those workers who have employed repeated small injections of antigen for sensitization, followed by an interval of three weeks or so".¹⁵

Zinsser²⁶ has cited convincing instances of laboratory sensitization with tuberculin. The evidences of bacterial anaphylaxis are, however, relatively slight in degree. Zinsser and Tamiya²⁷ attribute this limited formation of antiprotein antibodies, and consequently of true anaphylaxis, to the fact that coagulable protein, though present to a slight extent in bacterial extracts, does not predominate in the bodies of the bacteria. The bacterial hypersensitiveness which concerns us in asthma and other allergic conditions is essentially different from the anaphylactic phenomenon. Its development is usually dependent upon the presence of the whole bacteria in the organism and appears to be related to the nucleoprotein-carbohydrate combination of Avery, Zinsser and others. The complex chemistry of the bacterial cell body contains other substances which may well assume importance in sensitization phenomena when their properties have been more thoroughly studied.

CLINICAL OBSERVATIONS

Classification of Allergic Cases. In the absence of a better classification I have grouped my asthma cases according to their causes, into (a) non-bacterial, (b) bacterial, and (c) mixed bacterial and non-bacterial. Group (c) represents the experience gained from extensive testing with foods and dusts. Reactions to them, even though nu-

merous and definite, imply merely a sensitiveness of the skin to the individual allergen and do not in any sense preclude a coexisting bacterial sensitization which may be the underlying process. Many striking instances of this class might be cited.

The routine procedure in my practice is to test the dermal reactions to the foods and dusts with which the patient comes in contact. Regardless of reactions or their absence the possibility of bacterial causes is investigated. A careful history of previous outbreaks of infection, especially in their relation to asthmatic attacks and to seasonal variation, is of help. Certain laboratory procedures, such as the leukocytic and eosinophilic counts, the sedimentation velocity of the blood, the character of the sputum and the results of proper culturing, when combined with physical inspection and the diagnostic employment of iodides and other medication, usually give a fairly accurate determination of the type of asthma.

The choice of material for culture is as important as the technic. Sputum, and in particular Curschmann spirals, are washed in sterile saline, ground in a mortar with sterile sand and cultured with addition of the patient's blood or serum in pour plates and brain broth, also at times streaked on agar and Sabouraud's medium. The blood agar pour plates made on a decimal scale of dilution enable a count of the various bacteria of the sputum. These include in order of frequency *Streptococcus viridans*, hemolytic streptococcus, non-hemolytic streptococcus, *Staphylococcus aureus*, pneumococcus, and others of less importance. The

number of organisms in 1.0 c.c. of sputum ranges from a few thousand to many millions.

We are probably concerned equally in asthma with the intestinal flora. As stated by Zinsser²⁶ sensitization of the lung does not necessarily imply that the hypersensitive state is relatively more marked in the lung tissues. In my experience culture of the feces carried out according to a rigid technic²⁸ which inhibits the growth of the intestinal gram-negative organisms has yielded definite results in asthma and other allergic conditions. By this method the normal individual and the non-bacterial sensitization case usually give a negative or negligible culture, while the subject with bacterial allergy will, in the majority of instances, give a growth of pathogenic intestinal bacteria ranging from 100,000 up to many millions from each loopful of stool plated out. In one case it was estimated that one loopful of stool contained 127,000,000 green-producing streptococci. The organisms encountered are, in order of frequency, *Streptococcus viridans*, *hemolyticus*, *non-hemolyticus*, *Staphylococcus aureus* and rarely other organisms.

Many of these asthmatics showing a preponderance of pathogenic cocci in the feces have complained of colitis with loose movements and sometimes with blood and mucus in the stools, especially at the time of asthmatic seizures. Probably a still greater percentage have suffered with constipation. A minority, even in the presence of extreme infestation of the bowel by pathogens, complain of no irregularity in the matter of movements. The presence of a high grade infestation, with

or without noticeable clinical disturbance, is to be regarded as a potential cause of asthmatic paroxysms.

In addition to the almost routine culturing of the sputum and feces, cultures are made in selected cases from the sinuses, tonsils, teeth, and other foci. A variety of organisms is obtained.

In other allergic conditions than asthma, including bacterial rhinitis, eczema, dermatitis, urticaria, migraine, and certain rheumatic and ocular conditions, culturing has often been carried out according to methods suited to the condition. Particularly illustrative of the broad application of the principles of bacterial sensitization here enunciated are several cases of iritis referred to me for study. Two out of four such cases treated with streptococcus stool vaccines have shown diverticulosis of the colon on X-ray of the abdomen. Strangely enough, these two with diverticulosis have apparently recovered under vaccine treatment, while the others are still refractory. This subject will be presented in detail in a separate report. Infection in relation to eczema will also be reported separately.

Preparation of Vaccines. In an effort to obtain vaccines which should contain the specific principles of the causative organisms, the following types of bacterial preparation have been studied: (a) washed organisms killed at 60°C. for one hour; (b) unheated Berkefeld filtrates from brain broth cultures containing patient's serum; (c) whole broth cultures in brain broth containing patient's serum and including both the bacteria and their medium.

Each of these types of bacterial preparation has been used in a considerable series of cases for testing and treatment. All have been found specific and have been used with success in treatment. Their relative merits will be discussed following a short summary of the cutaneous reactions. In addition to these three preparations the protein fraction of thoroughly ground bacteria has, in certain instances, been obtained by precipitation with cold alcohol and tested cutaneously on patients. (Figure 1, D).

The requisites for success in vaccine treatment have been proper choice of foci for culturing, careful isolation of

the predominant organisms as determined by plate counts, and standardization of dosage by cutaneous tests and systemic reaction. It is also important to employ a type of bacterial preparation which shall include the specific causes of asthma.

Cutaneous Reactions. The reactions obtained in a series of 500 cases of asthma, including a smaller series of 232 cases studied in greater detail, lead me to agree with Thomas,²⁰ Famulener and Touart, Haibe³⁰ in Belgium and others that the reactions of intradermal tests in conjunction with the systemic effects of bacterial inoculation form the most reliable

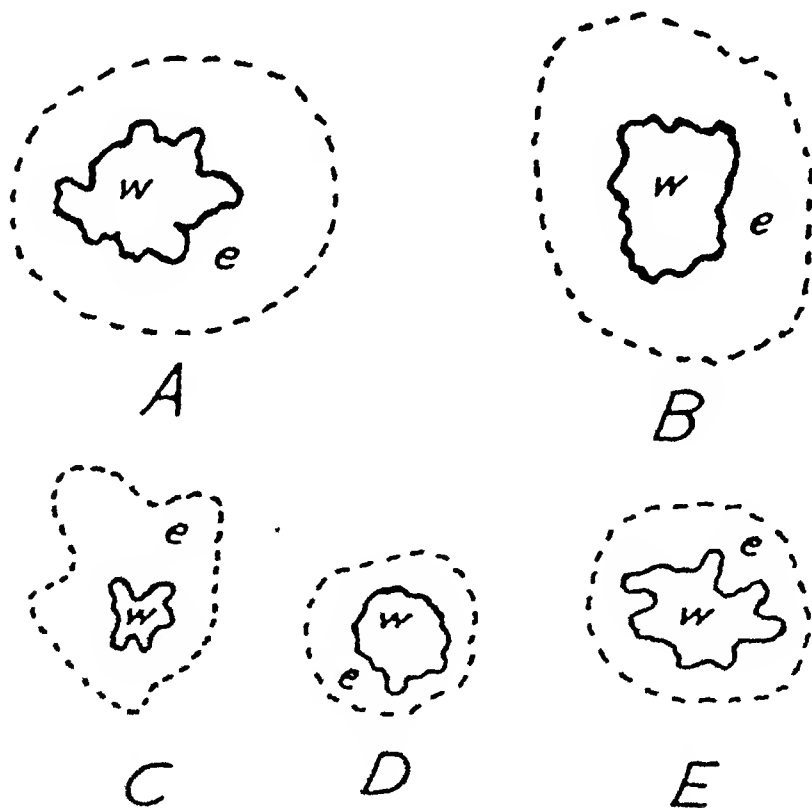

FIG. 1. Trailings of intradermal reactions to bacteria (natural size). w, wheal; e, erythema. A, immediate reaction to *Streptococcus viridans* stool vaccine in patient with earlier asthma. B, immediate reaction to *Streptococcus viridans* stool vaccine in asthmatic patient. C, spontaneous four reactions to hemolytic streptococcus showing small wheal to wheal size reactions. D, early reaction to purified protein from *Streptococcus viridans* of patient with asthma. E, reaction to mixed culture organisms as B. (The bacterial reactions are larger than the protein reactions.)

guide to vaccine therapy. It seems advisable to test the reactivity of the skin to the separate bacterial preparations—washed bacteria, filtrate, and whole culture—and to study the use in treatment of those which react.

In evaluating the reactions, most authors are of the opinion that the immediate wheal and its surrounding erythema are of non-specific origin due to the foreign material in the medium and the purely toxic effect of the bacterial extracts. In general my results support this contention. Having repeatedly tested patients with bacterial products and with the homologous sterile medium incubated under similar conditions, I can state that in the great majority of instances the medium produces an immediate intradermal reaction entirely comparable to that with the corresponding whole vaccine. In such cases the reaction must be regarded as non-specific.

Attention must, however, be called to occasional exceptions to this rule of which I shall cite only a few. Figure 1, B is from a tracing of the immediate wheal and erythema from intradermal inoculation of a *Streptococcus viridans* stool vaccine in an asthmatic four years of age. Control inoculations in normal individuals were small and lacking in pseudopodia. The twenty-four hour reaction was entirely negative, yet within ten hours following the inoculation the patient developed a severe attack of asthma. This fact, together with the favorable outcome of vaccine treatment, leads me to believe that this child's immediate reaction was of a specific nature and that it constituted the essential skin manifestation

of his bacterial sensitization. Figure 1, A represents a tracing of the immediate reaction to a *Streptococcus viridans* stool vaccine inoculation in a boy who had had canker sores in the mouth for years. Despite the absence of a twenty-four hour reaction this boy made a prompt recovery from his mouth condition and gained progressively in weight and strength. Other such instances might be cited indicating that the immediate reaction is occasionally of primary importance. To these might be added a few other cases in which a significant immediate wheal is followed by a definite delayed intradermal reaction.

As a rule, however, the characteristic cutaneous response to intradermal inoculations is represented by changes in the inoculation site occurring in ten, fifteen, or twenty-four hours, rarely later. Because of the variability in the length of this period it is advisable to make repeated inspections during the first twenty-four hours. I have even had cases of multiple inoculations in the same patient in whom certain reactions showed best at fifteen hours and later faded, whereas others were scarcely visible until twenty-four hours had elapsed.

The character of the cutaneous response is variable. The most usual type resembles that commonly seen in the Dick test and I have accordingly followed the practice of doing the latter test on the same arm as a control, particularly in connection with those cases infected with hemolytic streptococcus. At times the Dick test gives a result which agrees with that of the autogenous hemolytic streptococcus filtrate and vaccine; on other occasions

the two are at variance. A finding which is sometimes overlooked in both is the occasional appearance in fifteen or twenty hours after inoculation of a wheal followed several hours later by a reddish areola of the same size, or even much larger, (Figure 1, C). At times a deep reddish papule forms the center of the areola, especially in *Staphylococcus aureus* reactions (figure 2), and this may even have a

homologous with those found in scarlatina* or may be entirely dissimilar.

The site inoculated with washed hemolytic streptococci may react more strongly than the point inoculated with unheated filtrate from the same culture, or the reverse may occur. More often both respond about equally (figure 6).

Streptococcus viridans and non-hemolytic recovered from the respiratory

FIG. 2. Twenty-four hour reaction to intradermal inoculation of 0.02 c.c. *Staphylococcus aureus* nose vaccine of asthmatic. Note papule in center of areola.

yellowish purulent-looking but sterile apex (figure 3).

Reactions of *Streptococcus hemolyticus*, when present, are usually entirely comparable with the ordinary twenty-four hour response to the Dick test. Of interest in this connection is the observation that, in the definitely positive hemolytic streptococcus cases, the response to the Dick test may be equally erect (figure 4), or may be falling (figure 5). It seems probable that the hemolytic streptococci employed in the serum and tests of allergic response may be immunologically

or intestinal tract of asthmatics usually elicit cutaneous responses which are similar to those obtained with *Streptococcus hemolyticus*. In the case of the former groups the washed organisms, or the whole brain broth culture, usually react more strongly than the unheated filtrate (figure 7), although the reverse is occasionally true.

*In one child five years of age, apparently belonging to this group, I treated a violent asthmatic upset by intravenous injection of 200 c.c. of antiscarlatinal serum with such a prompt and gratifying result that I feel I should recommend the procedure for consideration.

Staphylococcus aureus, since it grows better in solid media, has been used in the form of emulsions of washed and heated organisms. The behavior of these following intradermal inoculation is similar to that of the streptococci except for the more frequent

bacterial capsule probably contain a predominating amount of the specific SSS hapten of Avery while the bacterial bodies retain the bulk of the less specific, but antigenic, nucleoprotein fraction. The choice of the particular cultures which enter into the vaccine

production by the former of reactions having a papular or pseudopustular center. Other organisms are occasionally employed in my vaccine therapy but have not received the same detailed study as the foregoing.

The vaccines employed usually include both heat-killed bacteria and unheated filtrate. This practice is based on the assumption that the filtrate and

is, however, made on the basis of cutaneous reactions and, to some extent, of the relative preponderance of each organism in the original focus.

Having mixed together those cultures which are considered of probable importance, a trial dosage is worked out on the basis of the sensitiveness manifested by the skin and on general reactions if such occur. The usual

dilution is 1:20 or 1:50 in terms of whole broth culture, or, if several strains are included, dilutions of 1:100 or occasionally even 1:1000. By starting with a minute dosage, say 0.05 c.c., it is generally possible eventually to desensitize the individual to the bac-

error owing to personal factors in the patient such as lack of coöperation and veracity, geographical considerations, overwork, and others. The figures have, however, been collected for what they may be worth and include those 232 cases of asthma in my prac-

terial antigens. When this is accomplished the dosage, and even the concentration, are increased in the hope that the individual may "pass through an allergic state into one of immunity to the same agent".

Results of Vaccine Treatment. The results of treatment along the lines mentioned have been entirely favorable. Any tabulation of figures in this regard is subject to a great range of

tice which have been worked out in sufficient detail to permit analysis. Of these, 21 were non-bacterial and were treated on the basis of elimination or of specific inoculations against the offending foods and dusts; 94 were classed as of bacterial origin and subjected to vaccine therapy; and 117 were considered of mixed bacterial and other origin and given vaccine treatment along with suitable attention to

the non-bacterial allergens. The results are best expressed in a simple tabulation.

The results in the bacterial group are almost identical with those in the other groups. In past years I have shared the prevailing American opinion that definite reactions to foods and dusts offered the only real outlook for successful asthma treatment. This feel-

ing has undergone a reversal accompanied by a corresponding improvement in results. The English insistence on metabolic and other systemic factors has wrought considerable change in our conception of asthma. The greatest single stride, however, has been a growing appreciation of the rôle of bacteria in asthma, and considerable credit for this phase of the develop-

TABLE I

	Non-bacterial	Bacterial	Mixed	Total
Cases	21	94	117	232
Complete or nearly complete relief	24%	22%	24%	23%

ment belongs to Sir Almroth Wright³¹ and Fleming in England and to Walker³² and Thomas²⁹ and his co-workers in America. I am forced to agree with Haibe³⁰ of Belgium that too much stress has been laid on the cutaneous reactions to foods and dusts in the American reports. He considers that many of these are false reactions and that in any case they may not furnish the key to the allergy.

Of more value than any table of figures is a detailed analysis of individual cases of bacterial sensitization with records showing relative bacterial desensitization through specific treatment. I could cite many instances in which a minute intradermal inoculation of autogenous bacterial antigen has, within one to several hours, precipitated a violent paroxysm of asthma, notwithstanding the fact that a control inoculation of fully 100 times the quantity of stock vaccine has failed to produce a similar effect. Equally convincing evidence for specificity is afforded by the prompt and complete cessation of asthmatic attacks which not infrequently follows the initial intradermal bacterial inoculation of the proper size. The following is a typical example. The patient, a girl of eleven years, had had asthma continuously without any complete intermission from the age of two. At the time of her first visit she was a pitiful spectacle, in an advanced stage of emaciation, and with chest deformity of the pigeon type. Cutaneous tests proved her sensitive to grass pollens, horse epidermal extract, housedust, and many foods. Stool culture yielded hemolytic streptococcus in large numbers, and culture from the nares gave *Staphylococcus*

aureus. Repeated inoculations with minute doses of the undiluted vaccines were followed by an increase of the asthma, and the patient returned home in a worse condition than when she came to me. Several months later she returned for observation. Her first week in Portland was devoted to laboratory procedures, and no relief of her asthma accompanied the change of climate. At that time an inoculation of 0.05 c.c. of a 1:10 dilution of the original vaccine was given her and resulted in a complete cessation of her asthma for the first time in nine years. There was no return of symptoms during the following week, at the end of which she left for home. This case is cited as an example of the aggravation of symptoms which frequently follows overdosage of vaccine and the prompt relief which can result from a proper dosage. Many cases might be cited which are equally convincing and in which the relief of symptoms has lasted over a period varying from one to several years.

Either type of specific systemic reaction, that with provoked paroxysm or that with prompt cessation of attacks, constitutes a favorable prognostic sign, especially when supplemented by definite cutaneous reactions. In either type subsequent repeated inoculations on an ascending scale of dosage has usually resulted in improvement. It has thus been found possible to decrease or remove the hypersensitivity to the bacterial causes and sometimes, though not always, to produce an eventual immunity. Two typical cases will be cited in this connection.

The first patient, a female past middle age, had had severe asthma dating

from an attack of lobar pneumonia in 1913. Sputum vaccine containing streptococcus and pneumococcus gave relief in this early phase of her infectious asthma. In 1917, following a recurrence of asthma, she had a cholecystectomy at the Mayo Clinic with good recovery. Her asthma, however, recurred intermittently until 1925. At this time she consulted Dr. A. Fleming at St. Mary's Hospital in London. This worker cultured the stool, found large numbers of streptococci of the viridans type and started vaccine treatment with small doses of this growth. Perfect relief occurred in three weeks and lasted without incident over a period of five years. In 1930 she suffered another mild attack which responded promptly to a similar stool vaccine made by me. This case affords a striking example of the outstanding infectious nature of this group of asthmas.

Another case, a boy of ten, had had asthma every winter from the time of his measles, diphtheria, and pneumonia six years before. Cutaneous tests resulted negatively with the exception of dog, mustard, and flaxseed, all of which gave good reactions. No specific treatment was given for any of these reactors. A high incidence of eosinophiles in the blood and sputum, together with an increased sedimentation velocity, and the hibernial nature of his attacks led to a diagnosis of bacterial asthma. The sputum, which was scanty and of a whitish milky appearance, yielded on culture over 12,000,000 green-producing streptococci per 0.05 cc. Stool culture gave 1,000,000 green-producing streptococci and 55,000 hemolytic streptococci to the helpful. Both

vaccines gave good twenty-four hour reactions on intradermal inoculation and significant immediate reactions were also obtained with the stool vaccine (figure 1, E) and with the protein prepared from the ground up green-producing streptococci. (Figure 1, D). This boy's asthma stopped within a few weeks after vaccine treatment and has not recurred during the whole winter season. In the meantime his weight has increased from 60 to 73¼ pounds during the past six months. Such cases as this represent bacterial asthma with complete desensitization following minute doses of the specific inciting cause.

DISCUSSION

An analysis of the results of specific bacterial therapy is made difficult by the complexity of the bacterial effects in the human organism. These include not only the over-emphasized foreign protein factor but the more significant specific nucleoprotein-carbohydrate antigens which have been established on a scientific basis by the brilliant researches of Avery and Heidelberger,²² Zinsser, Lancefield and many others. Sabin and Enders have contributed to our knowledge of these specific phenomena and the Dicks and Dochez have added an entirely different hemolytic streptococcus factor, a true toxin which is heat resistant but which incites a specific antitoxin. Any of these components may be present in the bacterial filtrate or capsule or cell body in varying degree, and it is conceivable that any or all of them may be concerned with the manifestations of asthma.

Some attempt has been made to de-

termine the relative importance of the bacterial cell bodies and filtrates. Intradermal tests with these separate bacterial preparations have shown at times a stronger reaction with the one or the other but just as often the two have reacted equally. There have been instances in which the washed organisms have produced a large twenty-four hour areola while the filtrate has scarcely reacted at all. The reverse has sometimes occurred. Such considerations have led me to a routine procedure of using in treatment those bacterial preparations from the sputum or stool or other sources which reacted best, including in most cases both whole organisms and unheated filtrate.

The results have been studied analytically but detailed tabulations have been omitted, because they were considered highly involved and to some extent misleading. The results do, however, lead to certain important generalizations. Table 1 shows that the outcome of treatment in the bacterial and mixed groups has compared favorably with that in the non-bacterial group, due to known foods or dusts. The success obtained is attributed to the selection of cases on the basis of

symptomatic and seasonal considerations, routine blood and sputum examination, and exhaustive culturing followed by administration, in carefully standardized dosage, of those bacterial preparations which have given significant cutaneous reactions. Cases conforming to these requirements and receiving an adequate course of specific treatment have generally had a successful outcome while the others have more often failed of a good result.

The importance of thorough attention to the various food and dust factors has been referred to in a previous report and need not be dwelt on here, nor have the metabolic, endocrine, and other general considerations been overlooked. Space has permitted only the detailed handling of the subject undertaken, namely, the rôle of bacteria.

CONCLUSION

The limited value of non-specific protein shock therapy is admitted. More important, however, in properly selected bacterial cases is the definitely specific desensitization which can be attained by the careful use of autogenous vaccines and filtrates.

A Method of Evaluation of Results in Hay Fever; Its Application to Certain Modes of Treatment*†

By SAMUEL M. FEINBERG, M.D., F.A.C.P., *Chicago, Illinois*

THERAPEUTIC progress in any field necessitates a means at our disposal for measuring therapeutic results. This may imply either an objective method or a good subjective method. In hay fever this is especially desirable because of the natural variations in the symptoms. From time to time various treatments are advocated in hay fever and it becomes necessary to measure their value. Modifications in technic of old accepted forms of treatment must also be evaluated. In addition, the measurement of therapeutic results in hay fever may be of worth also in the study of other factors such as age, complications, climate, etc.

Unfortunately there is no objective method for studying results in hay fever. We must rely entirely on a study of the subjective symptoms. The usual means of studying and reporting hay fever results are very unsatisfactory. The most common method, perhaps, consists of grading results according to the physician's impression of the symptoms for the entire season. Frequently the patient himself is asked to evaluate the season after it is over.

*Read before the Chicago Society of Allergy, January 18, 1932.

†From the Allergy Clinic, Department of Medicine, Northwestern University Medical School.

It hardly needs comment to contend that such a method has too many elements of unreliability. Our powers of recollection become diminished in proportion to the time that has elapsed, and this is especially true if the memory is an unpleasant one.

Even the impression gained day by day from studying the immediate or daily effect of treatment is not of great value unless certain factors are taken into consideration. As long ago as the middle of the nineteenth century Blackley¹ noted that there were marked variations in the pollen content of the air during the hay fever season. He also noted that the severity of the symptoms in himself, as well as in other hay fever sufferers, depended chiefly on the concentration of the pollen in the air. This concentration he measured by counting the number of pollens on a unit area of an oiled glass slide exposed to the atmosphere for a unit of time. Duke and Durham² in 1928 emphasized this dependence of severity of symptoms on pollen concentration. They say: "The marked irregularity of the charts (pollen) often accounts for variation in the symptoms displayed by patients from day to day during a given season".

For many years practically all men in the field of allergy have held or ex-

pressed similar views. It remained, however, for Rackemann and Smith,^{3,4} Acquarone and Gay,⁵ and Hopkins⁶ to show graphically this correlation of symptoms and pollen concentration. The symptom curve of Rackemann and Smith is drawn from results of 100 treated patients. The symptoms for each patient are shown by a horizontal line, a light one for mild symptoms and a heavy one for severe symptoms. The symptom curve is obtained by counting the individual lines where they cross the upright date lines, allowing two counts for the heavy lines, and plotting the totals to make the symptom curve. The objection to these curves is that the symptoms are not graded sufficiently, thus not making sufficient distinction between symptoms of varying severity from day to day. No attempt is made to show how treatment of one type or another may influence this symptom curve.

In 1931 Acquarone and Gay⁵ reported a study of the correlation of hay fever incidence in sixty-seven treated patients with that of pollen incidence during 1929. In this study the cases were divided into four groups: tree cases, grass cases, plantain cases, and ragweed cases. The percentage of cases in each group showing symptoms on each day was plotted with the curves made from the pollen counts. On the whole their figures show correlation between pollen counts and the percentage of patients showing symptoms. However, in the ragweed cases, judging from their chart, the correlation was not very constant. The objection to their data and figures is that no differentiation is made between mild and severe hay fever;

"a patient who had symptoms for as short a period as one hour is included in the curve".

Two months after the previous publication, Gay⁷ made a more extensive report of hay fever symptoms in relation to treatment. The patients kept their own records, marking the day "bad" if the symptoms persisted continuously throughout the twenty-four hours; "poor" if there were an hour or two of symptoms during the twenty-four hours; and "good" if there were no symptoms at all. He thus finds, for example, in 1929 that the treated cases averaged a total of 14.4 days of discomfort (8.4 mild symptoms and 6.0 days severe), as compared with a possible 46.2 days in untreated patients. In the ragweed group of that year the treated cases experienced 14.1 days of symptoms, against a possible forty-two days in untreated patients.

Hopkins⁶ also reported a study of the correlation of the pollen with the symptom curve, but she also did not differentiate between grades of severity.

METHOD

The first step is the grading of symptoms. The patient who goes through the season with a little sniffing and no discomfort has an entirely different result from one who has severe symptoms with frequent discomfort. It seemed to me, therefore, in order to arrive at any valuable conclusion as to treatment, etc., there must be a grading of symptoms intermediary between a few sneezes and the most severe form of hay fever. The following plan was adopted and carried out during the 1929 ragweed season. The

symptoms were graded into five classes. Grade 1, "very slight", consisted of only an occasional sneeze; this degree of irritation and sneezing would be ignored by many patients unless their attention was aroused by close inquiry. Grade 2, "mild", consisted of definite hay fever symptoms lasting an hour or two of the twenty-four hours. Grade 3, "moderate", was defined as including the more continuous symptoms, lasting a great part of the twenty-four hours, but not of a very violent nature and without much blocking of the nose. Grade 4, "severe", consisted of blocking of the nose, frequently repeated severe sneezing spasms, very marked rhinitis, or marked eye and throat symptoms; any or all of the above symptoms were present but not constant throughout

the twenty-four hours. Grade 5, "very severe", consisted of the same symptoms as Grade 4, except that they were practically constant throughout the twenty-four hours.

From such daily grading, individual symptom curves may be plotted as seen in chart 4. It may readily be seen that not only is there a tendency for these curves to be correlated with the pollen curve, but each individual curve gives us a graphic idea of the severity of the season for that particular patient.

Chart 1 represents a composite symptom curve obtained by charting and averaging the daily symptoms of a series of patients. Each patient's daily symptoms are represented by a dot. The dots for that day are then averaged, thus giving us an average

CHART I

daily symptom grade. When all these daily points are connected there is obtained a curve such as outlined in chart 1. The chart is made from a series of fifty ragweed hay fever patients.

Chart 2 shows the correlation of this composite symptom intensity curve with the pollen concentration curve. It

lag between the peaks of the pollen curve and those in the curve of hay fever intensity. Acquarone and Gay⁵ found such a lag of twenty-four to seventy-two hours, possibly because they were charting hay fever incidence rather than intensity of symptoms. At this point it may be observed that on

CHART II

will be noted that the severity of symptoms follows pretty closely the changes in pollen density. It will also be noticed that in some places on the graph sudden drops in pollen concentration are followed by more gradual changes in the symptom curve. This is probably due to the tendency for the nature of pathological changes in the nose even after the pollen has ceased to be present in the air. On the other hand, I fail to find any decided

chart 2 it is also apparent that the average maximum intensity of hay fever symptoms in the treated cases, occurring at the height of the pollen season, is Grade 3, or "moderate", and that during most of the season the average intensity was below Grade 2, or "mild" hay fever.

In chart 3 we have a comparison between the symptom curve of the previously described treated series and the curve of a series of thirty patients

who were untreated or only partially treated. It is evident that in the latter curve there is also a correlation between the intensity of symptoms and the pollen concentration. It is also apparent that the suffering of the average patient among these untreated

content to be thus neglected. It is therefore not unreasonable to think that the symptom curve of a series of absolutely untreated patients would be at a greater height than is depicted in chart 3.

Thus far it may be seen that in any

CHART III

cases reaches a greater intensity and is near the maximum for a large part of the season. The "untreated" patients in this series comprise chiefly those who came in at the beginning of the season and had only partial pollen treatment, and those who came in the middle of the season and had only palliative treatment. It is practically impossible to have a series of hay fever patients under observation during an entire season without any treatment whatsoever—the sufferers are not quite

group of hay fever patients the results may be ascertained from a consideration of the average symptom curve or from a consideration of the individual symptom curves. Chart 4 contains five such individual symptom curves, each of which illustrates the usual result under the conditions noted in the chart. It must be emphasized that these individual curves are only examples of their particular series, and that there is considerable variation within the series. However, they serve the

purpose of illustrating the types of curves usually obtained and their interpretation.

The bottom heavy curve shows the typical course of symptoms in a case in which treatment was fairly successful. It will be seen that this patient had many days with no hay fever

The upper three curves represent patients who had considerable hay fever and on whom various methods of treatment were tried during the course of the season. It will be noted in each case that the medication had no effect on the course of the disease. The symptoms continued to be severe

CHART IV

whatsoever, only one day of "severe" symptoms, and the remainder varying from "slight" to "moderate". The curve also shows the variation in the symptoms dependent on the pollen concentration. The curve immediately above it depicts the symptoms of a patient who has had insufficient treatment. The correlation of intensity of symptoms with the pollen curve is quite evident, but the curve is at a higher level.

and varied with the pollen density in about the same way as might have been expected without treatment. In the top curve it may be seen that the use of "salvamin" begun on August 26th apparently resulted in marked improvement in the patient's symptoms for the next two or three days; but when one consults the pollen curve it is obvious that the fall in the latter was responsible for this improvement. The continued use of this drug did

not prevent a recurrence of severe hay fever when the pollen count rose again.

For comparing results, it is seen that not only must the individual twenty-four hour periods be graded, but the results of the entire season must be evaluated also. The problem here is a little more difficult and there probably can be no absolute measure since the usual suffering of all hay fever patients is not the same and what would be a satisfactory result in an extremely severe case might be a decidedly poor result in another. Of course, it is possible to work out a complicated system for measuring degrees of such results, but it probably would add confusion. I have chosen the following designations: failure, poor season, fair season, good, and excellent. An "excellent" season may be defined as one in which the patient has had no hay fever or very slight symptoms. A "good" season is one in which there has been some hay fever but not enough most of the time to be annoying. A "fair" season is one in which there was definite improvement but in which nevertheless hay fever was present during much of the time. A "poor" season is one in which it can be ascertained that there was some improvement, but not enough actually to relieve the patient from his suffering. It is only slightly removed from a "failure", which latter term speaks for itself.

Thus, after evaluating the results in individual patients and then tabulating the results in a series, we can apply the data made available to finally determine the value of a mode of treatment in hay fever. For example, in a series of sixty-two cases of ragweed hay fever during the same season

treated by adequate pollen therapy 40.5 per cent had "excellent" results, 30.5 per cent "good", 13.2 per cent "fair", 8.9 per cent "poor", and 6.9 per cent "failures".

On the other hand, the nitrohydrochloric acid treatment, which has been so enthusiastically advocated by some,⁸ when evaluated by such a procedure as that discussed above, is shown to be unsatisfactory. For example, in a series of thirty cases during 1929 and 1930 only one had excellent results and possibly two more had fair results. Bromides,⁹ also lauded by some in hay fever, gave no results in a small series of cases. For several years "salvamin", which is the lactone of gallic acidethanolaminohydrochlorhydrate, has been enthusiastically advocated in Germany.¹⁰ A series of eight of our local ragweed cases treated with this drug, when tested out for results by the above discussed methods, showed no effects whatever from the use of this remedy.

In the 1931 ragweed season in a small series of nine hay fever patients the effect of intranasal applications of "cold quartz" radiation (ultraviolet) was tried at the request of the Council of Physical Therapy of the American Medical Association. The previously described method of evaluating results was employed in these cases. Except for slight temporary improvement in a few, lasting one or two hours, this therapeutic procedure failed to produce results.

SUMMARY

1. There is need for a method of evaluating the results in hay fever therapy.
2. Any such method must take into

consideration the natural variability in symptoms due to daily, seasonal, and local variation in pollen concentration. Daily pollen counts are absolutely essential.

3. The method of evaluating the results of any hay fever therapy consists of the following steps:

- (a) The grading of the individual patient's daily symptoms,
- (b) The grading of the patient's entire season,
- (c) The tabulation of the results of

the entire group under investigation,

- (d) The comparison of the total results in such a group as compared with groups treated by usually accepted methods and with untreated cases.

4. The above mentioned method was applied to such proposed remedies as nitrohydrochloric acid, bromides, "salvamin", and intranasal quartz light therapy and showed these to be of no practical usefulness.

The Patch Test in the Diagnosis of Contact Dermatitis*

By SAMUEL AYRES, JR., M.D., F.A.C.P., and NELSON PAUL ANDERSON, M.D.,
Los Angeles, California

THE greatest problem in the conquest of eczema is the determination of the etiology in a given case. Attempts have been made to differentiate between those cases of eczema due to internal causes and those due to external irritants, the former being designated as eczema and the latter as dermatitis or dermatitis venenata. Such a distinction is often impossible on clinical grounds and should be made only in the presence of positive substantiating proof. The possible exception is a clean-cut case of dermatitis due to poison oak or poison ivy. Here the presence of the eruption in irregular blotches and streaks where branches and leaves have rubbed against the exposed parts of the body is suggestive. Also the usual violent type of vesiculation and edema, especially if coupled with a history of exposure within twenty-four to forty-eight hours prior to the onset of the eruption, is usually sufficient to establish a diagnosis.

Fundamentally there is no difference either histologically or in most cases clinically between an eczema of inter-

nal or external origin. The essential point is not a matter of labelling a given eruption eczema or dermatitis venenata but of proving the etiology and of incorporating it in the diagnosis. No one could quarrel with a diagnosis of eczema (food allergy) or eczema (primrose), although if one preferred to use the designation dermatitis venenata (primrose) the diagnosis would be equally valid.

Sometimes the location of an eczematous eruption will suggest an external etiology, but too much dependence should not be placed on such evidence as it will often prove misleading. For instance, arsenical dermatitis due to intravenous therapy or to poisoning from contaminated food, may first manifest itself on the exposed parts of the body and may for a long time show a predilection for these areas. In such cases exposure to the sun aggravates the eruption, but it would be telling only half of the truth to say that such a case of eczema was due to idiosyncrasy to the sun's rays, and if the investigation went no further the patient certainly would not be cured.

Such misleading clues are frequently encountered. It becomes all the more important, therefore, to prove the relationship between a given eczematous

*Read before the Eighty-fifth Semi-annual Meeting of the Southern California Medical Association, Hollywood, California, Nov. 14, 1931.

eruption and a suspected irritant. The so-called scratch test, in which a small amount of an antigen, usually food, pollen, or hair protein, is mixed with tenth normal sodium hydroxide and applied to the skin by means of a small scarification on the arm, is useful, especially in cases of food sensitization and in some instances of eczema due to contact with animal hair or pollen. Instances have been encountered, however, in which a scratch test with a pollen was negative while the patch test was strongly positive.

The patch test, therefore, is particularly useful in detecting those substances, protein and non-protein, which by external contact produce an eczematous reaction. The test has been used for some years in Europe, but it is only during the past three or four years that it has been employed to any extent in this country.

The first essential is a detailed history with especial reference to contact with possible irritants in the patient's occupation, hobbies, surroundings, the local use of medication or cosmetics, etc. There are two important points in such a history which may be confusing. The fact that a patient has handled a certain substance for many years without irritation is no proof that this substance may not be the cause of the present eruption. The skin resistance to a given substance may break down or, to put it in another way, the skin may become hypersensitive after prolonged contact, so that an attack of eczema ensues after each subsequent exposure. The second confusing point is the fact that the eruption may be caused by contact with a given irritant at one point, for

example on the arm, and may spread over large areas of the body. It is also important to remember that any substance, no matter how benign it may appear, may be the cause of the eruption in question.

When a careful history has narrowed down the list of probabilities, the test is applied in the following manner. Every effort should be made to simulate the original condition under which the irritation took place. If the substance is a chemical it should be applied in approximately the same dilution to which the patient has been previously exposed. Leaves of plants and shrubs should be as fresh as possible. Dry powders may be moistened slightly with water. The substance to be tested is placed on a small square of cotton about the size of a postage stamp which is then applied to the flexor surface of the forearm, or other suitable area, and covered with a square of some impervious material such as cellophane, which should be about four times as large as the test area. This external covering is then held firmly in place by wide strips of adhesive tape. The space on all sides between the edges of the central cotton square and the edges of the cellophane is sufficient to prevent the adhesive tape from coming too close to the test area. Otherwise the mild temporary irritation which usually results from the adhesive tape might interfere with an accurate interpretation of the reaction. The patch test is allowed to remain undisturbed for twenty-four hours unless discomfort from irritation justifies its removal before this time. A positive reaction is characterized by a sharply defined square of

redness corresponding in size and shape to the central test area. Papules and vesicles are also usually present, corresponding to the appearance of the original eruption. Evidences of the reaction can usually be noted for three or four days or longer after the test is applied. In rare instances the reaction may not develop for forty-eight hours after the test is applied.

The test is simple, inexpensive, and closely simulates the natural conditions under which the dermatitis developed. It is usually very accurate. A few cases have been reported in which only certain areas of the skin were hypersensitive so that in the case of a dermatitis of the face, a patch test on the arm was negative while one performed on the face after the eruption had subsided was strongly positive. Such instances are probably uncommon, but the possibility should be borne in mind.

CLINICAL REVIEW

During the past two years, we have made patch tests on forty-seven private patients; of these twenty-four have been positive, twenty-one negative, and two of doubtful interpretation. The value of the test lies not only in the positive reactions which definitely establish the etiology, but also in the negative results which exclude certain suspected substances. In nine of the twenty-one patients who did not react to the patch test, subsequent investigations along other lines revealed other causative agents such as fungi, yeast, arsenic poisoning, food and pollen allergy, and infection with *demodex folliculorum*.

The following is a list of the substances which have given a strongly

positive reaction in the twenty-four cases in this series.

PLANTS:

Primrose, lantana, geum, wigandia, summer grass, wild mustard.

COSMETICS:

"Dew" (for hyperidrosis), henna, (red and bronze), Inecto (hair dye). These positive tests were all obtained on the same patient.

DRUGS:

Ammoniated mercury ointment (two per cent), butesin picrate ointment (three cases), adhesive tape (B & B), procaine (two cases), oil of eucalyptus, ephedrine sulfate solution, ephedrine butesin (Abbott 1755).

INDUSTRIAL IRRITANTS, ETC.

"Calcium", a liquid containing essentially 40 per cent calcium chloride, used in hardening cement.

Union cleaning solvent.

Gas gauge fluid (a red liquid used in the gasoline gauge on the dashboard of certain automobiles).

Ground rubber and cement.

Many other substances have been reported which have caused eczematous eruptions by local contact, and doubtless many others hitherto unreported will in the future be incriminated by means of patch tests. Cases of poison oak dermatitis are usually so characteristic that we have made no effort to control such a diagnosis by the patch test.

A few of the cases in this series are sufficiently interesting to justify reporting them briefly in order to illustrate certain points. The danger of placing too much reliance on circumstantial evidence and on the clinical appearance is well demonstrated in the cases of two dentists who were seen within a few days of each other, both of whom presented eczematous eruptions on the hands.

CASE I

Dr. D.S.B. had had an eruption of the hands and fingers at intervals for one and a half years. He had used procaine for two and a half years before the onset of the eruption. For a period of eleven months since the onset of the eruption he had remained away from his office and during this time the hands had remained well. The eruption had reappeared four or five days after his resumed use of procaine. A second vacation of six weeks resulted in a disappearance of the eruption which, however, recurred

within a few days after his return to work. A detailed general history did not reveal any abnormalities. The eruption involved the fingers and consisted of a scaling condition which extended beneath several of the nails. (Figure 1) The right index finger presented a few deep-seated vesicles. Microscopic examination of scales and vesicles was negative for fungi. "Mosaic" forms were found on microscopic examination of a few insignificant scales from between the toes. A patch test of procaine solution was still strongly positive four days (figure 2)

FIG. 1. Procaine dermatitis in a dentist. (Case I)

after it was applied and had not entirely disappeared four weeks later. The reaction was slow in developing, not reaching its height for at least forty-eight hours after the test was applied. Eight months later the patient injected two minims of procaine into his arm. An area of redness developed within twenty-four hours; the anesthesia lasted for three and a half days following which the entire area sloughed out. When the same amount was injected into the arm of his

associate, the anesthesia lasted only three and a half hours and there were no evidences of irritation.

CASE II

Three days after Dr. B. had made his last visit, Dr. L.W., also a dentist, consulted us about an eruption of two weeks' duration on the hands. There were areas of redness and scaling with a tendency to fissuring on the fingers and backs of the hands and an especially irritated area on the left

FIG. 2. Positive patch test with procaine. (Case I)

index finger. (Figure 3) There was some scaling between several toes. A patch test with procaine was negative after twenty-four hours and showed no sign of reaction during the next five days. Microscopic examination of scales from the hands, macerated in 40 per cent potassium hydroxide,

butesin picrate have been reported in the dermatological literature and three such cases occurred in this small series of twenty-four patients. One of these cases illustrates not only the type of the eruption but also the spreading of the rash to areas apparently not originally in contact with the irritant.

FIG. 3. Epidermophytosis involving index finger and thumb. Negative patch test with procaine (patient was a dentist). Positive microscopic examination for spores. (Case II)

showed typical chains of spores. "Mosaic" forms were found in scales from the feet. A culture from the toes was positive for monilia. No culture was made from the hand.

These two cases afford an interesting problem in differential diagnosis. The clinical appearance in both cases was similar and the exposure to procaine was suggestive of a contact dermatitis. The positive patch test and the negative microscopic findings in the one case, and the negative patch test and positive microscopic findings in the other established a clean-cut diagnosis in both.

Many instances of hypersensitiveness to

CASE III

J.M., a boy about twelve years old, injured his left elbow which was immobilized with adhesive strapping. A few weeks later a blister developed under the adhesive. The adhesive was removed and butesin picrate ointment applied. Considerable irritation resulted and several other remedies were tried, but were not successful in controlling the eruption. When he reported for observation the eruption had been present for about one month and had involved extensive areas of the body. The left arm was red, edematous, oozing, and crusted. The face, neck, chest,

FIG. 4. Dermatitis venenata due to butesin picrate. Note marked inflammatory reaction at site of application (left arm) and also involvement of face, neck, and anterior chest, e.g., areas not having had contact with the original irritant. A positive patch test was obtained. (Case III)

and other arm presented a more diffuse erythematous, blotchy appearance. (Figure 4) This diffuse eruption had been present only a week. Under the use of mildly astringent and antiseptic wet dressings the eruption gradually subsided. Patch tests were made with butesin picrate ointment and with adhesive tape. The adhesive tape did not irritate but the test with butesin picrate was strongly positive.

CASE IV

Mr. H.C. represents another instance of irritation from butesin picrate ointment, showing also a delayed reaction from the test. Two weeks before coming in, he was badly sunburned while driving in an open car with the top down. Two days later he applied butesin picrate ointment which seemed to irritate. The "sunburn" seemed to last an unusually long time but was gradual-

FIG. 5. Dermatitis venenata due to butesin picrate ointment. (Case IV)

ly subsiding, when the night before coming in he again applied butesin picrate ointment. This resulted in a severe flaring-up of the eruption. Examination revealed an eruption limited to the face and neck, and especially pronounced on the front of the cheeks and nose, which were diffusely red, covered with vesicles, yellow crusts, and serous exudation. (Figure 5) A patch test with butesin picrate ointment was negative on removal twenty-four hours later but began to develop redness and vesiculation within a few more hours. Two days after it had been removed the test area was still violently inflamed.

Butesin picrate contains two substances, both of which have been known to cause irritation. Picric acid is a tri-nitro-phenol and butesin is butyl-para-amino-benzoate.

Henna, a vegetable dye, is usually regarded as an innocuous coloring preparation for the hair. In fact some textbooks state definitely that it is non-irritating. Inecto, a proprietary dye, also claims to be free from irritating properties. That such dogmatic statements are unjustifiable is shown by the following case.

CASE V

Mrs. J.M., a beauty shop operator, had been having an eruption of the hands and arms at intervals for two months. The present eruption had been in evidence two days. The eruption was limited to the hands and arms, extending for a short distance above the cubital spaces. The entire involved areas were red, edematous, covered with exudate and crusts and fissured in places. The greatest involvement was on the flexor surfaces. (Figure 6) There was a mild erythematous-vesicular eruption on the face and chin. Patch tests were made with eleven preparations used in hair-dressing. Inecto, red henna, and bronze henna gave strongly positive reactions after twenty-four hours, the greatest reaction being caused by red henna. Five days after the eruption had subsided, a new outbreak began on the fingers, spreading to the hands, forearms and several days later to the anterior aspects of the thighs just above the knees where she had rested her arms. This recurrence followed shampooing a woman's hair which had previously been dyed with Inecto.

Each case history is a veritable detective story, at times taxing the powers of observation of both physician and patient. It is obviously impractica-

FIG. 6. Marked dermatitis venenata in a beauty shop operator who was shown to be sensitive to Inecto, red henna, and bronze henna by means of patch tests.

ble to test all of the substances with which a patient may come in contact. It is a serious error, however, to disregard any substance simply because it has not been reported previously as a cause of dermatitis. Assisted by a careful history and an intelligent clinical examination, the patch test is invaluable in determining the etiology of many eczematoid eruptions. It is just as much the duty of the physician to prevent recurrences of a disease as it is to treat the present attack. In the case of the eczematoid

eruptions as with most other diseases, an understanding of the etiology is the indispensable factor in preventing such recurrences.

SUMMARY

1. The advantages of the patch test in determining the etiology of certain cases of dermatitis are mentioned, together with a description of the method of applying the test.

2. Twenty-four cases of eczematoid dermatitis are reported, some of them in detail, in which the etiology was established by means of the patch test.

Some Observations Concerning a Possible Insulin-Inhibiting Substance in Urine*†

By E. M. WATSON, M.D., F.R.C.P. (Edin.), and W. S. DICK, M.D., M.Sc.,
London, Canada

RECENT investigations have pointed to the existence in the blood of a substance which is capable of inhibiting the activity of insulin. Karelitz, Cohen, and Leader,¹ as the outcome of an attempt to discover the cause of insulin resistance in a patient with diabetes mellitus, observed that the blood of diabetics, and to a lesser extent that of normal persons, apparently possessed something which was antagonistic in its action to insulin. While this inhibiting property was demonstrated by blood plasma, it was exhibited to a more marked degree by laked red blood cells. Their data were elicited by studying the blood sugar of rabbits before and after the subcutaneous injection into these animals of mixtures of blood and insulin.

The practical significance of these observations is as yet undetermined. While they may not warrant the elucidation of any new theory regarding the pathogenesis of diabetes, they at least provide grounds for speculation. The cause or causes underlying the principal manifestation of diabetes, namely hyperglycemia, is by no means thoroughly understood. While it is generally agreed that this disease is the result of a deficiency of active insulin in the organism, the known facts do not conform with the view that in every case there must be a deficiency in the production or output of this hormone by the islet tissue of the pancreas. In fact, Warren² refers to an "intriguing group of cases without definite anatomical change in the pancreas or other organs". In his series of 300 diabetic autopsies "the pancreas was available for detailed histological study in 259. Of these, 69 were normal so far as could be determined". Cases of clinical diabetes without a pathological background have baffled the pathologist and mystified the clinician. Surely such cases invite an explanation and anything which might throw light upon this dark corner of medicine should be welcome. Unfortunately, short of a postmortem examination, there is no means of distinguishing those cases which possess anatomical changes from those which do not. According to existing knowledge, there is as much, if not more, justification for explaining the latter type of case on the grounds of insulin inhibition as in any other way.

*Received for publication June 29, 1932.

†From the Division of Pathological Chemistry, University of Western Ontario Medical School.

Accepting the feasibility of neutralization of insulin within the blood stream, the exact nature of the substance or substances responsible for the phenomenon is unknown. Karelitz et al,¹ as a result of their experiments, concluded that the inhibiting agent was probably enzyme-like in character and suggested that it might be trypsin. Their assumption was based partly upon the fact that trypsin is known to inactivate insulin and partly upon their own observations that the insulin-inhibiting property of blood could be diminished or destroyed by heating the blood preliminary to the addition of the insulin. If their conjecture be true, it must be assumed that trypsin is present in the blood of normal persons and that its concentration is increased in diabetes thus accounting for the greater inhibitory effect of diabetic blood. Mauriac and Aubertin³ had reported previously the antagonistic action of diabetic and normal blood plasma and cells upon insulin action. They believed that a so-called anti-insulin substance resided within the red blood cells and that it diffused from there to the plasma. They also advanced the idea that possibly in some cases of diabetes the permeability of the cells was increased thus allowing more anti-insulin to enter the plasma. Epstein and Rosenthal,⁴ as an outcome of some experimental observations on animals, proposed the "trypsin theory" as a possible explanation of certain clinical cases of hyperglycemia and glycosuria. The gist of their contention is that under certain conditions changes in the permeability of the endothelium of the blood capillaries of the pancreas occur,

as a result of which the secretory products of the acini, particularly trypsin, gain access to the blood stream. Since the islets and acini of the pancreas possess a common blood supply, opportunity is provided for immediate contact of internal and external pancreatic secretions, hence neutralization of insulin by trypsin. The same investigators demonstrated also that when trypsin entered the portal blood stream glycogenolysis in the liver resulted.

PRESENT INVESTIGATION

Realization of the fact that further work along these lines is necessary before any practical application can be made of the above-mentioned contributions led to the idea that some information might be gained from investigating the urine in a manner similar to that which has been used by others in studying the blood, to decide whether or not the insulin-inhibiting factor passes from the blood stream into the urine. If such excretion does occur, provision thus might be afforded for learning something of its nature and properties when separated in a natural way from the proteins of the plasma.

If the blood does contain some soluble substance, enzymic or otherwise, capable of influencing insulin in the manner indicated, it is reasonable to surmise that its presence should be manifest in the urine. Therefore, the first requisite in pursuit of the problem would be to ascertain whether or not urine does show any evidence of insulin-inhibiting effect; if so, whether this is more pronounced with the urine of diabetics than with that of non-diabetics, and finally to attempt to gain

some information regarding the nature of this phenomenon.

At the outset, the undertaking is beset with difficulties and the opportunities for fallacious results and conclusions are numerous. However, the findings thus far have proved sufficiently enlightening to warrant the presentation of this preliminary report, the details of which follow.

METHODS OF INVESTIGATION

One c.c. of a solution containing one unit of insulin per c.c. was added to 5 c.c. of urine. After incubating at 37°C. for thirty minutes the mixture was injected subcutaneously into the flank of a rabbit which had received no food during the preceding twelve hours. As control tests, 5 c.c. of normal saline solution were used in place of the urine. Samples of blood for estimations of the blood sugar were obtained from the marginal vein of the rabbit's ear immediately before and at intervals of one, two, and three hours after the injection. The method used for estimating the blood sugar was that described by Pickard and Pierce⁵ employing 0.1 c.c. of blood.

One complete experiment consisted of one or more tests with saline and insulin to ascertain the normal response of the rabbit to one unit of insulin followed by a test using one unit of insulin with unheated urine from a patient with diabetes; another, using one unit of insulin with a sample of the same urine after it had been heated; and still another test, using one unit of insulin with urine from a non-diabetic hospital patient who was not acutely ill, or from a normal person. During the conduct of an experi-

ment as outlined above the same animal was used throughout. A different rabbit was used for each similar set of tests.

In the majority of cases, the urine employed was that excreted during the early part of the day before breakfast and in the case of diabetics before the morning dose of insulin had been administered. Instructions were given for the individual to empty the bladder immediately upon awakening in the morning. This urine was discarded so far as the purpose of the present investigation was concerned. About one and one-half hours later, the specimen for the test was obtained by voiding or, as in the case of adult female patients, by catheterization. By using the morning urine after a preliminary emptying of the bladder it was hoped to avoid the effect of any excreted insulin which might have escaped from the circulating blood during the night in insulin-treated diabetics. Also, by having the specimens secured at that time it was thought that a more constant and comparable concentration of the urine might be obtained. The series of cases under consideration does not include any patients with infections since it is known that infection in some way depresses the effectiveness of insulin. Routine examinations were carried out on all specimens of urine before use and any that were found to contain protein, pus, or blood cells were discarded. The presence of sugar or acetone in the specimens appeared not to influence the results as evidenced by control tests with solutions containing amounts of these substances comparable with those in the urine samples. For the purpose of non-dia-

betic controls, specimens from persons of similar sex and age as the individual diabetics were employed.

In order to test the effect of temperature upon the urine with regard to its insulin-inhibiting property, a portion of each sample of diabetic urine was heated in a water-bath. In some instances, it was subjected to a temperature of from 55° to 60°C. for from three to eight hours. In others, it was placed in boiling water for from five to twenty minutes. After the heating and subsequent cooling, any depletion in volume was made up by the addition of distilled water. The specimen was then kept at ice-box temperature until the next morning when the test with insulin was carried out in exactly the same manner as with the unheated urine.

In consideration of the importance of reaction conditions on the activity of insulin, the reaction of each sample of urine was adjusted to pH 6.4 before the addition of the insulin. This figure happened to be the reaction of the saline solution used throughout these experiments and for that reason was adopted as the standard.

In view of the relative inconstancy of the blood sugar concentrations of fasting rabbits and of their response to one unit of insulin, the method of expressing the results for purposes of comparison was that employed by Culhane¹ in the assay of insulin. According to this method, the blood sugar concentrations at one, two, and three hours were added together and the sum of these divided by three to obtain the average level of the blood sugar following the injection. The resulting figure was then subtracted from that

representing the blood sugar immediately preceding the injection. The difference was finally expressed in percentage of the original blood sugar finding. This gives what is referred to as the percentage fall of the blood sugar.

RESULTS

The basis of this report consists of the results obtained in twenty-five complete experiments as referred to above; each consisted of four parts, making in all 100 individual observa-

FIG. 1. Comparison of the average percentage fall in the blood sugar of rabbits following the injection of one unit of insulin and 5 c.c. of (1) unheated diabetic urine, (2) non-diabetic urine, (3) heated diabetic urine and (4) normal saline solution.

tions. Whereas no indisputable conclusions can be drawn from such a relatively small number of tests, some points of interest evolve from an analysis of the findings. As might be expected in an investigation of this kind, some discrepancies were encountered but comparison of the various parts of the experiments considered as groups yields some rather definite results.

By assembling all the data into four groups and comparing the average percentage fall of blood sugar thus obtained with unheated diabetic urine, heated diabetic urine, non-diabetic urine and saline as depicted in figure 1, it is seen that diabetic urine causes the greatest amount of insulin inhibition, non-diabetic rather less, and heated diabetic urine none at all as compared with the saline controls. Consideration of the series as a whole suggests at least some differences in the effects of the various test substances upon insulin

action. Further comparisons reveal the nature of the tendencies. Reference to table 1 shows that the fall in blood sugar following the injection of unheated diabetic urine and insulin was less than that obtained with similar amounts of normal saline and insulin in twenty out of the twenty-five experiments (80 per cent). The fall was greater in four cases (16 per cent) and showed no difference in one case (4 per cent). In every experiment the decline in the blood sugar was greater with the diabetic urines which had been heated than with the unheated portions of the same samples, indicating more marked insulin effect in the former or, in other words, destruction of the insulin-inhibiting factor by heat. The urine of non-diabetic hospital patients and of normal persons was capable apparently of causing at least slight inactivation of insulin. In eighteen cases (72 per cent) the fall in blood sugar was less with non-diabetic

TABLE I

Observation	Number of cases	Per cent
Fall in blood sugar with unheated diabetic urine and insulin <i>less</i> than with normal saline and insulin	20	80
Fall in blood sugar with unheated diabetic urine and insulin <i>greater</i> than with normal saline and insulin	4	16
Fall in blood sugar with unheated diabetic urine and insulin the <i>same</i> as with normal saline and insulin	1	4
Fall in blood sugar with unheated diabetic urine and insulin <i>less</i> than with heated diabetic urine and insulin	25	100
Fall in blood sugar with non-diabetic urine and insulin <i>less</i> than with normal saline and insulin	18	72
Fall in blood sugar with non-diabetic urine and insulin <i>greater</i> than with normal saline and insulin	6	24
Fall in blood sugar with non-diabetic urine and insulin the <i>same</i> as with normal saline and insulin	1	4
Fall in blood sugar with unheated diabetic urine and insulin <i>less</i> than with non-diabetic urine and insulin	15	60
Fall in blood sugar with unheated diabetic urine and insulin <i>greater</i> than with non-diabetic urine and insulin	9	36
Fall in blood sugar with unheated diabetic urine and insulin the <i>same</i> as with non-diabetic urine and insulin	1	4

urine than with saline. It was greater in six cases (24 per cent) and showed no change in one (4 per cent). The fall was less with diabetic urine than with non-diabetic urine in only fifteen instances (60 per cent). It was greater in nine cases (36 per cent) and the same in one (4 per cent).

With regard to the degree of severity of the diabetes in relation to inhibition of insulin by urine, there appeared to be some difference, although not pronounced, between the effect of urine from cases labelled severe and those classified as mild. Urine from the severe cases did tend to exhibit more marked inhibitory effect upon insulin than did that from the so-called mild cases.

It would appear from the data presented above that urine probably does contain a thermolabile substance which has an antagonistic influence upon insulin activity although its existence is not proved. While this substance appears to exist in the urine of non-diabetics it seems to be present in slightly greater concentration in the urine of diabetics. Since it has been shown by others that a thermolabile insulin-inhibiting agent is present apparently in blood plasma^{1,3} it would seem reasonable to assume that the substance in urine which is responsible for somewhat similar effects is the same as that which is present in the blood.

DISCUSSION

The only evidence in favor of an enzyme-like character of this special urinary constituent is its behavior toward heat. A more detailed study of its properties is in progress. While

it may be trypsin or trypsinogen no unmodified claim is made to that effect. As a matter of fact, the balance of evidence is rather opposed to such a view. Trypsin is a powerful proteolytic enzyme and normal blood contains probably only a very small amount of it in the active state owing to the presence of anti-trypsin. Of the pancreatic enzymes, diastase is found in urine normally but trypsin and lipase are believed to appear there only under special conditions. Trypsin is present chiefly as trypsinogen, especially abundant after a meat diet.⁷ Wago⁸ found that following the intravenous injection of pancreatin into rabbits the proteolytic pancreatic ferment was excreted rapidly and abundantly into the urine. Thus it is seen that it is possible for trypsin or trypsinogen to gain access to the urine under certain conditions. Its concentration there, apart from the factors which influence the concentration of the urinary constituents in general, might depend upon an increased trypsin content of the blood or diminished production of anti-trypsin. In this regard it should be mentioned that Iacono,⁹ in investigating the external secretions of the pancreas in the blood of diabetics, found that the trypsin content did not show any appreciable change over that of non-diabetics.

There are still other avenues of speculation. For example, Loewi¹⁰ has described a hormone-like substance called glycemin believed to be formed in the liver which interferes with the utilization of glucose by the tissue cells. The existence of this substance is, however, problematical.¹¹ Then there is the possibility of the absence or

deficiency of some complement or coferment which may be necessary for insulin to exert its full effect. But as pointed out by Karelitz and his co-workers,¹ acceptance of this conception implies inadequacy of these factors in normal blood *in vitro* and still more marked inefficiency in diabetics.

It has been suggested that normal urine contains insulin^{12,13} but the contention has been refuted by Lawrence.¹⁴ Lessened insulin content of diabetic urine could hardly explain the limited drop in blood sugar when standard amounts of the urine and insulin are injected into rabbits. If such be the case, however, heating the urine should not cause a more marked fall in blood sugar as compared with the effect of unheated urine. Also, if normal urine contains active insulin, the effect of this plus that which is added should result in a more marked fall in blood sugar than in the case of the saline controls. Actual observations prove these suppositions to be untenable.

There is still to be considered the possible influence of some chemical or bacterial constituent of urine upon the activity of insulin. It has been shown that insulin can be inactivated by ammonium hydroxide and other alkalies¹⁵ but estimations of ammonia in the various specimens both before and after heating indicate that variations in this constituent were not the cause of the differences observed in the specimens with regard to insulin effect. Certain bacterial and chemical toxins, e.g., diphtheria toxin and histamine, are reputed to have a deleterious influence upon the activity of insulin.^{16,17,18} It is a matter of practical experience that diabetics do badly in the presence

of infection. It is uncertain as yet exactly how infection exerts its influence in these cases, whether it is a matter of direct neutralization of insulin by the toxins produced by the bacteria, the elaboration of some chemical substance possessing anti-insulin properties, for example, some protein-split product, the passage into the blood stream of trypsin as the result of altered permeability of the endothelium of the blood vessels of the pancreas as suggested by Epstein and Rosenthal,⁴ or whether it is due to stimulation of certain glands of internal secretion, whose products are antagonistic to insulin such as the thyroid and the adrenals as favored by Lawrence and Buckley.¹⁷ The possible influence of some of these factors has been discussed already but with regard to the effect of any bacteria in the samples of urine employed in these tests, gross contamination was not permitted. On several occasions, cultures were made from the sediment of the centrifuged samples and suspensions of the organisms obtained by washing the surface of the media with normal saline. To these concentrated suspensions, insulin was added and injections made into rabbits in the same manner as in the tests described above. While there was evidence of slight insulin inhibition it was obvious that the presence of any bacteria or bacterial toxins ordinarily present in the urine could not account for the whole of the inhibitory effect exhibited by urine. This is rather in agreement with the findings of Sweeney¹⁹ who concluded that toxemia produced by diphtheria toxin in animals had little, if any, effect upon the action of injected insulin. His deduction was

that toxemia influenced carbohydrate metabolism by impairment of the animal's ability to store carbohydrate due to a suppression of the production of endogenous insulin.

The observation that insulin inhibition was more evident with diabetic urine than with non-diabetic urine in certain cases, but not in all, calls for some comment. Undoubtedly this substance, whatever it is, which is responsible for the inhibitory effect is an elusive body. If it is representative of something in the blood which has a pathogenic influence in certain diabetics, as pointed out above, there is reason for believing that it would operate to a greater degree in some cases than in others, and there is as yet no sure way of identifying the cases in which it would be most likely to be encountered in blood or urine.

SUMMARY AND CONCLUSIONS

1. A relatively small series of observations points to the presence of a substance in urine which causes partial inactivation of insulin when the latter is added to the urine, incubated and the effect of the insulin upon the blood sugar of the rabbit noted following subcutaneous injection of the mixture.

2. The urine of diabetic patients appears to possess the insulin-inhibiting property to a slightly greater degree than does the urine of non-diabetic hospital patients and normal persons. The difference is most marked in patients with severe diabetes.

3. This insulin-inhibiting factor is destroyed by heating the urine at 60°C. for several hours or by boiling the urine for a few minutes previous to the addition of the insulin.

4. It is assumed that this substance enters the urine from the blood stream by elimination through the kidneys. Whether or not it is identical with the insulin-inhibiting substance which is believed to exist in the blood of diabetics and of non-diabetics is undetermined.

5. The possible significance of the phenomenon relative to the pathogenesis of diabetes mellitus is discussed.

6. While no definite statement can be made concerning the nature of the insulin-inactivating principle in urine, its behavior with regard to heat suggests an enzyme-like character.

The authors wish to express their appreciation to Mr. A. S. Barber and to Mr. E. D. Carpenter for valuable technical assistance during the conduct of this investigation.

Observations on Human Adrenals with Especial Reference to the Relative Weight of the Normal Medulla*

By CLARENCE QUINAN, M.D., and ADOLPHUS A. BERGER, M.D.,
San Francisco, California

DESPITE the immense amount of work that has been done on various problems that have to do with the suprarenals, the question as to the weight of an average, fresh, normal gland still remains in doubt and no figures whatever are as yet available as to the weight of its medulla. Now to be sure, insofar as the first question is concerned, it is possible to set up a tentative average value by means of data to be found in the literature of the subject. For example, this can be done simply by combining the figures contained in the papers of Dietrich and Siegmund¹ and Materna.² This procedure, which brings together the experimental results of fourteen workers, yields a mean value of 12.3 grams for both adrenals or a value of slightly more than 6 grams for a single gland. However, it would appear that this figure is much too high. For Materna,³ on weighing presumably normal suprarenals secured from the bodies of twenty-five persons who had suffered violent deaths—eleven were those of suicides—found that the average weight of a single gland was approximately 4.5 grams; whereas with

glands removed from forty pathological subjects, he⁴ obtained the following average values for the left adrenal: in twelve cases in which death had been caused by various circulatory conditions, 5.8 grams; in twenty average hospital autopsy subjects, 6.2 grams; and in eight subjects with various septic diseases, 8.4 grams. Having found experimentally that more or less profound changes in the normal relation of the watery and lipoid elements of the suprarenal gland are characteristic of certain disease processes, Materna believes that this variable factor is chiefly responsible for the seemingly discrepant weight findings just described.

In regard to the second question—that as to the weight of the normal medulla—it should perhaps be stated in passing that Elliot and Tuckett,⁵ by means of planimeter measurements made with serial sections, determined the amount of medullary tissue in the left suprarenal glands of two rats and found that the medulla formed 9 per cent of the gland in a male rat of 120 grams, and 6 per cent in one of 190 grams; and that Donaldson,⁶ who examined by a similar method the supra-

*Received for publication March 30, 1932.

renal glands of seventeen albino rats, got a mean value of 8.4 per cent for the ratio of the volume of the medulla to that of the whole gland.

Such, it would seem, are some of the principal facts now available as to the two points under consideration.

In this paper a brief account is given of various data obtained during an experimental study of human adrenal glands. However, the main object in view was to determine if possible the relative mass of the normal medulla by dissecting it out and weighing it as a separate structure.

MATERIAL

All of the data used in the preparation of this paper were obtained in the autopsy department of a coroner's office, by means of postmortem examinations carried out among the unknown dead of a large city. These examinations were made from three to five times weekly during a period of nearly five months.

In the great majority of cases the subjects utilized were those of persons who had met death suddenly through violence of some sort—for example, in automobile accidents or through falls, blows, crushing injuries, or gunshot wounds. However, in five instances accidental drowning was the cause of death and there were a few cases of suicide. In all nearly 100 pairs of glands were examined. Since, for reasons that will appear later, occasionally it seemed advisable to reject suprarenals obtained from subjects that appeared to be normal and since, for comparative purposes, many of the glands examined were those found in the presence of various pathological

states such as occur, for example, in cardio-renal disease, in pneumonia or in septic infections only fifty pairs of glands are included in our series.

In regard to the question as to the sex factor, it may be stated that of the fifty normal subjects, forty-one were males and nine were females. The question as to the age factor cannot be answered definitely. However, the estimated age values of the fifty normal subjects ranged from seventeen to sixty-two years and gave an average of 39.7 years.

The general findings made in the course of this study have now to be considered. As several kinds of data must be dealt with, it will be convenient to describe in the following pages (1) certain factors that appear to modify the shape of an adrenal gland, (2) some data obtained by micrometer measurements, (3) the isolation of the medulla, and (4) the experimental results.

FACTORS THAT MODIFY THE FORM OF THE SUPRARENAL GLAND

Subcapsular Location of the Gland. Bartlett⁷ described this as "a rare condition in which the adrenals lie in part or entirely in direct apposition with the kidney parenchyma with no intervening capsule". In his case both of the adrenals were firmly adherent to the kidneys though this condition was more marked on the right than on the left side. He found that the right suprarenal measured 45 mm. vertically by 50 mm. in width at its widest part. As both glands were to be examined histologically, they were not weighed.

Other cases of subcapsular location of the suprarenals have been reported

by Apert and Vallery-Radot⁸ and by Omelskyj.⁹ Having observed heterotopia of the suprarenal in the kidney no less than four times, Omelskyj remarks "that in comparison with the frequency of this phenomenon it is astounding how rarely it is mentioned in the literature". Regarding the question as to what portion of the adrenal surface is prone to unite with the kidney substance, he noted that in each instance the adrenal was attached only at its under extremity. Many of these glands, he states, appeared to be very much enlarged.

Two cases of unilateral, right adrenal-renal heterotopia were examined in the course of this study. The bodies of the subjects concerned were those of powerfully built men who had suffered violent deaths apparently while in a state of perfect health—in one case from a fracture of the skull, in the other from a penetrating wound of the throat. In each instance the lower extremity of the right suprarenal was embedded to the depth of several millimeters in the substance of the kidney; so firm indeed was the union between the two tissues at this point that the gland could be separated from the kidney only by cutting deeply into the parenchyma of the latter organ. These glands were unusually large and in each one the tissue seemed to be thinned out in places. They were extremely bizarre in shape. Neither one is included in the normal series listed in table 1. Expressed in millimeters, the length and width measurements of the two glands were, respectively, 69 by 46, and 45 by 55. In grams, the weights of each whole gland and its

medulla were, respectively, 7.029–.765 and 6.475–.740.

On the whole, such as it is, the foregoing evidence seems to indicate that, when it is adherent to the kidney, the suprarenal gland gradually becomes pulled out of shape and enlarged—particularly in its transverse measurement. It may be added, as of some interest in this connection, that no distortion of the suprarenal was noted in those cases—and this condition was encountered a number of times—in which the gland was firmly united with the under surface of the liver.

Absence of One Kidney. This appears to be a rare condition. Guizzetti and Pariset¹⁰ found that one kidney was absent in 39 out of 20,000 autopsies. However, the statistics as to the incidence of this condition vary widely. Other authorities assign values that run as high as 1 in 4,000. Usually it is the left kidney that is missing.

What effect does the absence of one kidney have upon the shape of the corresponding suprarenal gland?

Miloslavich¹¹ answers this question by stating that, in such a case, the suprarenal is rounded in form and that neither of its surfaces exhibits the indentations and longitudinal ridges that usually characterize this gland. It is not to be denied, he affirms, that under normal circumstances the kidney and the liver offer a resistance to the suprarenal that probably exerts some influence upon its configuration. However, his paper contains no autopsy data obtained from cases of renal aplasia.

In a case of absent left kidney de-

FIG. 1. Normal adult adrenals photographed in the fresh state. Note pressure-ridge on each one.

scribed by Lucksch¹² the left adrenal was rounded in form and exhibited none of the usual surface markings. It measured 38 by 35 millimeters. The two glands weighed in the fresh state 10.5 grams. Curiously enough they were joined together by a narrow isthmus.

Congenital absence of the left kidney was noted in one of the normal

cases reported in this paper. The cadaver in question was that of a bandit, a man in the early fifties, symmetrically developed and athletic in type. The cause of death was a gunshot wound of the heart. In the course of the postmortem examination it was discovered that the left kidney was missing. Otherwise, however, nothing of importance was noted. The right

FIG. 2. Adrenals of normal infant four months old compared with adrenals of adult. Measurements of infant's adrenals: left 33 mm. by 9 mm.; right 28 mm. by 22 mm. Weights: left 0.939; right 0.963 gram.

kidney appeared to be perfectly normal. Unfortunately it was neither measured nor weighed. The left suprarenal was in the normal location, concealed—as it usually is—amid layers of fat. When dissected free, it was found to have a rounded, almost disc-like, form and to be almost entirely devoid of surface markings. However, both its color and its consistency were normal. Figure 3 (A-2) shows the medulla of this gland as it appeared after it had been hardened in formaldehyde solution. The other medulla (A-1) is that of an average normal left suprarenal gland. Further details concerning the adrenals of this subject are given elsewhere. (Table 1, No. 6.)

It will be noted that the findings made, both in Lucksch's case and in the one here reported, substantiate Miloslavich's opinion: namely, that when one kidney is congenitally absent the corresponding suprarenal gland is nearly round in shape and almost smooth on both of its surfaces. However, topographically speaking, it may be pointed out that such an unmodeled gland appears to be chiefly remarkable because of the absence of the prominent flange-like ridge that invariably marks the posterior surface of an adrenal when its kidney is in situ. The five pairs of glands shown in figures 1 and 2 give a fair idea as to the form of this ridge and as to its orientation. Incidentally, it should be remarked that these glands were photographed in the fresh state immediately after they had been weighed. It will be observed that the concavity of the ridge faces the inferior border of the gland and that, instead of lying in the prin-

cipal axis of the gland, the ridge crosses the adrenal obliquely.

The question as to when this peculiar elevation first makes its appearance seems to be unanswerable. But the fact that the ridge is present in typical form in the fourth month of infancy (figure 2), seems to indicate that it must be thrown up at a very early period, perhaps even before the onset of the cortical involution process. Almost equally unanswerable, it would seem, is the query as to how the ridge is formed. In this connection, however, it may be stated that there is some objective basis for the supposition that it is formed by pressure, since fairly numerous measurements made in the course of this study show that the inferior border of an adrenal gland is usually, if not invariably, much thinner than its superior border. This subject is treated more fully in the next section.

DATA OBTAINED BY MICROMETER MEASUREMENTS

Before proceeding to describe the measurement data, attention may be called to certain physical peculiarities that appear to be characteristic of normal and of pathological adrenals.

Physical Characteristics of Normal Adrenals. As a prefatory note, it should perhaps be remarked that unless great care is exercised during the autopsy the suprarenals are apt to be cut or torn. So greatly does the normal suprarenal resemble, both in color and consistency, the tissue in which it lies embedded that, even in a laboratory dissection, it was often no easy matter to find the gland in the collop of kid-

ney substance and fat obtained at the postmortem examination.

Careful notes on the subject kept throughout this study seem to show that in any given case there is no correlation between the size of the adrenals and the grade of physical devel-

opment. Thus, while it is true that men of outstanding vigor commonly have adrenals that weigh together around 8 grams, it is also true that many strongly built subjects had adrenals that weighed 7 grams or less.

In regard to the question as to the

FIG. 3. Normal and morbid adrenals compared. "S"—Superior border. "P"—Pressure ridge. "I"—Inferior border. Pneumonia adrenals weigh 16.0 grams. Normals weigh 6.79 grams. "A"—(1) normal left medulla. "A"—(2) left adrenal medulla in congenital absence of the left kidney.

consistency of a fresh, normal adrenal, it may be stated that such a gland is always limp so that it bends readily over the finger; that it is everywhere soft to the touch; and that its borders as well as its pressure-ridge seem rather delicate and thin. A normal gland is usually brownish-yellow in color. But in two subjects it was noted that the cortical lipoids as well as the abdominal fat were distinctly orange-colored, presumably because of the presence of an excess of carotinoid pigment.

Physical Characteristics of Morbid Adrenals. It seems to be characteristic of the adrenal capsule that it is rather tough to cut, though it tears easily. Hence it may be said somewhat to resemble so-called "dead-rubber". This peculiarity perhaps explains why it is that a suprarenal gland, without exhibiting any very striking changes either in its length or its width, may nearly double in weight. The whole gland appears to swell, as though it had been injected with a fluid of some sort. If this hydration process happens to be minor in degree, there may be nothing remarkable in the appearance of the gland, except that it may seem to have rather thick borders. Extreme grades of hydration, however, produce characteristic changes. The whole gland then has a sodden appearance and its substance feels unusually firm and resistant to the touch. It is often possible to palpate such a gland through the surrounding tissues even though the gland itself cannot be seen. On stripping away the adherent fat from such an adrenal, it will be seen that its surface shows but few of the natural indentations; that its borders, like

those of a mattress, are cushioned or "rolled" and that its pressure-ridge is very broad, especially at the base. These changes in the appearance of the suprarenals were noted most commonly in the presence of pneumonia. For example, in five cases of that disease the average length and width measurements of the adrenals were, respectively, 58 mm. and 28 mm.; whereas the average weight value was 16.2 grams.

Measurement Data. Numerous observations having shown that the superior and inferior borders of the suprarenal gland seemed to differ considerably in point of size, in order to find out how great this apparent difference was, some exact measurements were made. The instrument used was a Starrett micrometer. This instrument reads to hundredths of a millimeter. As this work was undertaken at a rather late stage of the investigation, relatively few glands were measured. Twenty were normal glands and four were obtained from pneumonia subjects. Stated in millimeters, the following average values were obtained for the inferior border, the pressure-ridge, and the superior border, respectively: normal adrenals, 1.8, 2.4 and 2.6; pneumonia adrenals, 4.0, 5.0 and 5.6. However, since these measurements show that the difference was a constant one and that it amounted to approximately one millimeter, they appear to establish the fact that the superior border of the adrenal gland is larger than the inferior border. Typical sets of measurements are shown in figure 3. This figure also illustrates very well, as regards their external appearance, the main points of difference between normal adrenals

and those sometimes found in the presence of pneumonia.

ISOLATION OF THE MEDULLA

Preliminary Note. Here the question as to the practicability of such an undertaking will be touched upon and the surface form of the adrenal medulla will be roughly described.

In regard to the first point, the experimental evidence obtained in the present inquiry seems to show that it is possible to isolate the medulla of an adrenal gland by dissection, provided that the two principal tissues of the gland can be separated from one another along a definite line of cleavage. Experience shows that this sep-

FIG. 4. Normal adrenals laid open to expose the medulla. In left-hand gland note fibrous attachments radiating from tip of medulla to gland border. In right-hand gland the cortex has been partly cut away in order to show arrangement of the medulla. Center figure shows body and membranous portions of medulla. In the two lower figures the membranous portion is curled up from the action of formaldehyde.

aration can be accomplished in about three out of four normal specimens. Naturally, the partition effected is never a quantitative one because of irregularities in the configuration of the medulla. However, with suitable material, it seems probable that the average error is considerably less than 5 per cent.

How is the adrenal medulla arranged within the gland? and what is its general appearance when isolated?

Often simply by inspecting an intact adrenal some idea can be obtained as to the disposition of its medulla. For the surface of a normal adrenal is always marked by irregular elevations (figure 1) and as a rule it is under the most prominent one of these that the main mass of the medulla will be found when the gland is opened. The arrangement of the medulla can also be made out dimly if an adrenal is studied by means of transmitted light. A convenient way to do this is to hold the specimen to be examined up against a 60-watt Mazda light and to observe it through an opening cut in a piece of pasteboard. Under such circumstances, the medullary masses appear as relatively darker areas against a diffuse rosy background.

When it is dissected out and viewed in its entirety, the medulla is seen to consist of two parts—a body and a membranous portion.

Usually the main mass of the body is aggregated about the emergent vein. Its form varies greatly. Sometimes its general shape is that of an Indian arrow-head, but more commonly the body of the medulla is elongated, its length corresponding to that of the pressure-ridge under which it lies.

Commonly, too, one of its extremities tapers to a point (figure 4). The posterior surface of the body of the medulla is always convex and as a rule it is marked by a fine, median longitudinal groove. The medulla is soft and delicate in texture. Its color usually is grayish-white.

The membranous portion of the medulla (figure 4) extends outward from the body of the medulla to the borders of the gland. It is found chiefly in those flat, thin areas of the adrenal where the two opposite cortical surfaces are virtually in direct contact with one another. Very thin and traversed by numerous blood vessels, the membranous portion of the medulla is attached at regular intervals to the periphery of the gland by fibrous trabeculae. Commonly its color is the same as that of the bed of brownish pigment in which it lies.

Dissection. Omitting unnecessary details, the isolation of the adrenal medulla is carried out as follows: A gland having been selected and freed from every bit of adherent fat, the summit of its pressure-ridge is opened by an incision that runs throughout its length. Starting about midway of this incision, the thin process of medullary substance sure to be present within the ridge is sought for and when found is cautiously separated from the adjacent cortical tissue with the aid of a scalpel. At the end of this stage of the dissection a thin, longitudinal fold of medullary substance should stand, nearly erect, in the center of the incision. This fold, which may be likened to a dorsal fin, is now followed on down until the convex surface of the main medullary mass is exposed and

TABLE I

Relative weights of normal suprarenal medullae. The weight determinations were made with glands secured from 50 selected coroner's subjects.

the dissection is continued until the entire body of the medulla is laid bare (figure 4). The body of the medulla having been fully exposed, the next step is to begin the work of detaching the whole medulla from its bed. In order to do this, after first cutting the fibres that attach it to the extremity of the gland, the pointed end of the medulla is gently separated from the underlying tissue. It is then folded upon itself and this process of separating and folding is continued until the entire medulla, body and membranous portion, has been dissected out, the adrenal vein being severed last of all. The size of this vessel is often out of all proportion to the size of the gland it serves. In some instances it was found to be no less than 5 mm. in diameter.

The detached medulla should be carefully dried with absorbent paper before it is weighed.

EXPERIMENTAL RESULTS

Since they speak for themselves, little need be said with reference to the results exhibited in table 1. It may be suggested, however, that, even though they are not strictly quantitative, the data as to the weight of the medulla are probably accurate enough for most practical purposes.

As a supplementary note, the fact may be mentioned that in eight of the fifty normal cases pigment spots were

found in the adrenals. In shape the spots were oval or roughly triangular and from 1 mm. to 2 mm. on a side. The largest spot measured 5 mm. by 1 mm. The color was the same in each instance, i.e., a very dark brown. As regards their location, it seems worthy of remark that these spots always were found precisely in the cleavage plane and broadside on to the medulla; but they were invariably on the cortical side of the contact zone. No pigment spots were found in the medulla.

CONCLUSIONS

1. Stated in grams, the weight of a pair of adrenals varied from 5.8 to 11.3. The average value for fifty pairs of normal glands was 8.3.

2. Stated in grams, the average weights of fifty left and fifty right adrenals were, respectively, 4.165 and 4.161.

3. Stated in fractions of a gram, the average weights of fifty left and fifty right adrenal medullae were, respectively, .431 and .448.

4. The medulla appears to form about 10 per cent of the gland.

5. It is pointed out that the superior border of the adrenal gland is larger than the inferior border.

6. Attention is drawn to peculiarities in the configuration of the adrenals that occur (1) in adrenal-renal heterotopia and (2) in congenital absence of the left kidney.

Bacteriophage Therapy in Bacillary Dysentery of the Flexner Type*†

By JOHN F. KESSEL, and EDYTHE J. RÖSE, *Los Angeles, California*

INTRODUCTION

SINCE the suggestion was first made that bacteriophage be used as a therapeutic agent, numerous reports have occurred in medical literature concerning its value. Some of them have been favorable in character, and others less certain as to its beneficial effects. Bacteriophage has been recommended for a great variety of conditions and, indeed, possesses the characteristics required of an ideal germicide in that it is harmless to the body tissues and theoretically destroys the pathogenic organisms. This phenomenon of lysis can be demonstrated easily in vitro with young cultures, but it is doubtful if the results obtained in the animal body by the administration of bacteriophage are always equally phenomenal. Its successful use has been most commonly reported in connection with the gram-negative intestinal bacteria, such as *Shigella*, *Vibrio cholerae*, and *Escherichia coli* and with staphylococcic infections, both cutaneous and systemic in character.

*Presented before the American College of Physicians, San Francisco, California, April 7, 1932.

†From the School of Medicine, University of Southern California, and the Los Angeles County General Hospital.

Unfortunately, however, many of the clinical reports demonstrate but one side of the picture; for instance, one report states that bacteriophage was used in fifty cases—in forty-two with excellent results, in five with mediocre results, and in three with unsuccessful results. No mention is made of control cases and no statements are given that would indicate how the cases might have progressed if the bacteriophage had not been used.

The present report on the use of bacteriophage in bacillary dysentery of the Flexner type represents the results of one group of bacteriophage studies made at the Los Angeles County General Hospital and at the School of Medicine, University of Southern California, during the last two years. Other studies in progress have to deal primarily with its use in typhoid fever and in staphylococcic infections.

METHODS EMPLOYED

During the period of these observations more than one hundred cases of bacillary dysentery have been encountered in the Contagious Unit of the Los Angeles County General Hospital. Only sixty-eight cases are included in the data here presented since only those cases were selected for discussion from which it has been possible, first,

to isolate a bacterium giving characteristic biochemical and serological reactions of *Shigella paradysenteriae*, Flexner type, and, second, to completely lyse the organism isolated with the bacteriophage used in treatment. Cases yielding other strains of bacillary organisms or strains of Flexner type which failed to lyse with our bacteriophage have not been included in this report.

The cases are divided into two groups, first the 1930 series and second the series of patients treated in 1931. In the 1930 series the lytic property of the bacteriophage was tested against each organism isolated before the phage was administered. This caused a delay of several days after admission to hospital before the phage could be administered, since this time was necessary to permit (1) the isolation of the organism and (2) the adaptation of the phage by growth with the organism isolated from the patient.

Since it was found that about 90 per cent of all our Flexner organisms tested were lysed by a single strain of bacteriophage, we decided to employ this strain in the second series and to administer it just as soon after admission as possible. Such administration of bacteriophage immediately after the admission of the patient should be advantageous since it saves the time usually required for routine laboratory procedures in isolation of the organism and for the preparation of the bacteriophage.

Insofar as it was practicable, alternate cases were selected for "phage cases" and for "control cases", care being taken that a phage case and a

control case exhibited as nearly uniform symptoms as possible.

The cases receiving bacteriophage were given a minimum of three doses of bacteriophage by mouth at approximately twelve hour intervals. The dose consisted of from 3 to 5 c.c. of the laboratory prepared broth filtrate which was added to a small amount of unheated water before administration.

Both treated and control cases received the same routine symptomatic treatment which consisted primarily of dietary precautions and methods to limit dehydration.

In children, fluids by mouth were withheld or limited for the first twelve or twenty-four hours, normal saline being given intraperitoneally and by hyperdermoclysis, and glucose intravenously. Following this period fluids were gradually added by oral administration, boiled skimmed milk, lactic acid milk, or protein milk and glucose water being alternated every two hours until the patient had improved sufficiently to receive small amounts of solid food in the form of custards, cereals, cottage cheese, etc.

Adult patients usually received their fluids by mouth, parenteral administration seldom being required. Boiled skimmed milk or buttermilk was allowed during the first forty-eight hours, after which other foods were gradually added. Fats were withheld from both children and adults until stools were normal.

Milk of bismuth or bismuth subcarbonate was given to both children and adults when dysentery was especially marked. Paregoric was allowed in event of severe cramps or tenesmus.

though only one patient in this series received it.

TABLES AND DISCUSSION

In collecting information regarding the cases, special data were assembled concerning the following points: (1) age of the patient, (2) onset and course of the disease prior to hospital admission, (3) temperature, before, during, and after giving bacteriophage, (4) the number and type of stool before, during, and following administration of bacteriophage, (5) special toxic or neurologic symptoms, (6) any unusual complications, and (7) the number of days of hospitalization. The relevant data for comparative purposes are included in the tables.

The number of days of hospitalization has been selected as the most significant criterion for comparison since it represents the most constant standard. It is a general rule that patients with fever are discharged from the hospital three days after a return of the temperature to normal unless other symptoms contraindicate release. In this series of cases the number of stools had also returned to normal before the patient was discharged. Owing to the pressure for admission of patients to the Contagious Disease Unit of the hospital, patients were discharged just as soon as symptoms permitted.

Many mild cases of diarrhea or dysentery caused by bacteria belonging to the genus *Shigella* occur in this region which never become sufficiently severe for hospitalization. Quite commonly within two or three days the patient recovers without special medical attention. If bacteriophage or any other

therapeutic agent were employed in such a group without adequate controls, the results obviously would be interpreted as being favorable. The cases herein recorded, however, represent individuals either who were ill several days at home before coming to the hospital or whose symptoms were sufficiently severe to warrant immediate hospitalization. They, therefore, represent an ideal group for consideration in the testing of any therapeutic measure.

Table 1 gives a summary of the cases treated during the first season when a specific bacteriophage was prepared for each organism. In this series the average number of days elapsing between admission of the patient and administration of the bacteriophage was four. It will be seen that there is no marked difference between the ages, nor between the intensity of symptoms in the group treated with bacteriophage and in the control group; the temperature range, the type of stools, and number of stools per day being about the same in both series. Likewise, the average number of days of hospitalization in each group does not differ markedly, it being 11.9 days for the treated cases and 10.1 for the control series. It is true that the treated cases show a longer period of hospitalization than the control cases, but since bacteriophage was not administered until several days after admission, and since the series was small, it was decided not to lay too much emphasis on the results and to study another series of cases by the second method.

Table 2 gives a summary of the cases treated during the 1931 season when bacteriophage was administered

as soon after admission to the hospital as it was possible to collect a stool from the patient. Organisms recovered from such a stool were later tested for lysis with a portion of the bacteriophage employed and only those cases are recorded in this table where complete lysis occurred. In this series, as well as in the first series, the ages and

fatal cases died during the first twenty-four hours of admission, two having received bacteriophage and one being a control; it seems fair to consider that these reached the hospital too late for any treatment to be of value. The other four fatal cases, two treated and two controls, were of approximately equal intensity. One of the control

clinical manifestations of the patients in the treated and control groups compare favorably. It will be noted that the average period of hospitalization of the treated group is eleven days, while in the untreated or control group it is 12.1 days, there being a difference of 1.1 days between the two groups.

Though there were no deaths in the 1930 series, there were seven in the 1931 series, four among those treated with bacteriophage and three in the untreated series. Since three of the

cases died in two days as did one of the treated cases, while the other control case died in five days and the other treated case in eight days. It is recognized that the number of fatal cases is too small to be of significance but since there is little difference in the fatalities in the treated and untreated series, significant affirmative evidence for the therapeutic value of bacteriophage is lacking.

D'Herelle, in 1917, first called attention to the presence of a substance

lytic for dysenteric bacteria after having isolated this substance from the stool of a patient convalescing from bacillary dysentery of the Shiga type. In 1926, he further cites in detail sev-

action on the specific bacteria, and it is assumed that lytic action of a bacteriophage assures protection.

With this possibility in mind, some have accepted bacteriophage as a de-

eral cases of bacillary dysentery of the Shiga type and shows that bacteriophage lytic for the Shiga bacterium is commonly present in association with the organism. It is suggested that fatalities result from a failure of the bacteriophage to exert a destructive

sirable treatment for bacillary dysentery, especially in those regions where the disease is common in epidemic form. A number of the earlier reports indicated favorable results from its use therapeutically, and with due consideration to these findings the present

study was begun. During its progress a number of recent papers have come to our attention and brief summaries of some of these may be mentioned.

Compton (1929) reports the use of bacteriophage in 66 cases and states the results were very good in 35 cases, good in 10, medium in 6, and a partial failure in 10. He cites no controls in his series.

Burnet, McKie and Wood (1930) in an investigation of 21 cases found that the presence of a highly active phage was generally of favorable import for the patient, though in children of over one year the presence or absence of bacteriophage was not of prognostic significance.

Sen (1930) reports decided success in the treatment of children by bacteriophage.

Asheshov, Taylor, and Morison (1930) in a summary state that in Shiga and Flexner types of bacillary dysentery no effect on the disease is traceable to the administration of bacteriophage. Morison does state, however, that in three epidemics he had 15 deaths in 57 treated cases, and 50 deaths in 92 untreated cases.

London (1930) administered bacteriophage orally to 141 cases of bacillary dysentery; 129 were cured and 12 died. Here again no controls were mentioned.

Riding (1930), in recording the results of 48 cases in which lysis of the organism isolated from the patient was apparent, concludes that bacteriophage is probably quickly eliminated or destroyed and that the clinical course of acute bacillary dysentery is not altered by the oral administration of bacteriophage. He used some of his cases for controls.

Taylor, Greval, and Thant (1930) report a series of 20 controls and 26 cases given 2 c.c. of bacteriophage three times a day and conclude that, in spite of the presence of phage of higher activity in the stools of treated cases as compared with controls, no significant difference exists in the progress of cases either in regard to effect on mortality or as to duration of the period of attack. It is of interest to note that they draw similar conclusions from their controlled series of cholera cases treated with bacteriophage.

Results of the study here reported do not differ from the conclusions of the workers just mentioned who used untreated control cases for comparison. In our series 68 cases are recorded, 35 who received bacteriophage by mouth in addition to symptomatic hospital treatment, and 33 cases who did not receive bacteriophage. The severity of symptoms and ages of patients in the two series compare favorably. It was found (1) that there were four deaths in the bacteriophage treated group and three deaths in the control series and (2) that the average days of hospitalization per patient in the bacteriophage series is 11.45 days while in the control group the average period is 11.1 days.

Conclusions from this study indicate that the oral use of bacteriophage in bacillary dysentery of the Flexner type by the methods here employed does not alter the clinical course of the disease, does not appreciably reduce the number of days of hospitalization, and does not lower the death rate. Continued studies in which larger and more frequent amounts are being given orally in conjunction with bacterio-

phage by retention enema are in progress.*

SUMMARY

1. Sixty-eight cases of bacillary dysentery from which *Shigella paradysenteriae* of the Flexner type was isolated are considered in a study of bacteriophage therapy.

2. Thirty-three of the cases received no bacteriophage and are therefore used as controls.

3. Twelve of the treated cases appeared in the 1930 season when a specific bacteriophage was prepared for each case. Such phage was administered by mouth, an average of four days after admission to hospital. The average number of days of hospitalization of this group was 11.9 days

while in the control group for the same period the average was 10.1 days. No deaths were recorded in either series during this season.

4. Twenty-three cases in the 1931 series received a bacteriophage which was later tested for lytic properties. Such bacteriophage was administered by mouth within a few hours after admission to hospital. The average number of days of hospitalization of this group was 11 days while in the corresponding control group, the average period of hospitalization was 12.1 days. There were four deaths in the bacteriophage treated series and three in the control series during this season.

5. These results indicate that the oral administration of bacteriophage, as used in this study, produces no marked clinical benefit over the recognized symptomatic care and treatment.

*These studies were continued during the 1932-33 season when amounts of bacteriophage ranging from 50 to 100 c.c. were given by retention enema to each patient in addition to the bacteriophage by mouth. The treated series shows a hospitalization period of 12.3 days and the control series one of 12.5 days. These continued observations do not alter the previous conclusions.

Doctors M. F. Bigler, E. M. Kittredge, and Ruth Anderson have coöperated in this work by supervising the clinical studies. Their assistance has been greatly appreciated.

Tuberculosis in Officers of the Regular Army*†

By LT. COL. A. T. COOPER, M.C., *Fort Myer, Virginia*

THIS study of officers of the United States Army who have been under treatment for pulmonary tuberculosis at Fitzsimons General Hospital since January 1923 was undertaken in order to assist in arriving at an opinion of the results obtained by treatment of pulmonary tuberculosis in officers on the active list of the United States Army. All too frequently it is the usual opinion throughout the Army that when any officer contracts tuberculosis his days of usefulness for the Army are to a large extent over. Those of us who have been following the officers unfortunate enough to develop chronic pulmonary tuberculosis during their service in the Army have always realized that a large percentage of such officers can be cured and after a suitable period of time return for many years of useful service in the Army.

It is noteworthy that while this group of patients is not large, their progress and disposition have been closely followed over a number of years, as no matter where an officer may be stationed, if clinical pulmonary tuberculosis becomes evident, he is sent to the Fitzsimons General Hospital.

It has been the belief of the Medical

Service at Fitzsimons General Hospital that a large percentage of officers who developed tuberculosis could, after a period of definitive treatment, be returned for active duty to the service. The records of all officers of the Regular Army on active duty who have been admitted to Fitzsimons General Hospital because of chronic pulmonary tuberculosis since January 1, 1923 have been studied. The total number was 102. It was rather a surprise to the investigator to find that the number of officers treated for pulmonary tuberculosis during a period of slightly over eight years was so small.

The following is a table showing the number of officers according to the branch of service and according to grade who have been admitted since 1923 for pulmonary tuberculosis. (See Table I).

It is seen that the junior officers, Captain, 1st Lieutenant, and 2nd Lieutenant, furnish the majority of admissions. Table 2 shows that a higher average percentage incidence of the disease occurs in these grades.

Calculating the percentage of officers admitted from each branch of the service, as is shown in table 3, gives some rather interesting information. It is seen that the Medical Corps stands out with a very much higher percentage of admissions than any

*Received for publication March 3, 1932.

other branch of the service, with the Dental Corps a close second. No comment is made on the possible reasons why Medical Corps and Dental Corps

officers should be more prone to develop chronic pulmonary tuberculosis than officers in other branches. However, the data as obtained are herewith

end of hospitalization and the officers are then sent to protected duty. Such duty usually consists of ordinary post duties but is limited to stations in the southwestern portion of the United States, including Colorado and Wyoming, with definite recommendations that such officers not be sent on foreign service. Authorities at this hospital base these recommendations on the

to Fitzsimons General Hospital, forty-four were at their initial disposition returned to duty, this being approximately 43 per cent.

It is to be expected, of course, that a certain number of officers who are returned to duty with chronic pulmonary tuberculosis will have relapses, and table 7 shows that of the forty-four officers who, having been hospitalized for tuberculosis, were returned to duty, twenty were readmitted to Fitzsimons General Hospital because of reactivation of their pulmonary lesions. Eleven of these twenty were again returned to duty, so that of the original 102 officers, thirty-four are now on active duty. Table 7 shows the number of officers by grades who were readmitted and their disposition. Twenty-four of the forty-four officers are still on active duty and have never been returned to the hospital as patients.

The present condition of the thirty-three officers who have been retired to September 1, 1931, as to whether living or dead, is shown in table 8.

Those of us at Fitzsimons General Hospital who have followed the progress of chronic pulmonary tuberculosis in individual cases have realized that cavities and hemorrhages are serious complications and that unless hemorrhages are controlled and cavities are obliterated by some form of collapse therapy, the prognosis in the case is rather grave as to ultimate recovery.

Table 10 shows that fifteen, or 14.7 per cent, of these officers had hemorrhages, and that 61.76 per cent showed cavities; but only 9.8 per cent

ing cavity with a hemorrhage have either died or been retired, three are still in the hospital and only two have been returned to duty. Forty-nine per cent of the officers having a cavity without a hemorrhage have either been retired or died, and 28.3 per cent have been sent to duty. Eleven, or 20.75 per cent, are still in the hospital. This bears out the clinical observation that cavity and hemorrhage are two very serious complications. Of those that had a hemorrhage without any demonstrable cavity, four were returned to

TABLE X

50-60	6	2	4
Total	102	57	45

The disposition of these officers divided into groups on the basis of positive or negative sputum is shown in table 13. It is to be noted that

Table 14 shows the cases grouped in accordance with the types of treatment employed; and table 15 shows the disposition of the groups treated by various measures. The great majority of these patients, 81.37 per cent, either did not require any other therapy than hygienic and rest treatment, or their tuberculosis was so distributed that other therapeutic measures were not feasible.

Table 15 is of interest because it shows that of three cases on which thoracoplasty was done, two were returned to duty. Such a result should be encouraging to those officers upon whom it is necessary to do a surgical collapse. The two officers returned to

duty are now on protected duty and one of them, at least, is making a very definite and outstanding recovery, so

that there is very little doubt but that at the end of two years he can be marked apparently cured.

Rocky Mountain Spotted Fever*

By G. GILL RICHARDS, M.D., Salt Lake City, Utah

ROCKY Mountain spotted fever may be described as an acute tick-born infectious disease. It was formerly thought to be indigenous to the West where it is most prevalent in the states of Idaho, Oregon, Wyoming, and Montana, but recently cases have been reported from the Atlantic states by Badger, Dyer and Rumreich¹ of the United States Public Health Service. These cases, of which there were forty in Maryland alone in 1931, are clinically and immunologically identical with those seen in the West.

The disease probably existed in the Rocky Mountain region for years before the coming of the white man. Indians feared certain valleys in the late spring and early summer because they felt that these districts were visited by evil spirits and that it was dangerous to enter them during these seasons. Cases of Rocky Mountain spotted fever were discovered in Colorado as early as 1885 but the first medical report was sent to Washington in 1896 by M. W. Wood,² an army surgeon, who collected data from several Idaho physicians treating these cases. In 1899 Dr. E. E. Maxey,³ of Boise, Idaho, published his description of this disease as a distinctly new entity.

In 1902 G. T. McCullough⁴ described a type of the disease in the Bitter Root Valley of Montana which was much more virulent than that seen in Idaho.

In the same year, at the solicitation of the Montana State Board of Health, L. B. Wilson and W. M. Chowning,⁵ of the University of Minnesota, made an investigation as to the nature, cause, and possible means of prevention of this disease. They described an hematozoa which they found in the blood corpuscles of patients and of gophers. They concluded that the disease was transmitted to man by the wood-tick which had become infected from certain rodents. They did not, however, offer sufficient experimental proof of this claim to lead to its general acceptance.

In 1903 J. F. Anderson,⁶ of the United States Public Health Service, studied and classified the ticks of the mountain region. Stiles named the tick, which has been shown to be the chief vector of spotted fever, *Dermacentor andersonii*.

It remained for Howard Taylor Ricketts,⁷ who later sacrificed his life in the interest of medical science, to establish through his painstaking scientific labors the methods by which the relationship of the tick to the disease could be demonstrated. He was able to produce the disease in laboratory

*Read before the American College of Physicians at San Francisco, California, April 7, 1932.

animals by means of the tick. He demonstrated the infected tick in nature and the hereditary passage of the virus from one generation of ticks to the next. He also described a micro-organism whose etiological relationship to the disease was fully demonstrated by Wolbach in 1919.

In 1908 Dr. L. P. McCalla⁸ reported the transmission of the disease from man to man by means of a tick taken from a patient's body and allowed to feed on two volunteers who contracted the disease in four and nine days respectively.

In 1916 L. D. Fricks⁹ described protozoan-like bodies in the red blood cells of patients but hesitated to draw any conclusions as to their etiological significance.

In 1919 Wolbach¹⁰ described micro-organisms which he found in the blood of many laboratory animals and in tissues of ticks infected with Rocky Mountain spotted fever. He named them *Dermacentor.venus rickettsi*.

Noguchi,¹¹ who like Ricketts was later to die in a foreign country of the disease which he was investigating, made many studies of Rocky Mountain spotted fever. He was chiefly interested in attempts to cultivate the microörganism and in the study of immunological reactions. In 1923 he prepared a sero-vaccine which protected the guinea pig against the disease but did not effectively protect the monkey or man.

From 1922 to 1928 R. R. Spencer and R. R. Parker¹² carried on an intensive joint research. Their studies have added many important points to our knowledge of the life cycle of the tick and the maintenance of the virus

in nature. The virus has been shown to exist in an avirulent phase in the fasting tick and to become infective again shortly after the tick has fed. The ability of tick virus to pass through the intact skin has been proved, thus demonstrating how the disease may be acquired without tick bite if infective ticks are crushed in the fingers. The rôle played by other ticks than the *Dermacentor andersonii* in the transmission of the disease from animal to animal has been studied and it has been shown that at least two other species of ticks may be carriers of Rocky Mountain spotted fever virus. To Spencer and Parker is due also the successful development of a vaccine now issued by the laboratory at Hamilton, Montana and shown by several years' experience to be of great prophylactic value.

SEASONAL INCIDENCE

Rocky Mountain spotted fever has occurred in all months of the year but winter cases are very rare. Generally it is most prevalent in the spring from March to June and corresponds to the seasonal abundance of the wood tick. In the higher altitudes it often occurs in the later summer months.

The disease occurs most frequently in those people whose occupation or pleasures necessitates their presence in infected areas in the season of the year when it is most prevalent. Its incidence is therefore more common in men than in women. Children withstand the infection much better than adults. In the regions of high mortality unvaccinated adults past middle life seldom recover.

INCUBATION PERIOD

In man the incubation period is from two to twelve days. Its average duration is from four to seven days. The more virulent the infection the shorter the incubation period. It is also dependent upon the length of feeding time of the infected tick prior to the bite.

SYMPTOMS

Usually the engorged tick can be found still feeding on the patient at the time of the first examination. No lesion develops at the site of the bite, nor is there, as a rule, any enlargement of the regional lymph glands such as is seen in tularemia.

During the prodromal stage of one or two days the patient complains of listlessness, some aches and pains, loss of appetite, chilly sensations, and slight fever. These symptoms progress into a real chill, followed by high fever up to 104 and 105 degrees which lasts fourteen to twenty-one days, with morning remissions, and falls by slow lysis. The pains become general and severe, especially in the back and legs, resembling an early stage of acute articular rheumatism. The calves of the legs become very sensitive and painful to touch or movement. Hyperesthesia of the skin is often very troublesome. Nose bleed occasionally occurs. There is often a slight dry and irritating cough. The conjunctivae are often injected and sometimes hemorrhagic with accompanying photophobia. Gastrointestinal symptoms are not as a rule marked or common. As the disease progresses, the patient usually becomes increasingly anxious and restless. During the height of the fever he is often delirious.

The rash is the most constant and characteristic single sign in the course of the disease. A few patients may, however, die before the appearance of the eruption. The rash is first seen on the wrists, forearms, and ankles, usually appearing on the third or fourth day and gradually spreading to the rest of the body. It begins as a discrete, rose colored, macular eruption which at first disappears under pressure. Later it becomes blotchy and petechial in character. If the rash remains discrete and pinkish it is a favorable prognostic sign. Large spots are more favorable than small ones. The more severe types progress to a darker color, the lesions coalesce and may develop into hemorrhagic and necrotic spots. The life cycle of any given group of spots is about fourteen days, with a gradual change of the lesions to brownish pigmented areas before they entirely disappear. In the more severe types the eruption occurs in the throat and may result in some sloughing. In some cases the rash appears in one, two, or even three crops, each crop running its separate course.

The pulse is often a valuable guide to the condition of the patient. Early in the disease it is slow in proportion to the temperature, and in the milder types it often does not exceed 90 per minute. As the toxemia progresses in the severe forms the pulse becomes increasingly rapid and poor in quality. A rapid pulse is a very unfavorable sign.

Urinary changes are not common except in the older patients who often develop a suppression and die of uremia.

The blood picture is not characteristic. There is a moderate leukocytosis in the first week, increasing up to 15,000 and 18,000 in the second week with a relative increase in large mononuclear cells. Icterus is often a terminal sign in the fatal cases.

DIFFERENTIAL DIAGNOSIS

The disease must be differentiated from typhoid fever, cerebrospinal meningitis, especially the septicemic type, measles, typhus, and even smallpox.

In an area known to be infected the history of tick bite or, as often occurs, the finding of a tick on the patient's body, may lead to an early and an easy diagnosis.

The Weil-Felix reaction has been found to be present in the majority of cases of Rocky Mountain spotted fever, but this does not differentiate it from certain other diseases due to rickettsiae. Immunity tests may be necessary to differentiate it from typhus. Animals which have recovered from typhus are still susceptible to Rocky Mountain spotted fever and those recovering from spotted fever are susceptible to typhus but not to another inoculation of spotted fever virus.

Generally one attack of Rocky Mountain spotted fever produces a permanent immunity against subsequent exposures. There have been a few authentic reports of second attacks.

PATHOLOGY

The gross pathology is not distinctive. The subcutaneous hemorrhages and enlargement of the spleen are the only constant and striking macroscopic

lesions. The lymph glands are enlarged in some cases.

Microscopically there is a perivascular infiltration of the subcutaneous tissue and the small blood vessels may be completely occluded with mononuclear cells. In the endothelial and smooth muscle cells of the media, large numbers of the minute rickettsiae bodies were first described by Wolbach and have subsequently been confirmed by others. Wolbach¹⁰ considers spotted fever as a disease of the peripheral blood vessels or an acute endangeitis.

COMPLICATIONS AND MORTALITY

Sloughing of the soft parts in the mouth or of the scrotum occasionally occurs with secondary infections. Phlebitis is not an infrequent complication. A persistent neuritis lasting for many months was very troublesome in one of my cases. Broncho-pneumonia may develop and be the cause of death. Suppression of urine resulting in uremia is seen in the older patients.

The mortality rate varies greatly in different sections and in different years, ranging from 4 and 5 per cent in the Snake River Valley in Idaho to as high as 90 per cent in some seasons in the Bitter Root Valley in Montana. Death probably occurs from a severe toxemia, which seems to affect chiefly the heart muscle and peripheral blood vessels.

TREATMENT

General treatment should consist of complete rest in bed in order to conserve all possible strength. The patient should be kept as quiet as possible physically and mentally by any safe

measures such as baths, packs, and the use of barbital, phenobarbital, or chloral and bromides, or even morphine if necessary. Cardiac stimulants such as caffeine and digitalis should be given if there is any indication of impending cardiac failure. The intake of fluids and nourishment must be maintained as in any acute fever. If there be nausea and vomiting, as occasionally occurs, fluids may be given by bowel, or subcutaneously.

SPECIFIC THERAPY

Up to the present time there is no specific drug or antiserum. Convalescent serum and transfusions from

convalescent patients have been tried without benefit.

The avoidance of known infected areas during the tick season is the most important prophylactic measure. When of necessity such areas are visited it is important to search the body several times a day for ticks, since their prompt removal in the first hours after attachment may obviate infection. The use of the vaccine as a prophylactic is advised for all whose occupation subjects them to exposure.

The author wishes to acknowledge his indebtedness to Dr. R. R. Parker of Hamilton, Montana for assistance in the preparation of this paper.

The Biological and Clinical Importance of Ovary-Stimulating Hormones*†

By C. F. FLUHMANN, M.D., C.M., *San Francisco, California*

ALTHOUGH it has been recognized for over a quarter of a century that a definite inter-relationship exists between the anterior hypophysis and the gonads, it is only within recent years that it has been possible to study the action of substances which definitely produce anatomical effects in the ovaries. This has been due mainly to the pioneer work of Evans and Long with alkaline extracts of the anterior lobe, and to the experiments of Smith and Engle and Aschheim and Zondek with gland implants in immature animals. These findings have afforded the basis for fundamental biological tests and have led to a vast number of laboratory and clinical investigations. The object of the present paper is to present a brief summary of the more important known facts regarding "ovary-stimulating substances" and at the same time to indicate the trend of modern research in attempting to solve some of the perplexing mysteries of the "female sex hormones".

*Read before the American College of Physicians April 5, 1932, San Francisco, California.

†From the Department of Obstetrics and Gynecology, Stanford University School of Medicine.

DEFINITION AND BIOLOGICAL TESTS

The "ovary-stimulating substances" which form the subject of this paper may best be described by a brief reference to the biological effects that they produce, which form the basis of the laboratory tests employed for their recognition, namely, (1) the stimulation of graafian follicle development with the consequent elaboration of the ovarian hormone "estrin", (2) corpus luteum formation with the production of its hormone "progesterone", and (3) ovulation or follicle rupture.

The first of these effects, follicle ripening, is demonstrated in the immature rat or mouse ovary by means of the Aschheim-Zondek test, and is commonly referred to as "Anterior Pituitary Reaction I", abbreviated to APR I. In addition to the growth of the follicle, however, it is very important to remember that there is also a resultant elaboration of the ovarian hormone "estrin", which manifests itself by a number of important changes. The vaginal outlet of the immature mouse or rat, which is normally closed by a thin membrane, swells and opens. The vaginal mucosa develops from a low cuboidal type of epithelium to a thick, cornified, squamous epithelium, and the cornua of the uterus become markedly hypertrophied.

The second change which may be produced in the immature rat or mouse ovary is an extensive luteinization, a development of granulosa cells into corpus luteum cells. This change is so intense that follicles may become completely transformed into lutein-cell bodies before ovulation has occurred and so produce the histologic picture of "imprisoned ova", the "Anterior Pituitary Reaction III" (APR III) of Aschheim and Zondek. As in the first experiment, this anatomical effect is also accompanied by the production of a hormone, "progesterin", the hormone of the corpus luteum. This likewise results in the opening of the immature vagina, but the mucosa is now not cornified but composed of high cylindrical cells secreting mucus (mucification), while the uterus has acquired the property of responding to an abnormal stimulus and developing a placentoma or deciduoma. The animal, in other words, is in a state of "pseudopregnancy".

In some instances of rats or mice yielding an APR I, it may be possible by delaying sacrificing the animal for a period of twenty-four hours, to demonstrate a rupture of the fully-developed graafian follicle and the presence of ova in the cornua of the uterus. This was very well shown by Smith and Engle¹ with implants of the anterior lobe when they produced a "superovulation" in immature mice. The production of ovulation, however, is more readily demonstrated by the use of rabbits as recommended originally by Friedman.² The ovary of this animal normally contains fully-developed graafian follicles which may be seen grossly as small clear cysts

near the surface of the organ. Following the administration of an "ovary-stimulating substance", such as is found in the urine of pregnant women, a very radical change occurs. The cysts rupture and this process is accompanied by a local hemorrhage, so that within thirty-six hours small, red, protruding areas may readily be seen grossly in the ovaries.*

It is thus apparent that the main function of the "ovary-stimulating substances" is in determining the growth, maturity, and rupture of the graafian follicle, as well as its subsequent development into a corpus luteum. Associated with these anatomical changes there is the elaboration of two ovarian hormones, (1) estrin, which in the human produces a growth of the endometrium, pelvic hyperemia, and turgor of the uterus, and (2) progesterin, which is responsible for the secretory changes found in the pre-gravid phase of the endometrium (figure 1). This hormone (or hormones)† also seems to have a definite influence on lactation (Grüter and Stricker,³ Corner,⁴ Evans and Simpson⁵), and although not entering into the scope of this review it must be remembered that it has an influence on the male sexual organs and so is, more prop-

*In this connection attention must be directed to the presence of hemorrhage into graafian follicles or luteinized cysts which may also be found in rats or mice, and which Aschheim and Zondek refer to as APR II in their "pregnancy test".

†More recent studies by Riddle and his co-workers (Proc. Soc. Exper. Biol. and Med., 1932, xxix, 1211) suggests that there is a separate hormone of the anterior hypophysis, which they call *prolactin*, concerned with lactation.

erly speaking, a "gonad-stimulating" principle rather than merely "ovary-stimulating".

FIG. 1. Diagram illustrating the action of the anterior pituitary ovary-stimulating hormone on the ovaries, with the consequent production of *estrin* and *progesterin*.

IS THERE MORE THAN ONE OVARY-STIMULATING HORMONE?

It has been shown that three very definite effects may be assigned to "ovary-stimulating substances", namely, follicle development, ovulation, and corpus luteum formation. The question immediately arises as to whether we are dealing with only one hormone which provokes these reactions in the ovaries, or whether these reactions are

due to two or more hormones each of which has a specific function.

The possibility that there may be two distinct ovary-stimulating hormones was first brought out by an apparent contradiction in the work of Evans and Long, and Smith. The former workers found that the ovarian response of rats to their growth hormone extracts consisted of a delay in the appearance of estrus in immature animals with the formation of abnormal lutein bodies in the ovaries; whereas Smith, and Smith and Engle found that direct implants of the anterior hypophysis produced an early appearance of estrus accompanied by a premature development of normal follicles. In addition, it was found that the administration of Evans' luteinizing hormone inhibited the effect of implants, thus suggesting that not only were two sex hormones concerned but that they were directly antagonistic in their action (Evans and Simpson⁹). The conception of a dual hormone was also advanced by Bellerby,⁷ and later Aschheim⁸ supported this theory on the basis of his findings in numerous biological tests. Since then, most writers on the subject, chiefly in Germany, have assumed the existence of two ovary-stimulating hormones—one termed anteriorpituitary hormone (APH-A), stimulating growth of follicles, and a second (APH-B) responsible for luteinization (Zondek¹⁰). Further evidence in favor of this theory has been advanced in a number of articles (Crew and Wiesner,¹⁰ Evans and Simpson,¹¹ Loeb¹²), and Revold, Hisaw, and Leonard¹³ have reported a method of extracting and separating two gonad-stimulating hor-

mones from anterior lobe tissue. They have found that one of these stimulates follicular growth while the second causes luteinization, and it is of especial interest that the luteinizing hormone they have isolated does not act on the immature ovary unless it has previously been stimulated to follicular activity by the first extract.

There is thus some evidence that there exists more than one ovary-stimulating substance, but on the other hand this conception is not widely accepted as having received sufficient experimental corroboration. It is not generally held that a chemical separation of more than one substance has been clearly accomplished (Dodds¹⁴), and it is possible that the different effects may be due simply to variations in dosage and methods of administration. In a recent extensive report Wallen-Lawrence and van Dyke¹⁵ state that they encountered no evidence of two principles, and further work by Smith and White¹⁶ indicates that under physiological conditions follicular growth and luteinization cannot be explained by the successive secretion of two hormones.

DISTRIBUTION

The development of simple biological tests for the ovary-stimulating substances has resulted in an extensive search for their presence in various organs and body fluids, so that an amazing number of reports are now available on this phase of the subject. In order to simplify an analysis of these findings in the human it would seem advisable to consider them under three separate headings, namely, their occurrence (a) in normal individuals,

(b) during pregnancy, and (c) in pathological conditions.

A. *Normal*. Of primary importance in this work are the findings resulting from the direct examination of the human anterior hypophysis, and it may be stated that both APH-A and APH-B effects have been obtained from the anterior lobes of men and women of all ages and even during intrauterine life (Zondek,⁹ Schultze-Rhnhof and Niedenthal,¹⁷ Siegmund and Mahnert,¹⁸ and others). The same finding applies to animals, as for instance, cattle, sheep, pigs, rats, cats, rabbits and so forth. These observations are of great importance in view of the prevailing conception that the anterior lobe is the main, if not the only, source of the gonad-stimulating hormones.

There is as yet but little known regarding the occurrence of gonad-stimulating hormones in the blood or urine of normal women during adult sexual life. However, a recent study by Zondek¹⁹ shows that by concentrating the urine it is possible to find APH-A at all stages of the menstrual cycle, although the greatest concentration is to be found during the premenstrual phase. In a preliminary communication, Frank, Goldberger and Spielman,²⁰ and Frank²¹ announce that they have conducted similar studies with blood and have also been able to demonstrate APH-A in various individuals, although in this case the greatest concentration has been found early in the cycle, namely between the sixth and ninth days. On the other hand, Neumann and Péter²² report that they find APH-A in the blood at a late stage of the menstrual cycle, between

the twenty-second and twenty-seventh days, so that this phase of the problem must for the present be considered as undetermined.

B. Pregnancy. The widespread dissemination of ovary-stimulating hormones in women during pregnancy is one of the most interesting discoveries relating to this work. The test in these cases is characterized mainly by the reaction attributed to APH-B, and forms the basis for the well-known Aschheim-Zondek pregnancy test which has now received worldwide recognition. In addition to urine (Aschheim and Zondek²³) and blood (Fels²⁴; Fluhmann²⁵) positive tests have been obtained from the placenta, decidua, corpus luteum graviditatis, amniotic fluid, fetal blood, tubal mucosa (Aschheim and Zondek²³), colostrum and milk (Heim²⁶), saliva (Trancu-Rainer²⁷), and the serum in blisters resulting from the application of cantharides (Heim²⁸). Closely related to these findings are the strongly positive reactions from the urine of women with hydatidiform mole or chorioepithelioma (Rössler²⁹ and others). However, a remarkable observation was made by Philipp,³⁰ and corroborated by Ehrhardt and Mayes³¹ and others, that the anterior hypophysis of pregnant women is practically devoid of ovary-stimulating substances. This would seem to be paradoxical; the significance of this finding will be discussed later.

C. Pathological Conditions. In normal individuals the demonstration of ovary-stimulating hormones is a complicated and uncertain procedure, though in pregnancy the tremendous amounts present render it a comparatively simple matter. However, there

are certain endocrinological conditions which are also characterized by the presence of unduly large amounts of these substances in the blood or urine. As the result of the examination of a large series of patients, Fluhmann^{32,33,34} has shown that a definite relation exists between ovarian function as determined by the history of the menstrual cycle and the finding of excessive amounts of ovary-stimulating hormones in the blood. These observations obtained from a large series of patients are listed in table 1, and it is seen that they may be grouped into four categories. The first two are characterized by negative blood tests, and include women with normal menses or with manifestations usually referred to as of "hypo-ovarian" origin, namely, irregular delayed menses, scanty periods, and amenorrhea. In the third group are women in whom there is a total absence of ovarian function, namely castrates, patients in the post-climacteric, and a certain number with prolonged periods of amenorrhea, and it is seen that a large percentage have given positive tests. These findings have received corroboration from the work of Zondek⁹ and Mazer and Hoffman.³⁵ The fourth group also presents a number with unduly large amounts of ovary-stimulating substances in the blood and is of particular interest because it includes a type of patient with symptoms suggesting a possible primary hyperpituitary function.

Zondek³⁶ has drawn attention to similar findings in the urine of women at the time of the climacteric, following castration, and in genital carcinoma. His latter observation is of interest

because he has noted that just as in pregnancy the anterior hypophysis of these patients likewise contains a marked diminution in the amount of stored sex hormones (Zondek³⁷). Neumann³⁸ has found that the urine of children up to the age of ten frequently gives a positive test for the presence of ovary-stimulating hormones.

same characteristics as those made from other sources, such as the urine of pregnant women (Zondek⁹). Although the two ovarian substances, estrin and progesterin, are readily taken up by lipoid solvents such as ether and chloroform, this is not the case with the ovary-stimulating hormones which are soluble in alcohol at a concentration of 40 per cent but insoluble

TABLE I
Results of the examination of the blood serum of 266 non-pregnant women for the presence of excessive amounts of ovary-stimulating hormones.

	APR I	APR III	APR I-III	Total Positive	Negative	Total
I. NORMAL OVARIAN FUNCTION

CHEMICAL PROPERTIES

Since it has not yet been possible to isolate the ovary-stimulating principles in pure form, their exact chemical constitution is as yet unknown, but a number of important properties have been determined as a result of the studies of Zondek,⁹ Collip,³⁹ Dickens,⁴⁰ Wallen-Lawrence and van Dyke,¹⁵ Goss and Cole,⁴¹ and others. In the first place, no final chemical differentiation between APH-A and -B has been accomplished, and in the second, extracts made from the anterior pituitary gland have shown essentially the

in concentrations of over 70 per cent. They are also precipitated from an aqueous solution by high-grade acetone, sodium or ammonium sulfate, "colloidal iron" or tannic acid. They are readily adsorbed to charcoal, are destroyed by temperatures above 70°C., and are very sensitive to the action of acids or alkali, since Dickens⁴⁰ noted that 0.2N acid or alkali completely inactivate extracts made from the urine of pregnant women.

An exception must be made in the case of "Emmenin", an estrogenic substance which was isolated by Collip

from the human placenta and which he considers as an ovary-stimulating hormone. This extract is readily soluble in alcohol, is effective when administered orally, and although it causes the appearance of estrual changes in immature rats it only acts on the spayed adult animal in very high concentration. It is evident that this preparation does not fall into the same category as the ovary-stimulating substances under discussion, but it is important to note that Collip also obtains a second principle from the placenta which agrees fairly closely in its general properties to those described above.

Numerous extracts of high potency are now being prepared and used for biological and clinical studies. The anterior lobe has been used as the source of the ovary-stimulating substances by Evans and Long,⁴² Putnam, Teel, and Benedict,⁴³ R  th et al.,⁴⁴ Bugbee et al.,⁴⁵ Reiss et al.,⁴⁶ Bellerby,⁴⁷ Wallen-Lawrence and van Dyke.¹⁵ The urine of pregnant women has yielded large amounts of the hormones and has been employed by Zondek⁹ who gives the name of Prolan to the resultant extract, and by Biedl,⁴⁸ Dickens,⁴⁹ Wallen-Lawrence and van Dyke,¹⁵ Evans et al.,⁴⁹ and others. The human placenta has been employed by Crew and Wiesner,¹⁰ and Collip,³⁹ and potent extracts have also been made from the blood of pregnant women (Fluhmann⁵⁰), and of mares (Goss and Cole¹¹).

SOURCE OF OVARY-STIMULATING HORMONES

Since the first studies on this problem were conducted with the anterior hypophysis, it was natural that this organ should be considered as the sole

source of the ovary-stimulating hormones. However, their wide dissemination has led to some doubt on this question and a number of investigators believe that they may also have an extra-hypophyseal origin. This conception has been advanced by Philipp,⁵¹ Collip,³⁹ Fels,⁵² Motta,⁵³ and others, who claim that the placenta must be considered as capable of manufacturing as well as storing such hormones. The chief arguments advanced in favor of the theory for a placental origin of the ovary-stimulating hormone in the blood and urine during pregnancy may be summarized briefly as follows: (1) The placenta contains very large amounts of an ovary-stimulating substance (or substances); (2) the characteristic histologic pregnancy changes in the anterior pituitary gland of women do not appear until the fifth month of gestation, although large amounts of APH are found very early in the blood and urine; (3) the Aschheim-Zondek test is positive in cases of hydatidiform mole and chorioepithelioma, and becomes negative following the removal of the tumor growth; (4) the anterior hypophysis of pregnant women contains no demonstrable amount of sex hormone (Philipp,⁵⁰ corroborated by Ehrhardt and Mayes,⁵¹ Zondek,³⁷ and others); (5) the substance Emmenin which Collip obtains from the placenta, and which he maintains should be considered as an ovary-stimulating hormone, differs from anterior hypophyseal extracts in its chemical properties and in many of its biological effects; (6) some differences in the effects of urine extracts and anterior pituitary implants have been reported, thus suggesting that

they may not be identical* (Engle,⁵⁴ Wallen-Lawrence and van Dyke,¹⁵ Evans et al,⁴⁹ Loeb⁵⁵); (7) the report of Hill and Parkes⁵⁶ and of Reichert et al^{57,58} that urine extracts are relatively ineffective in inducing ovarian changes in hypophysectomized rabbits, dogs, and rats may be interpreted as meaning that these preparations are not hypophyseal hormones since they apparently cannot substitute for this organ.

It would seem that there is evidence in favor of an extrahypophyseal origin for ovary-stimulating hormones, but on the other hand there has been considerable opposition to accepting this theory. In the first place, the presence of the hormones in the placenta by no means necessitates their manufacture there, and it would be just as reasonable to state that ovarian cysts and the mammary and salivary glands also can produce ovary-stimulating substances since they have been found in cyst fluid (Zondek³⁷), milk and colostrum (Heim²⁶), and saliva (Trancu-Rainer²⁷). The characteristic pregnancy changes of the anterior lobe may not be complete until the fifth month, but on the other hand the large amount of hormones in the urine appears so early in pregnancy that some doubt must be expressed as to whether the placenta has sufficiently developed at that stage to produce such quantities (Zondek³⁷). The diminished amounts of ovary-stimulating substances present in the anterior lobe of pregnant women may not mean a lowered production on the part of this gland but an increase in

their utilization by the body so that none remains stored up in the hypophysis (Zondek³⁷). In pregnant cows and pigs there is no hormone demonstrable in the blood or urine, and since there is not the same call for large amounts of this substance as there is in the human, the anterior lobe of these animals has a normal hormone content. The experiments of Collip with Emmenin show that he is dealing with a hormone which apparently has no counterpart in the anterior lobe, and some doubt must be expressed as to whether it can strictly be included in the group of "ovary-stimulating" substances considered in this paper because it does not produce histologic changes in the ovaries of immature rats and is effective in young castrates (Collip³⁹). The biological differences between anterior lobe and urine extracts is an important observation, but is not necessarily conclusive evidence that the hypophysis is not the source of the ovary-stimulating substances. Some of the variable results may be due to differences in dosage, and the preparation of the extracts may possibly cause chemical changes interfering with the normal action of the hormones. This is well illustrated by the experiments of Hill and Parkes⁵⁹ who found that they were unable to induce ovarian changes in hypophysectomized rabbits with urine extracts but could produce this effect fairly readily by the injection of untreated urine.

This question must therefore remain open for the present. It is considered proved that an ovary-stimulating hormone is manufactured by the anterior hypophysis, but the origin and the exact nature of that found in women during pregnancy is not established.

*Since this paper was written a year ago additional evidence has accumulated pointing to biological differences in the ovary-stimulating principles of the anterior hypophysis from those of blood or urine of pregnant women.

THERAPY

It was only natural that as soon as active preparations of this hormone were available, attempts should be made to utilize it as a therapeutic agent. It was also to be expected that it should be applied to the treatment of functional conditions which have generally been considered as of "hypo-ovarian" origin. It is very generally appreciated that there are many difficulties associated with the care of such symptoms and not diseases are treated and that there is an unknown percentage of spontaneous recoveries. In addition, the question of determining proper dosage and methods of administration is one which is as yet unsolved. However, a number of favorable reports dealing with the use of ovary-stimulating preparations in women with amenorrhea, delayed menses, and scanty menses are available (Zondek,⁹ Campbell and Collip,⁶⁰ Seitz,⁶¹ Hirschhardt,⁶⁴ and others) and suggest that this method of approach must be thoroughly investigated. The good results from the injection of whole blood or blood serum from human pregnant donors reported by de Maortua⁶⁵ and Esch,⁶⁶ as well as Zondek's experiments with the extracts⁹ suggest that a solution may be found in the combined administration of ovary-stimulating and ovarian hormones. It is also worthy of note that Zondek⁹ observed a congestion of the pelvic organs and an increase of the temperature of the vagina and rectum following the use of Prolan, and recommends this procedure as part of the conservative treatment of pelvic inflammatory dis-

ease. This is of interest since it has been shown that a much more extensive response of tissue histiocytes to a local irritation can be elicited in the rabbit's uterus when a condition of pseudopregnancy has been set up by the injection of pregnancy urine (Fluhmann⁶⁷).

The most hopeful therapeutic result reported to date, however, is the use of ovary-stimulating extracts made from pregnancy urine or placentae for the treatment of certain types of menorrhagia and metrorrhagia (Martin,⁶⁸ Campbell and Collip,⁶⁰ Novak and Hurd,⁶⁹ Siebke⁷⁰). The large percentage of favorable results which has been obtained by this method for the control of the hemorrhages associated with hyperplasia of the endometrium is very impressive, and it would seem that we now have an effective medical treatment for these patients.

COMMENT

It is thus seen that the ovary-stimulating hormone (or hormones) is a very important factor in the normal physiology of the sexual organs, but it would be hazardous to attempt an exact evaluation of its rôle owing to the obscurity that yet exists as to the interrelationship of the ovaries and the anterior hypophysis. It is evident, however, that it does play a vital part, and as future work yields further information regarding the factors that control the interaction of these glands it will be possible to understand more fully many obscure features concerning puberty, menstruation, pregnancy, and lactation.

On the other hand, it cannot be denied that much progress has also

been made from a clinical standpoint. In the first place, this work has given a new diagnostic procedure, the Aschheim-Zondek test, which has received worldwide approbation and is in general usage. This test is not only highly efficient in recognizing early pregnancy but has been utilized as a control for the successful treatment of chorioepithelioma and hydatidiform mole. Secondly, a more extended use of this test has yielded an additional method of approach for the study of certain endocrinological conditions which are accompanied by disturbances of menstruation. As these investigations are carried further and coupled with studies on the ovarian hormones, there is no doubt that new light will be thrown on the etiology of various disturbances such as amenorrhea, polymenorrhea, and the menopause. And finally, some progress has been recorded from the therapeutic use of ovary-stimulating principles. The results in no way can be said to compare with the hopes and enthusiasm that their discovery initiated, but the mere fact that there is now an effective medical treatment for the uterine hemorrhage accompanying hyperplasia of the endometrium justifies all these endeavors.

SUMMARY

The term "ovary-stimulating hormone" is used for certain biological

substances which stimulate the growth of graafian follicles, ovulation, and corpus luteum formation, resulting in the production of the ovarian hormones estrin and progesterin. It is believed that there are two such hormones, but the evidence is incomplete. The ovary-stimulating principles are chiefly in the anterior hypophysis, but during pregnancy in the human they are widely disseminated in the body of the mother and of the fetus. They have been demonstrated also in the blood and urine of patients with amenorrhea, following castration, and in the post-climacteric period. The evidence obtained to date favors the conception that the anterior lobe of the hypophysis is the main source of these hormones, but it has been suggested that one type may have an extra-hypophyseal origin. From a clinical standpoint, three important advantages have resulted from these studies: (1) the development of an important test for the diagnosis of pregnancy and the control of the treatment of chorioepithelioma and hydatidiform mole; (2) the employment of a new method of approach for the study of certain endocrinological conditions which are accompanied by ovarian disturbances; and (3) the use of extracts of ovary-stimulating hormones for the successful treatment of the uterine hemorrhages accompanying hyperplasia of the endometrium.

Animal Experiments with Adrenal Cortical Extracts*†

By J. L. CARR, M.D., and C. L. CONNOR, M.D.,
San Francisco, California

SINCE the extraction of a potent principle from the adrenal cortex by Swingle and Pfiffner¹⁰ and by Hartmann⁸ much greater interest has centered upon this gland than ever before. Animal experimentation has at last acquired a tool to work with, and it is being used extensively. Great hopes have been entertained for the successful treatment of Addison's disease, and the cortical extract has been used for this purpose with some degree of success by Rowntree and others.¹⁰ The very nature of this condition, however, would preclude the possibility of a cure, since it is caused in most cases by a progressive, destructive lesion of the adrenal glands. The only hope therefore is that cortical extract can replace the normal secretion. This would mean lifelong treatment, though in rare instances of tuberculosis of the glands, it might be that treatment would be necessary only through a critical period of greatest adrenal insufficiency and could be discontinued if the disease in the glands became arrested. Examples of cured

or healed tuberculosis of the adrenals, however, must be very rare.

One is reminded of the discovery of insulin, and the optimism which prevailed as to the cure of diabetes; but in spite of insulin, the mortality from this disease is greater than ever.¹⁴ Also, the failure of Collip's parathormone to replace completely the secretion of the parathyroid glands has been reported by Lisser and Shepardson.¹⁰ Because of these recent experiences, adrenal cortical extract has probably not excited clinicians as much as it has those working in the field of experimental biology. For the present, its biological significance far outweighs the possibility of its clinical application.

Even before a cortical extract was available, a considerable amount of knowledge had been assembled through clinical observation and pathological study, as well as by experiments upon the effects of adrenalectomy. Briefly, lesions causing hypofunction of the cortex have been associated with: (1) pseudohermaphroditism in the newborn; (2) a questionable failure of development of the central nervous system in anencephaly (probably coincidental); (3) hyperplasia of the

thyroid²¹; (4) Addison's disease; (5) myasthenia gravis.

Lesions which cause hyperfunction of the adrenals (hyperplasia, adenomas, functioning carcinomas) are associated with, or may cause: (1) precocious puberty; (2) so-called adrenal virilism, masculinism, or a condition of pseudohermaphroditism in the adult female; less well-defined sexual changes (as gynecomastia) in the adult male. This list omits, of course, all conditions which have been attributed to malfunction of the adrenal medulla.

It is these physical and sexual changes which have interested us most. The adrenal cortex is so intimately bound up with, not only the phenomenon of reproduction, but the physical configuration of the body, that these aspects seem to be of much greater biological significance (and probably, in the future, of greater practical significance) than the more dramatic, but much more rare disease called Addison's disease. We have, therefore, confined our studies to a few of the thyroid and sexual phases now susceptible of investigation. Rats were used advisedly, despite the impression that the adrenals cannot be removed completely from these animals. Pencharz, Olmstead and Giragossintz¹⁵ and Freedl, Brownfield, and Evans⁶ have shown that when a careful operation is performed, all rats die in from five to eight days. Carr, in this work, has had an average mortality of 88 per cent in less than eight days. In those rats which did not develop signs of acute insufficiency in six days, it was concluded that the operation had not been complete, and the animals discarded, unless the experiment called

for animals in a state of chronic insufficiency. It is not our purpose in this paper to detail the large number of animal experiments which have been made, but rather, by citing some of the results, to point out the trend of adrenal gland investigations, and to show how these, in time, will undoubtedly clear up many clinical problems. Biological research can no more be divorced from clinical medicine than can mathematics from astronomy.

The connection between the adrenal glands and the gonads is obvious in spite of many apparent contradictions. The production of precocious puberty and the neutralization of the sex glands after puberty by hyperfunction of the adrenal cortex presents a seeming paradox. One case of masculinism reported by Gibson,⁷ and seen by us, had the hirsutism and enlarged clitoris of adrenal virilism (she had a large adrenal tumor at operation), but while presenting these masculine features, she also had definite hyperplasia of the endometrium exactly similar to the decidual reaction of pregnancy. Corey and Britton⁵ have reported a change in the ovaries and testes of rats following the administration of Swingle and Pfiffner's extract which they interpret as evidence of precocious puberty, and Connor³ has reported degeneration of the ovaries of chickens following injections of a watery extract of adrenal cortex. Müller¹² likewise produced regressive changes of the sexual apparatus of rats. We were able⁴ to stop the estrus cycle of mature rats by injections of watery extracts of adrenal cortex, but, using an extract prepared by us after Swingle and Pfiffner's method, we

could not confirm Corey and Britton's results as to precocious puberty. It is nevertheless obvious that at least some of the sexual changes which have been found clinically have been reproduced experimentally, and that certainly progress towards the solution of these problems may be reported.

The retrograde sexual changes in adrenal insufficiency were first noted in a series of eighty normal animals. Following the estrus cycles of mature female white rats by vaginal smear we found that the normal sexual rhythm stopped following adrenalectomy. Autopsy findings in these animals showed a consistent and early degeneration of the corpora lutea of menstruation. It was this association that led Vincent²⁰ to suggest that the corpora lutea acted as accessory adrenal cortices, and by this mechanism Stewart and Rogoff¹⁸ explained the longer postoperative survival period of pregnant dogs. The corpora lutea of rats are constantly present in the rat ovary as bodies of menstruation, lactation, or pregnancy. We were able to observe the same degeneration of the corpora lutea in three biological stages, that is not only during the estrus cycle but also in the ovaries of either lactating or pregnant animals after adrenalectomy. Similarly, subsequent to the degeneration, lactation ceased and if occurring on or before the sixteenth day of gestation, pregnancy was interrupted. The corpora lutea are not essential in pregnancy after the seventeenth or eighteenth day of gestation, and although after this period the same degeneration of the corpora lutea was noted, the animals went on to term, either delivering without lactation and

dying a few days after parturition or dying in labor from asthenia and uterine inertia with the young stuck in the birth canal. It would seem then that these retrograde changes in adrenal insufficiency work by a secondary mechanism through the corpora lutea which degenerate, interrupting all normal sexual processes.

With an extract made after the manner of Swingle and Pfiffner, and known, through constant assay on adrenalectomized rats to contain the viable principle described by them, we attempted to prevent this degenerative change. With this extract we were unable to do so. The corpus luteum degeneration with inhibited estrus, or lack of lactation and abortion in the pregnant animal, continued as usual. In fact the degenerative changes were more marked in several injected cases than in those animals with untreated adrenal insufficiency. In the male, loss of libido and potency were noted due to degeneration of the cells of the seminiferous tubules. Here again a cortical extract known to contain the viable principle was ineffective in maintaining potency and preventing this degenerative change. It seemed to hasten rather than to retard it.

To study Vincent's theory that the sex glands contribute a substance to augment or replace cortical secretion, the postoperative survival period of adrenalectomized animals with and without the gonads was taken. Both in males and females the animals without gonads lived longer than those with, although cortical extract would keep either class alive indefinitely.

For many years Warthin²¹ insisted that Graves' disease was a constitu-

tional disease of which hyperplasia of the thyroid was only a part. He called attention to the presence also of hyperplasia of the thymus and lymphoid apparatus and hypofunction of the adrenal glands. Experimental evidence has been accumulating that part, if not all, of this anatomical complex can be produced by causing adrenal insufficiency. Jaffe⁹ noted hypertrophy of the thymus in adrenalectomized animals. Marine, Manley, and Baumann¹² observed the same thing, with also hypertrophy of the thyroid. More recently Scott and Bradford¹⁷ regularly found an enlargement of the thymus in adrenal insufficiency. We can add that animals suffering from total or partial lack of adrenal cortical secretion show definite enlargement of the thymus as well as generalized lymphoid tissue hyperplasia, and a peculiar change in the thyroid to be regarded as an hypertrophy rather than a true hyperplasia. There is a change in the staining quality of the colloid, and a prominence of the acini not found in the normal gland. A more prolonged experiment may produce more pronounced changes.

Zwemer and others have found that thyroidectomized cats live longer after adrenalectomy than normal adrenalectomized animals. If the normal adrenalectomized cats are given thyroid extract the postoperative survival period is still further shortened. We have found this mechanism operative in the rat, the animals with both adrenals and the thyroid gland removed living 35 per cent longer than adrenalectomized animals retaining the thyroid gland. If the simple adrenalectomized animal is given thyroid ex-

tract, the survival period is still further shortened. We are at present giving both thyroid and adrenal cortical extract to adrenalectomized rats to discover whether or not this antagonism, biologically suggested, exists in the chemically extracted gland substance.

These specific changes are interesting but still less important clinically than the reaction of animals with adrenal insufficiency to environment and diet. For instance, we have been able to vary the postoperative survival period of adrenalectomized animals over 100 per cent by regulations of diet alone. Certain vitamin deficiencies and a high protein diet shorten the survival period, while a high fluid intake, additions of starches and other substances, extend it. Wide daily fluctuations in temperature influence the animals badly, while a climate a degree or two above that of the body is beneficial.

We believe that the diet and other elements of general treatment are as important in maintaining the life of animals with adrenal insufficiency and of patients with Addison's disease as is the extract itself, and that while this extract does maintain life it still lacks certain components essential to a biological equilibrium.

SUMMARY

We have shown that a definite connection exists between adrenal insufficiency and such changes in the lymphoid apparatus as regeneration or hypertrophy of the thymus and hyperplasia of the lymphoid elements.

In the thyroid an increase in size accompanies adrenal insufficiency. The

removal of the thyroid gland extends the postoperative survival period of adrenalectomized animals. Those with adrenal insufficiency are killed by a dosage of thyroid extract which does not affect the normal animals.

The reproductive system responds to adrenal insufficiency by: a cessation of estrus; a softening and atrophy of the testicles; abortion or resorption of the fetuses (if the insufficiency occurs before the seventeenth day of gestation); and cessation of lactation. All of these changes apparently operate

through the secondary atrophy of the gonads.

We were unable to prevent any of these changes by administering cortical extract carrying the viable principle.

The effect of the extract in normal animals has produced a cessation of the estrus cycle of rats, and degeneration of the ovary of chickens.

Finally, cortical extracts as made by us either contain more than one principle or else we have not extracted the complete biological unit.

Editorials

"MEDICAL CARE FOR THE AMERICAN PEOPLE"

At a meeting of the Board of Regents of the American College of Physicians on February 7, 1933, the Committee on Public Relations offered a report on the final publication of the Committee on the Costs of Medical Care, entitled "Medical Care for the American People." By a resolution, the Board of Regents approved the report of the Committee on Public Relations and directed that it be printed in the ANNALS OF INTERNAL MEDICINE.

REPORT OF THE COMMITTEE ON PUBLIC RELATIONS

The final report of the Committee on the Costs of Medical Care is entitled: "Medical Care for the American People."

It is the twenty-eighth publication of a series representing an extensive and intensive effort to collect the factual data concerning numerous problems involved. These studies were made over a period of five years, with the expenditure of an extraordinary amount of thought, effort, and money.

The facts presented are of immense importance to the country as a whole and the medical profession in particular. They deserve the most careful study and consideration.

The detailed information is contained in the twenty-seven interim reports previously published, and only

a brief summary is included in the final report. The main emphasis of the final report is placed upon certain definite recommendations proposed by the Committee as the basis for a plan of reorganization of medical practice, so as to meet the social and economic defects of the existing system brought out by the factual data.

These recommendations are in the form of separate majority and minority reports with a few members of the Committee declining to assent to either report.

The widespread discussion which has followed the publication of the final report is centered upon the recommendations suggested. This is most unfortunate as it has overshadowed the great value and significance of the studies upon which these recommendations are presumably based.

It is the opinion of your Committee that the publication of definite recommendations was premature and unjustified by the facts presented. A careful analysis of the text of the reports shows that the recommendations are really only tentative suggestions for future consideration and careful experimentation, and in our opinion should have been offered as such.

It is also our belief that the actual factual data contained in the various reports are of such value that they deserve most careful study on the part of the medical profession. These facts reveal a situation which calls for con-

sideration and action leading to modification of existing medical practice, and in any such modification the medical profession should take a leading part.

It would be very unfortunate if prejudice caused by differences of opinion concerning the recommendations should belittle the value of the facts themselves. It would be still more unfortunate if either prejudice or inaction should deprive the medical profession of its rightful position of leadership in any program for remedying existing inequalities or injustices in the operation of the practice of preventive and curative medicine.

Our Committee, therefore, recommends that the individual Fellows of the American College of Physicians be urged to study the facts presented in the report of the Committee on the Costs of Medical Care, uninfluenced by the acrimonious discussion which has been raised by the publication of the various recommendations; and we also recommend that the organized representatives of the medical profession in each community be urged to consider these problems in the light of their varying local needs and conditions, for it is our belief that by this method the enlightened leadership of the medical profession can point the way to improvements of great value, both to the public and to the medical profession itself.

THE NATIONAL BOARD OF MEDICAL EXAMINERS

Examinations and the testing of knowledge have ever been an essential part of medical training. The extraordinary development of medical knowl-

edge within the last three decades has had a bewildering effect on the entire problem, and it seems almost as if we have outrun our educational system framed in simpler days and under simpler conditions.

Osler once remarked that examinations may be the best or the worst of an education. He further stated that they can be very helpful if an integral part of the training, but have been known to be the intellectual ruin of many good men.

The multiplicity of examinations, college, hospital, and licensure, with the general lack of uniformity, emphasized the need of a central qualifying body such as the National Board of Medical Examiners. It was organized in 1915 and the first examination was held in October 1916. During the first six years the examination included written and practical tests in the six fundamental sciences and four clinical branches and lasted for a period of seven days.

In 1922 the examination was divided into three parts, the first, which is taken after the completion of two or more years of the medical school course, being a written test in the six pre-clinical sciences: anatomy, biochemistry, physiology, pathology, bacteriology, and pharmacology. The second written test includes the four clinical branches, medicine, surgery, obstetrics and gynecology, and public health, and is taken at the completion of four years of study. Part three is taken only after one year of satisfactory hospital interne service.

This examination comprises: clinical surgery, including applied anatomy, surgical pathology, and the surgical

and head specialties; clinical medicine, including neurology, pediatrics and dermatology, clinical laboratory, medical pathology and applied physiology, biochemistry, pharmacology, and roentgenology; obstetrics and gynecology, and public health (which also includes applied bacteriology).

The written tests are conducted on the proctor plan and are held in the different medical college centers in the United States and Canada. The practical and clinical part three examination is conducted at twenty centers in different sections of the country. At each of these centers a subsidiary board of examiners has been organized, under whose supervision the examination is conducted.

The membership has been gradually increased from the original fifteen members to the present membership of twenty-seven, representing the three federal medical services, the Association of American Medical Colleges, the Council on Medical Education of the American Medical Association, the Federation of State Medical Boards, and twelve members from the profession at large, selected with special reference to their geographical distribution. To prevent "life membership" and to ensure the frequent election of new members, the Constitution provides that, with the exception of the members from the Federal services, each member is elected for a term of six years and can succeed himself for one additional term only.

By continuous and intensive study a comprehensive examination has been developed in keeping with the highest medical training now prevailing in American medical schools. Successful

candidates are granted a certificate as a Diplomate of the National Board, and are permitted to use the letters D.N.B. after their names. They are so designated in the Directory issued by the American Medical Association. This certificate has been recognized by forty-two states, being accepted in lieu of the required state medical licensure examination. It is also accepted as satisfying by the qualification boards of England, Scotland, and the Irish Free State for admission to the clinical part of the final examination for entry on the British registry.

The plan of examination has served as a model for state boards and has greatly promoted the more extensive use of the practical and clinical tests in licensure examinations. The national boards of examiners in the different specialties organized in recent years have patterned their examination largely after that of the National Board.

The adoption of the examination by a number of leading medical schools is a significant endorsement. Yale University Medical School requires all students to take and pass the National Board examinations; the answer papers are graded by National Board examiners. The students at Yale take an oral comprehensive examination at the end of their second and fourth years respectively, and unless successful in these oral and practical examinations, they are not eligible for the National Board examinations.

Beginning this year Duke University requires all its students to take the National Board examination. The answer papers are held for three days, examined by the Faculty for their own purposes and records, then forwarded

to the National Board's office where they are graded in the usual way. The same plan prevails at the College of Medical Evangelists, Los Angeles, where all students are required to take the National Board examination.

At the University of Minnesota the students have the choice of taking either the National Board's written examination, or the Medical College comprehensives at the end of their second and fourth years. The papers are first graded by the Medical Faculty and then forwarded to the National Board office.

Georgetown University has announced that beginning next year it will require all students to take the National Board examination. The plan is also being considered by the University Medical Schools of Iowa, Illinois, Columbia, Colorado, Buffalo, and Washington (St. Louis), as well as several of the two-year schools.

It is interesting to note that each year a considerable number of candidates are completing their National Board examinations, after having secured their medical license, which indicates that it is steadily gaining recognition as an honors examination.

By influencing the present tendencies of medical education, unifying examination procedure, and developing a comprehensive qualifying test to determine fitness to practise, the National Board is to a certain extent fulfilling its purpose and destiny.

WALTER L. BIERRING, M.D.

SPOTTED FEVER IN THE EASTERN STATES

The identification in the rural districts of the southeastern states of a

form of Rocky Mountain spotted fever was reported by Rumreich, Dyer, and Badger in 1931. In several papers in the Public Health Reports of that year^{1,2,3} they published the evidence on which the identification was based. A clinical study was made of fifty cases of a spotted fever occurring during the tick season in rural districts of Delaware, Maryland, Pennsylvania, Virginia, North Carolina, and the District of Columbia. These cases were compared with fifty urban cases of typical endemic typhus occurring in Baltimore, Savannah, Tampa, and in smaller urban communities in Georgia and Florida. Suggestive clinical differences were found between the two groups of cases. The rural group showed evidence of a more severe infection by greater prostration, higher fever, and a faster pulse. The rash in the typhus group appeared first on the trunk, was less marked on the forearms, and rarely involved the palms. In the rural cases, however, the rash appeared first about the wrists and ankles, usually involved the palms and soles, spread rapidly over the whole

¹DYER, R. E., RUMREICH, A., and BADGER, L. F.: Typhus fever; a virus of the typhus type derived from fleas collected from wild rats, Pub. Health Rep., 1931, xlv, 334-338.

²RUMREICH, A., DYER, R. E., and BADGER, L. F.: The typhus-Rocky Mountain spotted fever group; an epidemiological and clinical study in the eastern and southeastern states, Pub. Health Rep., 1931, xlv, 470-480.

³DYER, R. E., BADGER, L. F., and RUMREICH, A.: Rocky Mountain spotted fever (eastern type); transmission by the American dog tick (*Dermacentor variabilis*), Pub. Health Rep., 1931, xlv, 1403-1413.

trunk, and frequently became purpuric and confluent.

Disturbances of the central nervous system of a severe order, such as meningismus, clonic twitching, and coma, were more common in the rural group. The death rate in this rural group was 14 per cent, while there were no fatalities among the fifty cases of endemic typhus. The duration of the disease in the endemic typhus group was from eleven to sixteen days, with twenty-eight of the cases terminating on the fourteenth day. Over half of the rural cases, however, persisted to between the seventeenth and the twenty-second day. It was felt by the authors that the disease in the rural group of cases did not correspond to the clinical picture of endemic typhus but resembled the spotted fever of the Rocky Mountains more closely than it did any other disease. This suggestive clinical differentiation was supported by epidemiologic data showing that in addition to the distinguishing feature of urban, as opposed to rural, residence the typhus group gave a history in thirty-nine cases of association with rats and presumably rat fleas, whereas in the rural group rodent infestation of patients' homes was determined in only seven cases. Twenty-four of these rural cases, however, gave a history of tick bite within three weeks prior to the onset, and three more of the patients had crushed engorged ticks removed from dogs. All had lived in tick-infested localities.

Blood from three cases of the rural type was injected into guinea pigs that proved susceptible, and strains of virus were perpetuated through many generations of these animals by transfers.

The lesions of the disease in guinea pigs were found in general to be similar to those caused by the Rocky Mountain spotted fever virus. Guinea pigs which had recovered were found to be still susceptible to the virus of endemic typhus and of European epidemic typhus but to be unaffected by inoculation with the virus of Rocky Mountain spotted fever.

An account of the gross and microscopic pathology of the eastern type of Rocky Mountain spotted fever, based on a study of five autopsies, has been presented in an article by Lillie.⁴ In general the lesions found were similar in character, if not always in degree of severity, to those described in the twenty-one reported autopsies of Rocky Mountain spotted fever. In such small series minor variations might well be expected. It would seem, however, that in the eastern type focal brain lesions of vascular degenerative, proliferative, and focal gliotic character were more frequent than in the western form of the disease. These brain lesions were apparently closely similar to those described in European typhus. Lillie mentions the finding of "cell inclusions resembling rickettsiae in the endothelia and walls of small vessels". A more definite identification of rickettsiae in the human tissues is reported by Pinkerton and Mancy⁵ in connection with their study of a fatal case which at the time was

⁴LILLIE, R. D.: Pathology of the eastern type of Rocky Mountain spotted fever. Pub. Health Rep., 1931, xlv, 2840-2859.

⁵PINKERTON, H., and MANCY, K. F.: Pathological study of a case of endemic typhus in Virginia with demonstration of *Rickettsia*, Am. Jr. Path., 1931, vii, 95.

thought to be one of endemic typhus, but which Maxcy now believes to have been spotted fever. More recently the identification of rickettsiae in the tissues of three cases of spotted fever has been reported by Pincoffs and Shaw.⁶

The occurrence of spotted fever on the eastern coast is therefore established by clinical epidemiological, immunological, and pathological data. Our knowledge, however, of the occurrence of the virus in nature in this eastern territory is still entirely fragmentary. It has been shown that the American dog tick (*Dermacentor variabilis*), which is the most common man-biting tick in most of the known infected area, can transmit the virus from guinea pig to guinea pig and that the virus in the tick persists through at least one moult. The importance of this species of tick as a vector of the disease in the east is further established by the finding, in an infested area, of dog ticks which were proven to be infectious by animal inoculation.⁷ Further extensive studies of the other

eastern ticks that may be possible vectors, and of the susceptibility of eastern rodents and small mammals which may serve as hosts, will no doubt be carried out to bring our knowledge of the maintenance of the eastern virus in nature at least abreast of what is known concerning the western virus of this disease.

It cannot readily be determined whether we are witnessing the appearance of spotted fever in the east or merely its discovery. The striking clinical characteristics of the disease favor the presumption that it could not have gone unrecognized as a clinical entity for many years. The heavy tick infestation of the southeastern states and the relatively dense human population in the same area make of all this region a potentially more important focus of the disease than the sparsely settled mountain states. That there are as yet unknown factors which affect the extension of the disease is shown, however, by the well known example of the situation in the Bitter Root valley. In this region spotted fever in humans has been known on the western side of the valley for over thirty years but has not yet spread to the eastern side, though the wood tick which transmits the virus and the rodents which serve as hosts are present on both sides. Study of this disease in the east may disclose similar instances of geographic limitation.

⁶PINCOFFS, M. C., and SHAW, C. C.: The eastern type of Rocky Mountain spotted fever; report of a case with demonstration of rickettsiae. Medical Clinics of North America, March, 1933. (In press)

⁷BADGER, L. F.: Rocky Mountain spotted fever (eastern type); virus recovered from the dog tick *Dermacentor variabilis* found in nature. Pub. Health Rep., 1932, xlvii, 2365-2369.

in science, whose interests in the developments of physical chemistry are secondary.

The subjects discussed are: The Methods of Science, Atomic Structure, Transmutation of the Elements, Valence, Radiations on Chemical Systems, New Elements and New Uses for Old Ones, and the Elixir of Life.

The first chapter, "Methods of Science", embraces many of the fields of the biological and physical sciences. The interrelationship of the development of each is emphasized. Although the treatment of each subject is superficial, owing to the nature of the volume, much striking philosophy has been included. Thus under psychology one reads, "The function of philosophy is to integrate all branches of science and form from them a closely interrelated whole."

The chapter on the "Elixir of Life" should be found interesting by medical readers. Herein the history of the futile search by the chemist for the "Elixir of Life" is reviewed. The rise of iatrochemistry, the work of Pasteur, the major conquests in the field of bacteriology and the advance of chemotherapy are developed. The sociological and international difficulties involved in the control of communicable disease are discussed.

In the introduction the authors mention that the writing of this volume was suggested by the late Dr. E. E. Slosson. In the book the spirit of Slosson is perpetuated, lending to the volume a warmth of interest and ardor which was so characteristic of the pen of that great master in this field of literature.

J. C. K., Jr.

The History of Dermatology. By WILLIAM ALLEN PUSEY, A.M., M.D., LL.D., Professor of Dermatology Emeritus, University of Illinois; President of the American Dermatological Association and of the American Medical Association from time to time. Fabricoid Linen. 233 pages, 33 illustrations. Charles C. Thomas, Springfield, Ill. and Baltimore, Md., 1933. Price \$3.00.

Any work from the pen of William A. Pusey, the Nestor of American Dermatology, must be good, and his latest *History of Dermatology* is no exception. It is a concise, absorbing story of the growth and development of dermatology from ancient times to, and including, its present status as a branch of medicine burdened with a nomenclature fearfully and wonderfully

made. The history is written in a plain unassuming style, readable and understandable by lay and professional alike. The very close, intimate, and inseparable relation between dermatology and medicine is made evident in the introduction. Since skin lesions in many instances are simply reflections of a disturbance of the general economy, it is difficult to draw a hard and fast line between the specialty and general medicine.

The early chapters deal with the development and the observations of the ancients and their interpretation of the macroscopic appearance of lesions. Later the story is taken up by periods in the various countries, Germany, Austria, Great Britain, and the United States.

It is disappointing, however, to note that Henry Stelwagon's work in dermatology is dismissed with but a few words. His monumental work on the *Diseases of the Skin* is lauded, but there is no mention of his other writings.

The intimate association of dermatology and venereal diseases as practised in foreign countries is recognized in a graphic account of the life of Neisser, whose name is inseparably associated with the discovery of the gonococcus. Ricord, whose fame rests upon his urological contributions, is given credit for his epoch-making experiments by which he differentiated the local results of the inoculation of gonorrhoeal pus from the systemic reaction of pus originating from a primary luetic lesion.

A unique and praiseworthy contribution to the literature is an *Historical Index of Dermatology* in which is given historically a sketch of the various diseases from Acanthosis Nigricans to Zona.

The appearance of the volume is not to be overlooked. It is printed on heavy glazed paper in large readable type. The cover design and the binding of fabricoid linen are additional attractive features. The numerous illustrations and photographs are unusually well reproduced and of a kind seldom seen in historical works.

The volume should find a place not alone in the library of every dermatologist but should be read and treasured by everyone interested in the growth and development of medicine.

M. S. R.

GEORGE MORRIS PURSON, B.S., M.D., Philadelphia
President, 1933-1934

GEORGE MORRIS PIERSOL, B. S., M. D.,

Philadelphia

President of the AMERICAN COLLEGE OF PHYSICIANS

1933 - 1934

Born, Philadelphia, October 13, 1880; graduated, William Penn Charter School, 1898; University of Pennsylvania, B. S., 1902; University of Pennsylvania School of Medicine, M.D., 1905.

Resident Physician (1905-1906), and Chief Resident Physician (1906-1907), Hospital of the University of Pennsylvania, Philadelphia; Professor to the Professor of Anatomy (1907-1910), and Associate in Medicine (1912-1921), University of Pennsylvania School of Medicine; Physician, Episcopal Hospital, Philadelphia, 1912-1916; Professor of Medicine, Woman's Medical College of Pennsylvania, 1917-1922; Lieutenant Colonel, Medical Corps, U. S. Army, 1917-1919; Commanding Officer, U. S. Army, Base Hospital No. 20, A.E.F., 1918; Medical Consultant, Fourth Army Corps, A.E.F., 1918-1919.

Professor of Medicine and Vice Dean of Medicine, Graduate School of Medicine of the University of Pennsylvania; Physician, Graduate Hospital of the University of Pennsylvania; Physician-in-Chief, Abington Memorial Hospital, Abington; Active Consultant in Medicine, Philadelphia General Hospital; Consultant to the Preston Retreat and the Chestnut Hill Hospital; Medical Director, Bell Telephone Company of Pennsylvania; Editor, *The Cyclopedia of Medicine*; ex-Editor, *The American Journal of Medical Sciences*; author of numerous medical articles.

Member: Delta Tau Delta, Alpha Mu Pi Omega, Sigma Xi and Alpha Omega Alpha fraternities; Member and ex-President, Philadelphia County Medical Society; Member, Medical Society of the State of Pennsylvania; Fellow, American Medical Association; Member, Association of American Physicians; Member and ex-President, American Gastro-Enterological Association; Member and ex-President, American Climatological and Clinical Association; Fellow, College of Physicians of Philadelphia; Member, Philadelphia Pathological Society; Member, Philadelphia Pediatric Society.

Dr. Piersol became a Fellow of the College in 1922. From 1926 to 1932 he held the office of Secretary-General. He served on the Committee on Credentials for six years and gave unstintingly of his time to this laborious task. In spite of many other activities and heavy responsibilities he has always given freely of his energy and ability to the work of the College. He enters upon his term as President with an intimate knowledge of the College's problems and with a wide acquaintanceship and popularity among its Fellows.

JONATHAN CAMPBELL MEAKINS, M.D.C.M., LL.D. (Edin.), Montreal
President-Elect, 1933-1934

JONATHAN CAMPBELL MEAKINS, M.D.C.M., LL.D. (Edin.),
F.A.C.P., F.R.C.P. (C), F.R.C.P. (Edin.), Hon. F.R.C.S. (Edin.),
F.R.S.C., F.R.S.E.,

Montreal

President-Elect of the AMERICAN COLLEGE OF PHYSICIANS
1933 - 1934

Born, Hamilton, Ontario, May 16, 1882. Graduated, Hamilton High School; McGill University, M.D.C.M., 1904. Resident Physician, Royal Victoria Hospital, Montreal, 1904-1906; Assistant in Medicine, Johns Hopkins Hospital, 1906-1907; Resident Pathologist, Presbyterian Hospital, New York City, 1907-1909; Lecturer in Clinical Medicine, McGill University, and Assistant Physician, Royal Victoria Hospital, 1909-1913; Canadian Army Medical Corps, 1914-1918; Member, Inter-Allied Chemical Warfare Conference; Consultant Physician, Canadian Army Medical Corps, 1918-1919; Christison Professor of Therapeutics and Professor of Clinical Medicine, Edinburgh University, 1919-1924; Director of Medical Research Laboratories, Edinburgh University and Royal Infirmary, 1920-1924; Consulting Physician, Royal Maternity and Simpson Memorial Hospital, Edinburgh, 1923-1924.

Director of the Department of Medicine and Professor of Medicine, McGill University, Montreal; Director of the University Clinic, McGill University; Physician-in-Chief, Royal Victoria Hospital, Montreal.

Member: The Physiological Society (Great Britain); The British Medical Association; The Canadian Medical Association; Association of American Physicians; The American Physiological Society; Society of Experimental Biology and Medicine; The Montreal Medico-Chirurgical Society; and others.

Dr. Meakins has made numerous and important contributions to the medical literature in many fields. His investigations on the pathological physiology of the respiration and the circulation are very widely known.

Dr. Meakins was elected a Fellow and a Regent of the American College of Physicians in 1928. He was appointed Chairman of the Seventeenth Annual Clinical Session in Montreal, the first meeting of the College in Canada. Under his guidance, this very successful meeting set a high standard in the excellence of arrangements and the quality of the program of clinics.

College News Notes

Dr. Henry J. John (Fellow), Cleveland, Ohio, and Dr. William D. Sansum (Fellow), Santa Barbara, California, are members of the Advisory Editorial Board of the newly established journal, *Diabetes*, which made its first appearance in November, 1932.

Major George R. Callender (Fellow), Fort Sam Houston, Texas, has been elected President of the American Society of Tropical Medicine for the year 1933.

At a dinner given in his honor at the Drake Hotel, Chicago on January 3, 1933, the Honorable René Weiller, Consul-General of France, awarded to Dr. Frank Smithies the Cross of Knight of The Legion of Honor of The French Republic in recognition of his achievements with respect to Post-Graduate Medical Education in France and in medical science.

SOCIETY FOR THE ADVANCEMENT OF GASTROENTEROLOGY

The objects of the Society are:

- (a) To unite in one organization those physicians who are engaged in the specialty of Gastroenterology.
- (b) To correlate closely the clinical and experimental work of the specialty as it is performed everywhere and to make practical application of all recent advances in this field.

- (c) To stimulate and encourage research work in every phase of Gastroenterology.
- (d) To act as a control agency through which all qualifications and all requirements relating to the specialty may be standardized.
- (e) To formulate the highest standards and principles for the practise of the specialty.
- (f) To encourage legislation and public support as related to the specialty.
- (g) To edit and publish the proceedings of the Society and all matters, papers, articles, subjects and reports considered.

OFFICERS ELECTED FOR 1933

Dr. G. Randolph Manning.....President
Dr. I. L. Ritter.....1st Vice-President
Dr. E. Katz.....2nd Vice-President
Dr. Wm. C. Jacobson.....Secretary
Dr. S. Munson.....Treasurer
Dr. S. Weiss.....Editor-in-Chief

ADVISORY BOARD

Dr. E. L. Kellogg, Honorary President
Dr. Max Einhorn
Dr. Jacob Kaufmann
Dr. Anthony Bassler
Dr. A. F. R. Andresen

Meetings are held on the fourth Wednesday of the month.

OBITUARIES

DR. WILLIAM SYDNEY THAYER

William Sydney Thayer, Fellow of the American College of Physicians, died suddenly of heart failure on December 10, 1932.

Dr. Thayer was born into a distinguished New England family at Mil-

ton, Massachusetts, on June 23, 1864. On his maternal side he was descended from Ralph Waldo Emerson; his father, James Bradley Thayer, and a brother, Ezra Thayer, held chairs in the Law School of Harvard University. Reared in the university atmosphere of Cambridge, where he lived

after the age of ten, he never lost contact with Harvard. He was graduated from the University as Bachelor of Arts in 1885, and as Doctor of Medicine in 1889, served as Visiting Physician (pro tem) at Peter Bent Brigham Hospital in 1914, and had completed two terms, beginning 1915, as a member of the Board of Overseers of Harvard University.

Meanwhile, he had been called to Baltimore by Osler from the Massachusetts General Hospital in 1890, and for the remaining forty-two years of his life he made his home in this city. He was, successively, Assistant Resident Physician, Resident Physician, and Head of the Medical Department of the Dispensary (1898-1906) of the Johns Hopkins Hospital. He practised medicine and held the position of Professor of Clinical Medicine in Johns Hopkins University from 1905 to 1918. In June 1917, he went to Russia as a member of the Red Cross Mission, and in March 1918, entered upon active duty with the United States Army in France and was appointed Chief Consultant, Medical Services, A.E.F., in June 1918; Brigadier-General, October 1, 1918. While in France he was asked to accept the position of Professor of Medicine on the university basis at Johns Hopkins. Returning from France, he relinquished his practice and held this post together with that of Physician-in-Chief of the Johns Hopkins Hospital until 1921. He then resigned, resumed his consultation practice, and became Emeritus Professor of Medicine; he continued to teach until the day of his death.

Many honors were heaped upon him. He was President of the American

Society of Tropical Medicine (1910), President of the American Society for Clinical Investigation (1913), President of the Congress of American Physicians and Surgeons (1915), of the Association of American Physicians (1921), and of the American Medical Association (1928-1929). He held honorary degrees from Washington College, University of Edinburgh, University of Chicago, University of Paris, and McGill University. He held Honorary Membership in the Therapeutical Society of Moscow, in the Association of Physicians of Great Britain and Ireland, and in the Industrial Society of Medical Hydrology. He was Honorary Fellow of the Royal Society of Medicine of Budapest, of the Royal College of Physicians of Ireland, of the Royal Society of Tropical Medicine and Hygiene, London, of the Royal Society of Medicine, London, and of the Royal College of Physicians of Edinburgh. He was associate foreign member of the Académie de Médecine, Paris, corresponding member of the Société des Hôpitaux de Paris, of the Société des Hôpitaux de Lyon, and of the Société Royale des Sciences Médicales et Naturelles de Bruxelles. His other affiliations and honors, some of outstanding importance, are too numerous to record in full; mention must be made, however, of his appointment to Commander, Legion of Honour (1927), and of his selection as Orator at the Bright Centenary at Guy's Hospital in 1927.

Dr. Thayer married Miss Susan Chisolm Read, of Charleston, S. C. in 1901. Although in ill health during the latter years of her life, she lived until 1917, and died during her husband's

absence in Russia. No children survive.

The loss to the medical profession of the United States from the death of Dr. Thayer is great; this is especially true because of the peculiarly individual nature of his contribution. The unique quality of the man lay in the imponderables of character, of brilliant linguistic accomplishment, of personal charm, of intense loyalty to persons and institutions and ideals. Though sought on every hand for the wisdom of his clinical judgment, which was second to none, he will be remembered by those who knew him best as one who transcended medicine and became a great man.

(Furnished by JOHN T. KING, JR., M.D., F.A.C.P., Baltimore, Md.)

DR. HENRY DASPIT

Dr. Henry Daspit died December 19, 1932, as a result of influenza-bronchopneumonia. He had been sick but a few days and was rapidly overwhelmed by the severity of the infection.

Dr. Daspit graduated from Tulane University in 1907 and promptly obtained a position in the Louisiana State Hospital for the Insane, at Jackson, which led to his subsequent interest in neuropsychiatry, in which he specialized thereafter. On his return to New Orleans from Jackson he served in various ranks in the Department of Nervous and Mental Diseases of Tulane Medical School, obtaining in 1921 the Professorship of Neurology and, in 1926 when the chair of Psychiatry was combined with that of Neurology, he held this twofold po-

sition. In 1928 he became Dean of the Graduate School. In addition to these two positions, at the time of his death he was a senior visiting physician at Charity Hospital, superintendent of the City Hospital for Mental Diseases and City Alienist; he was consultant in Neurology for the United States Marine Hospital No. 14 and held a similar position in some four or five other hospitals. His interest was not confined solely to his specialty and to his pedagogic activities. He was a public-minded citizen and a goodly portion of his time was occupied with many sociologic and hygienic activities.

A member of an old French family, Dr. Daspit happily combined attributes of friendliness, charm and sociability, so that he had a host of friends as well as innumerable acquaintances. Clear thinking, kindly and always willing to help others, his advice and assistance were sought by many.

He was well known in Louisiana, Mississippi, Alabama, and Texas through his contact with the undergraduate students and the graduate students of the Medical School of Tulane University. His death came as a shock to the many who had been taught by him and who have always known him as a keen, physically active, and industrious teacher.

In 1927 he became a Fellow in the American College of Physicians and was interested intensely in its activities and its program. He did much to further the purposes of the organization and was enthusiastic in his belief in what could be accomplished by it.

(Furnished by J. H. MUSSER, M.D., F.A.C.P., New Orleans, La.)

DR. FENTON BENEDICT TURCK

Dr. Fenton Benedict Turck (Associate), New York City, died November 16, 1932, of angina pectoris; aged seventy-five years.

Dr. Turck received his medical degree from the Northwestern University Medical School in 1891. He did postgraduate work at the Pathological Institute of Berlin. He was House Surgeon in the Alexian Brothers Hospital, Chicago, 1891-92; Instructor in Internal Medicine at the Postgraduate Medical School, Chicago, 1893; Lecturer, Jefferson Medical College of Philadelphia, 1896; Lecturer, University of Rome, Italy, 1906; and the Founder and Director of the Laboratory, Turck Foundation, at the time of his death.

Dr. Turck was the author of 102 articles published in the United States and Europe. During the World War, he held the rank of Captain in the Medical Corps of the U. S. Army. He was a member of King's County Medical Society, the New York State Medical Association, the American Association for Advancement of Science, the Association for the Study of Internal Secretions, the Royal Geographic Society (Lisbon), Société d'Urologie de France, and a Fellow of the American Medical Association and of the New York Academy of Medicine. He had been an Associate of the American College of Physicians for many years.

DR. ALFRED HENRY

Dr. Alfred Henry (Associate), Indianapolis, Indiana, died suddenly De-

cember 12, 1932, of angina pectoris; aged fifty-seven years.

Dr. Henry graduated from the Indiana Medical College, School of Medicine of Purdue University, Indianapolis, in 1907. He did postgraduate work at the Trudeau Sanatorium and at Bellevue Hospital of New York City. From 1914 to 1920, he was Professor of Anatomy, Normal College of Gymnastic Union; from 1916 to 1921, Professor of Physiology, Indiana Dental College; and since 1912, he had occupied various teaching positions on the staff of the Indiana University School of Medicine, being Clinical Professor of Medicine at the time of his death.

In 1911, Dr. Henry aided in the organization of the Marion County Tuberculosis Association, becoming its first president and serving in that capacity until 1927, when he retired. He was prominent in state anti-tuberculosis activities and was elected President of the Indiana Tuberculosis Association in 1917. He was a director of the Indianapolis free tuberculosis clinics from 1911 to the time of his death. In 1916, he was president of the Mississippi Valley Conference for Tuberculosis Workers. He was president of the National Tuberculosis Association for the year 1931-32.

Some of Dr. Henry's additional appointments included: President of Board of Directors, Sunnyside Sanatorium, Oaklandon; Member of Staff, St. Vincent's Methodist Hospital, Robert W. Long Hospital and the James Whitcomb Riley Hospital for Children. He had been an Associate of the American College of Physicians since 1921.

absence in Russia. No children survive.

The loss to the medical profession of the United States from the death of Dr. Thayer is great; this is especially true because of the peculiarly individual nature of his contribution. The unique quality of the man lay in the imponderables of character, of brilliant linguistic accomplishment, of personal charm, of intense loyalty to persons and institutions and ideals. Though sought on every hand for the wisdom of his clinical judgment, which was second to none, he will be remembered by those who knew him best as one who transcended medicine and became a great man.

A member of an old French family, Dr. Daspit happily combined attributes of friendliness, charm and sociability, so that he had a host of friends as well as innumerable acquaintances. Clear thinking, kindly and always willing to help others, his advice and assistance were sought by many.

He was well known in Louisiana, Mississippi, Alabama, and Texas through his contact with the undergraduate students and the graduate students of the Medical School of Tulane University. His death came as a shock to the many who had been taught by him and who have always known him as a keen, physically active, and industrious teacher.

In 1927 he became a Fellow in the American College of Physicians and was interested intensely in its activities and its program. He did much to further the purposes of the organization and was enthusiastic in his belief in what could be accomplished by it.

(Furnished by J. H. MURPHY, M.D., F.A.C.P., New Orleans, La.)

DR. FENTON BENEDICT TURCK

Dr. Fenton Benedict Turck (Associate), New York City, died November 16, 1932, of angina pectoris; aged seventy-five years.

Dr. Turck received his medical degree from the Northwestern University Medical School in 1891. He did postgraduate work at the Pathological Institute of Berlin. He was House Surgeon in the Alexian Brothers Hospital, Chicago, 1891-92; Instructor in Internal Medicine at the Postgraduate Medical School, Chicago, 1893; Lecturer, Jefferson Medical College of Philadelphia, 1896; Lecturer, University of Rome, Italy, 1906; and the Founder and Director of the Laboratory, Turck Foundation, at the time of his death.

Dr. Turck was the author of 102 articles published in the United States and Europe. During the World War, he held the rank of Captain in the Medical Corps of the U. S. Army. He was a member of King's County Medical Society, the New York State Medical Association, the American Association for Advancement of Science, the Association for the Study of Internal Secretions, the Royal Geographic Society (Lisbon), Société d'Urologie de France, and a Fellow of the American Medical Association and of the New York Academy of Medicine. He had been an Associate of the American College of Physicians for many years.

DR. ALFRED HENRY

Dr. Alfred Henry (Associate), Indianapolis, Indiana, died suddenly De-

cember 12, 1932, of angina pectoris; aged fifty-seven years.

Dr. Henry graduated from the Indiana Medical College, School of Medicine of Purdue University, Indianapolis, in 1907. He did postgraduate work at the Trudeau Sanatorium and at Bellevue Hospital of New York City. From 1914 to 1920, he was Professor of Anatomy, Normal College of Gymnastic Union; from 1916 to 1921, Professor of Physiology, Indiana Dental College; and since 1912, he had occupied various teaching positions on the staff of the Indiana University School of Medicine, being Clinical Professor of Medicine at the time of his death.

In 1911, Dr. Henry aided in the organization of the Marion County Tuberculosis Association, becoming its first president and serving in that capacity until 1927, when he retired. He was prominent in state anti-tuberculosis activities and was elected President of the Indiana Tuberculosis Association in 1917. He was a director of the Indianapolis free tuberculosis clinics from 1911 to the time of his death. In 1916, he was president of the Mississippi Valley Conference for Tuberculosis Workers. He was president of the National Tuberculosis Association for the year 1931-32.

Some of Dr. Henry's additional appointments included: President of Board of Directors, Sunnyside Sanatorium, Oaklandon; Member of Staff, St. Vincent's Methodist Hospital, Robert W. Long Hospital and the James Whitcomb Riley Hospital for Children. He had been an Associate of the American College of Physicians since 1921.

DR. GAYFREE ELLISON

Dr. Gayfree Ellison, Norman, Oklahoma, died December 22, 1932. He was born in 1875 and received his A.B. degree from Bethany College, Lindsborg, Kansas. He served in the Spanish-American War with the 7th Kansas Infantry under General Fred Funston, and took part in the pursuit and capture of Aguinaldo.

He received his M.D. degree from Rush Medical College in 1903; interned, Augustina Hospital, 1903-1904; assistant to Dr. A. J. Ochsner, 1904-1906; practised at Muskegon, Michigan, 1906-1908; practised at Oklahoma City, 1908-1911; Bacteriologist, Oklahoma State Board of Health, 1911-1914; Professor of Bacteriology, Medical School of University of Oklahoma, 1914-1928; World War, medical service, 1917-1919; Professor of Epidemiology and Public Health, 1928 to time of death. He was also school physician in charge of student health in the University of Oklahoma from 1928 until the time of death.

Dr. Ellison was a member of Cleveland County Medical Society, Oklahoma City Academy of Medicine, Oklahoma State Medical Association, American Medical Association, Southern Medical Association, Society of American Bacteriologists, and a Fellow of the American College of Physicians.

Dr. Ellison left a wife, a son, Gayfree, and a daughter, Helena. He was a man of exceedingly high principles, a student, and had the highest ideals of medicine. He had always taken an active part in the betterment of the medical profession in his local, state and national affairs.

(Furnished by LEA A. RIELY, M.D., F.A.C.P., Governor for Oklahoma.)

DR. EDWARD LOUIS HEINTZ

Dr. Edward Louis Heintz (Fellow), Chicago, Ill., died suddenly December 7, 1932, of heart disease; age fifty-eight years.

Dr. Heintz was born in Rolla, Mo., April 27, 1874. He attended the University of South Dakota from 1891 to 1893, which institution honored him in 1922 with an LL.D. degree. He graduated from the St. Louis College of Pharmacy in 1898, with the degree of Ph.G., and from the University of Illinois College of Medicine, 1901, with the degree of M.D. For many years he occupied the chair of Assistant Professor of Medicine and Clinical Medicine at the University of Illinois College of Medicine, having retired to emeritus rank at the time of his death. Dr. Heintz was Attending Physician to the University Hospital, and Secretary of the University Hospital School of Nursing. He was a member of the Illinois State Medical Society, the Chicago Medical Society, the Research Club of the University of Illinois College of Medicine and a Fellow of the American Medical Association. He had been a Fellow of the American College of Physicians since 1919.

Dr. Heintz was also active in civic and public affairs, being Chairman of a Chamber of Commerce Committee, working toward the development of a large park around the west side schools and hospitals. He was a member, and for over thirty years a Grand Officer, of the Alpha Kappa Kappa Fraternity.

**DR. FREDERICK TREMAINE
BILLINGS**

Dr. Frederick Tremaine Billings (Fellow), Pittsburgh, Pa., died January 5, 1933; aged fifty-nine years.

Dr. Billings was born at Ridgewood, N. J., attended Public Schools in Washington, D. C., the Lake Mohican Military Academy and the United States Naval Academy at Annapolis, Maryland. He received his medical training at Yale University, graduating in 1898. Dr. Billings interned at Patterson (N. J.) General Hospital, and in 1922 became chief examiner of the Equitable Life Assurance Society, whereupon he went to Pittsburgh.

Dr. Billings served on the staffs of several Pittsburgh Hospitals including the Allegheny General, St. Joseph's, St. Francis, Western Pennsylvania, Presbyterian and Southside Hospitals. At one time he was chief of the University of Pittsburgh Medical Dispensary and was an instructor in Internal Medicine in that institution. During the World War he held the rank of Lieutenant Commander in the Medical Corps of the U. S. Navy (Reserve Forces).

Dr. Billings was a member of the Allegheny County Medical Society, the Pennsylvania State Medical Society, the Pittsburgh Academy of Medicine, the Central States Pediatric Society and of the American Medical Association. He had been a Fellow of the American College of Physicians since 1919.

(Furnished by E. BOSWORTH MCCREADY, M.D., F.A.C.P., Governor for Western Pennsylvania.)

**DR. FRANK HARTON
PRATTEN**

Dr. Frank Harton Pratten (Fellow) London, Ontario, although suffering with hypertension for the past year, died rather unexpectedly December 10, 1932; aged forty-six.

Dr. Pratten was born in Waterford, Ontario, obtained his elementary education in Ontario and graduated in medicine from the University of Toronto in 1911. He was Resident Physician of Muskoka Hospital for Consumptives at Gravenhurst from then until 1914, when he became a member of the staff of the Toronto General Hospital, remaining there until he went overseas in 1915. He was in charge of the chest wards at Moore Barracks' Hospital for some time, following which he served with a front line unit in France, taking part in the historic engagement of Vimy Ridge. He returned to England, in 1917, as officer in charge of medicine at the Canadian Special Hospital, Diseases of the Chest, at Lenham, Kent. He attained the rank of major during his army service. Shortly after demobilization in 1919, he became Medical Superintendent of Queen Alexandra Sanatorium at Byron.

The steady growth of the Sanatorium at Byron, from 250 beds in 1919 to 600 beds at present, and the high standard of efficiency which it has maintained are monuments to the administrative ability of Dr. Pratten. Although burdened with the affairs of so large an institution, he was never too busy to receive his medical associates, students, patients or anyone to

whom he could give an encouraging word or helpful bit of advice.

Dr. Pratten, along with his administrative ability, was an outstanding authority on diseases of the chest. He had been a Fellow of the American College of Physicians since 1923. He was also a Fellow of the Royal College of Physicians of Canada, a member of the Western Ontario Academy of Medicine, the Academy of Medicine of Toronto, the Harvey Club of London, the Ontario Medical Association, the Canadian Medical Association, the Ontario Laennec Society, and for several years had been a member of the Executive Council of the Canadian Tuberculosis Association.

He was a retiring man and, although well known in the medical world to which he devoted his life and talents, he was unknown to many out-

side the profession. However, those who were privileged to know him sense keenly the great loss, not only to the medical world but to humanity at large, in the untimely demise of a man whose outlook on life was an inspiration to those with whom he came in contact. The funeral services were attended by many of his fellows in the Ontario Laennec Society from all parts of the Province who paid loving tribute to a beloved associate. His ashes will lie in St. Luke's-in-the-Garden, the little chapel on the Sanatorium grounds, a building dear to his heart, on the details of which he devoted much time and care; a building which he happily lived to see completed and consecrated for service.

(Furnished by JABEZ ELLIOTT, M.D., F.A.C.P., Governor for Ontario.)

The Heart in Myxedema*†

Electrocardiograms and Roentgen-Ray Measurements before and after Therapy

By J. LERMAN, M.D., R. J. CLARK, M.D., and J. H. MEANS, M.D., F.A.C.P.,
Boston, Massachusetts

REVIEW OF THE LITERATURE

IN various articles and textbooks dealing with myxedema, very little has been said regarding the heart. The literature covering the subject of the heart in myxedema is marked by paucity, contradiction, and confusion.

In 1918 Zondek¹ introduced the term "myxedema heart" and described its characteristics as follows:

I. Before treatment with thyroid.

1. Dilatation of the left and right heart which may be of a very high degree.
2. Slow, indolent heart action with normal blood pressure.
3. Lowering of the auricular wave and the T-wave of the electrocardiogram.

II. Following treatment with thyroid.

1. Return of the heart from marked dilatation to somewhere near normal size.
2. More lively heart action and more rapid pulse without change in blood pressure.
3. Gradual return of the P- and T-waves to normal.

In this article he reported four cases which showed the above characteristics. An illustration of the roentgen-ray shadow of the heart and measurements were given in one case. The following year he presented two additional cases² giving similar results.

Assmann³ in 1919 reported a confirmatory case. Meissner⁴ in 1920 reported three cases of myxedema with cardiac studies before and after treatment. The first case showed the marked shrinkage of 4.5 cm. The second was complicated by chronic nephritis and showed no change in size. The third showed a normal heart before therapy and no change in size following it. Laubry et al⁵ reported a

*Received for publication October 22, 1932.

†From the Thyroid Clinic and Metabolism Laboratory of the Massachusetts General Hospital.

case of myxedema in a patient with typical angina and cardiac hypertrophy without valve lesion. There was no response to digitalis but a marked response to thyroid. No cardiac measurements were given.

In 1925 Fahr⁶ published the first paper on the heart in myxedema in this country. He stated that in spite of the neglect of the subject of heart failure in myxedema in works on both myxedema and heart disease, he believed that it was a prominent feature of all outspoken cases of myxedema. He added to the picture described by Zondek a negative *Q-R-S* complex in Lead III of the electrocardiogram which disappeared on thyroid administration, showing that it was not due to left ventricular preponderance. He described in detail one case showing a shrinkage of 6.3 cm. in the transverse diameter over a period of seven weeks of treatment. This patient had all the signs of decompensation, including orthopnea, ascites, a large liver, and râles at the lung bases. Previous trial with digitalis for three weeks had given no improvement. The signs and symptoms all cleared under thyroid medication. As a control the patient was taken off thyroid for six weeks and thereupon the size of the heart increased and again was brought back to normal by thyroid. The electrocardiogram at the beginning showed negative T_1 and T_2 and negative *Q-R-S*. These returned to normal in seven weeks.

In 1925 Christian⁷ reported 32 cases of myxedema at the Peter Bent Brigham Hospital and stated that "such a change in a heart as pictured in Fahr's case, I have never observed in any

form of cardiac disease". Twenty-two of his patients had no suggestion of a cardiac lesion by physical examination or history. Of the remaining 10, two had chronic valvular disease, five had myocarditis, two had hypertension, and three had minor cardiac disturbances. There was no case of notable cardiac enlargement. Unfortunately neither roentgen-ray nor electrocardiographic studies were given.

Willius and Haines⁸ reported a study of 162 myxedema patients. From this group 91 per cent showed no signs or symptoms of organic cardiovascular disease. The 9 per cent that did, could be accounted for on grounds other than those of myxedema. They did not mention roentgen-ray examination of the heart in any case. Fifty-five patients had electrocardiograms taken, of which 54 per cent were normal. Twenty-three per cent of the abnormalities disappeared under thyroid. In 23 per cent studies were too incomplete for conclusions. They took the position that the data presented did not justify the establishment of a cardiac syndrome characteristic of myxedema.

Case⁹ analyzed 58 patients with myxedema, without finding any to correspond to Fahr's cases.

Means, White and Krantz,¹⁰ in 1926, gaining the impression from Fahr's paper that the cardiac disturbance which he described was of frequent occurrence in myxedema, studied 48 cases of myxedema seen in the Thyroid Clinic of the Massachusetts General Hospital in the twelve previous years. The nearest approach to Fahr's case was one showing moderate enlargement and a shrinkage of 2.3 cm. over a two-week period of treatment.

The electrocardiogram showed an inverted T_2 which returned to normal under treatment. They concluded: "Myxedema heart, in the sense of Zondek and Fahr, is far from common. On the other hand we are not prepared to join those who feel that it does not exist. The evidence presented by Zondek and Fahr of a marked cardiac dilatation rapidly subsiding under thyroid seems incontrovertible, and our own case in a less striking way is one in point."

Thacher and White¹¹ that same year studied the electrocardiographic findings in 14 cases. All of these showed low T -waves, that is below 2 mm., or inverted T -waves, pulse rate average of 68, P -waves present in every case, but often small, and Q - R - S complexes of low potential which in some cases increased, as did the T -waves, with thyroid. There was no abnormal axis deviation and no auriculoventricular or intraventricular block. The P - R interval was less than 0.18 second except in one case where it was 0.20 second. There was considerable parallelism between the height of the T -waves and the level of basal metabolic rate. Thacher and White concluded that myxedema results in an abnormal and more or less characteristic electrocardiogram corrected by thyroid therapy.

From this same clinic, Sprague and White¹² reported that hypothyroidism was a common cause of low voltage in the electrocardiogram. Of the 57 cases studied, myocardial failure from arteriosclerosis accounted for 34 and hypothyroidism for 10. The low voltage of the latter disappeared in those cases reacting favorably to thyroid medication.

Also in 1926 Zins and Rösler¹³ reported a case of myxedema heart and cardiac insufficiency in a woman of 47, being reduced 3.3 cm. after three weeks of thyroid. Schittenhelm and Eisler¹⁴ presented a case with reduction of 3.3 cm. in the heart size along with return of small P -waves and negative T -waves to normal.

Fahr¹⁵ returned to the subject in 1927 with a review of his first case and five additional cases of large hearts shrinking with the taking of thyroid. The cases were well substantiated with roentgen-ray findings (table 1). He says, "Willius and Haines' conclusions are very hard to understand. With the largest material of myxedema cases in the world they have been unable to find a single case of cardiac failure attributable to myxedema, whereas in other clinics where the amount of material is very much smaller, numerous cases of heart failure, unquestionably due to the same factor as the myxedema, have been found. In the past four years we have seen just six cases of myxedema at the General Hospital and the University Hospital. All six cases showed more or less heart failure, the symptoms and signs of which receded partially or completely on thyroid medication." In three of his six cases such signs of cardiac failure as râles at the bases, big liver, and ascites were observed. In the other three, edema, dyspnea, etc., could be part of the myxedema picture without postulating cardiac failure.

From the Washington University Clinics¹⁶ in 1929 came the report of a case of myxedema with cardiac decompensation which disappeared under thyroid medication. In a period of six

weeks the heart decreased in size 3.5 cm. The electrocardiogram showed all T -waves inverted before treatment with T_2 and T_3 becoming normal and T_1 diphasic after six weeks.

Holzman¹⁷ gave a good review of the situation and reported a case with marked cardiac enlargement (transverse diameter of heart 19.7 cm., and of chest 30.5 cm.). Electrocardiogram showed left axis deviation, low voltage and flat T_3 . In seven weeks the basal metabolic rate had risen from minus 20 to plus 9. The heart was narrower by 1.7 cm., but this change was attributed to the different positions of the diaphragm. The electrocardiogram remained unchanged. This patient had a myxedema history of twelve years' duration, and the author suggests that this may have produced a true hypertrophy rather than dilatation.

In 1930 Ziskin¹⁸ reported one case with a change in the transverse diameter of 1 cm. after four weeks of treatment. The electrocardiogram showed diphasic T_1 and T_2 and delayed P - R interval. The T -waves returned to normal with treatment. Davis¹⁹ reported a case from Fahr's clinic with a shrinkage of 6.2 cm. in six weeks. This patient also showed low T -waves and a P - R interval of 0.2 second, all of which returned to normal. Tung²⁰ reported one case showing a shrinkage of 2.2 cm. in transverse diameter of the heart. He followed the electrocardiograms of seven patients, which showed low P - and Q - R - S waves, and inverted and flattened T -waves. These returned to normal after thyroid medication. Recently Ayman, Rosenblum, and Robinson-Lessner²¹ reviewed the lit-

erature and reported two of their own cases. They found decreases in the size of the heart and return to normal of small or flat P - and T -waves with treatment.

Reid and Kenway²² studied the electrocardiographic changes in 260 cases of low metabolic rate, five of which had genuine untreated myxedema. They found that there was no change characteristic of low rate, but that myxedema showed the typical changes described by others: low P - and T -waves and small Q - R - S complexes. They comment upon the fact that those who have found cardiac changes as first described by Zondek have not reported more than a small number of cases. This study made them aware of the great necessity of carefully distinguishing myxedema cases from simple low rate cases, and they suggest that insufficient distinction between these two may in itself account for the diversity of opinion regarding myxedema heart.

We have summarized in tables 1 and 2 all of the known cases of myxedema in the literature which have data regarding the heart size and electrocardiogram.

Thus we have seen that complete reports of the size of the heart in myxedema have been made in relatively few cases. Most of these were published because of a strikingly large heart or marked response to thyroid. Nowhere has any number of cases been reported as a series giving the findings of the size of the heart before and after treatment. Possibly changes in the size of the heart and in the electrocardiogram take place in many treated cases of myxedema. Conse-

TABLE I
CASES REPORTED WITH ROENTGEN-RAY MEASUREMENTS OF HEART

Author	Transverse Diameter before Treatment	Transverse Diameter after Treatment	Shrinkage	Time
	cm.	cm.	cm.	
Zondek ¹	19.7	14.0	5.7	8 weeks

TABLE II
SUMMARY OF ELECTROCARDIOGRAPHIC REPORTS IN THE LITERATURE

Author	No. of Cases	Findings before Treatment	Findings after Treatment
Zondek ^{1,2}	6	Low <i>P</i> - and <i>T</i> -waves in all cases	Normal
Fahr ^{6,15}	1	Negative <i>T</i> ₁ and <i>T</i> ₂ ; negative <i>Q</i> - <i>R</i> - <i>S</i> ₃	Normal
	1	Inverted <i>T</i> ₁ , flat <i>T</i> ₂	Normal
	1	Flat <i>T</i> ₁	Normal
Means et al ¹⁰	1	Inverted <i>T</i> ₂	Normal
Thacher and White ¹¹	14	All low <i>T</i> ₂ ; several with low complexes	All normal
Wash. Univ. Clinics ¹⁶	1	Inverted <i>T</i> -waves	<i>T</i> ₁ diphasic; <i>T</i> ₂ and <i>T</i> ₃ normal
Holzman ¹⁷	1	Left axis deviation; low voltage; flat <i>T</i> ₂	No change
Reid and Kenway ²²	5	All low <i>P</i> - and <i>T</i> -waves; 3 with low <i>Q</i> - <i>R</i> - <i>S</i>	Normal
Willius and Haines ⁸	55	54% normal; 23% changes in <i>T</i> and <i>Q</i> - <i>R</i> - <i>S</i> ; 23% incomplete studies	All normal
Ziskin ¹⁸	1	Diphasic <i>T</i> ₁ and <i>T</i> ₂ ; delayed <i>P</i> - <i>R</i> interval	<i>T</i> -waves normal; <i>P</i> - <i>R</i> interval unchanged
Davis ¹⁹	1	Low <i>T</i> -waves; <i>P</i> - <i>R</i> = 0.2 sec.	Normal
Tung ²⁰	7	Low <i>P</i> and <i>Q</i> - <i>R</i> - <i>S</i> ; inverted and flattened <i>T</i> -waves	Normal
Ayman et al ²¹	2	Small or flat <i>P</i> - and <i>T</i> -waves	Normal

quently it appeared desirable to study the heart in a large series of patients with myxedema before and after treatment. Such a study would have the additional advantage of giving us statistical data for purposes of comparison with similar studies in other diseases.

METHOD AND MATERIAL

With these things in mind we began a systematic study of the heart in myxedema about three years ago. Being especially interested in the size of the heart, we tried to obtain a teleroentgenogram before treatment and one or more after treatment with thyroid. About half of the patients included belong to a group whose treatment started before the beginning of this study but who had had measurements of the heart and electrocardiograms taken before treatment. These patients were recalled and the cardiac studies repeated.

All but one of the cases reported are patients who were studied in the hospital and had repeated metabolism tests done. They were carefully separated from cases of simple low metabolic rate showing no clinical evidence of myxedema. Cases of postoperative myxedema or cases where there was any question regarding the diagnosis were excluded. Any case of luetic or rheumatic heart disease was excluded, but cases with possible hypertensive heart disease were included.

ROENTGEN-RAY STUDIES

The available teleroentgenograms were remeasured and those taken before and after thyroid compared with special reference to the position of the diaphragm, rotation of film, and sim-

ilarity of points of measurement. Special attention was also paid to the internal diameter of the chest. Assuming that a larger diameter on the repeat plate indicates a greater degree of inspiration, then the diaphragm may be assumed to be at least as low or lower than in the first plate. Since a low diaphragm gives an apparent decrease in heart size and a high diaphragm an apparent increase, it was necessary to repeat the roentgen-ray examination of the heart in several instances on account of the position of the diaphragm. It may be noted that in table 3, the chest diameter of seven cases is found to be more than 0.5 cm. greater in the teleroentgenograms after thyroid medication than in the one before medication. However, only two of these cases (E. J. and J. W.) belonged to the group with a significant change in the size of the heart. Direct comparison of the plates for any given case showed very little variation in the position of the diaphragm. In only one instance (R. M.) was the diaphragm of the repeat plate lower by a whole space than in the first plate. It is therefore correct to state that errors due to position of the diaphragm did not play an important rôle in these cases.

In table 3 are given the complete cardiac measurements in 30 patients with myxedema, before and after treatment with thyroid extract. A total of 86 teleroentgenograms is recorded. Table 4 summarizes the changes in the size of the heart and in the blood pressure as a result of treatment. Both tables are arranged in the order of the degree of shrinkage in the transverse diameter of the heart.

TABLE III
MEASUREMENTS OF THE HEART IN 30 PATIENTS WITH MYXEDEMA
BEFORE AND AFTER THYROID MEDICATION

Initials	Right	Left	Trans. Diam.	Length	Base	Half Diam. Chest	Time Interval*

Mr. J. G.	53	-25	12.8	13.7	-0.4	4 yr.	130/ 90	128/ 76

Considering any heart above normal size where the transverse cardiac diameter is greater than half the internal diameter of the chest, then we find that 25 of the 30 patients had enlarged hearts, as follows:

Transverse cardiac diameter minus one-half internal chest diameter cm.	No. of cases
0 - 1.0	5
1.0 - 1.9	7
2.0 - 2.9	4
3.0 - 3.9	5
4.0 - 4.9	2
5.0 - 5.9	1
6.0 +	1

In the remaining five cases the trans-

verse cardiac diameter was either equal to or less than half the internal chest diameter.

Of the 30 cases, 20 showed a maximum decrease in transverse diameter of the heart after treatment of more than one centimeter and seven of less than a centimeter, distributed as follows:

Decrease in transverse cardiac diameter cm.	No. of cases
0.1 - 0.9	7
1.0 - 1.9	6
2.0 - 2.9	8
3.0 - 3.9	3
4.0 - 4.9	0
5.0 - 5.9	2
6.0 - 6.9	1

The remaining three cases showed increases of 0.1 to 0.4 cm. The age of the patient bore no relation to the change in the heart size under therapy. As for sex, there were only four males in the series. The presence of hypertension did not prevent the heart from shrinking. In fact, nine of the 20 patients who showed changes in the transverse cardiac diameter of more than a centimeter had some degree of hypertension before treatment. However, in these cases the repeat teleoroentgenograms were obtained usually less than six months after the beginning of treatment so that the factor of hypertrophy due to long-standing hypertension did not obscure the picture. Moreover, the hypertension disappeared in five cases. There is a close relationship between the degree of cardiac enlargement before treatment and the amount of shrinkage in the heart under treatment. The greatest changes in the size of the heart occurred in the large hearts. Expressed mathematically, the coefficient of correlation between the degree of cardiac enlargement and the degree of cardiac shrinkage is -0.70 ± 0.067 for all the cases, and $+0.83 \pm 0.050$ for the 20 cases which decreased more than one centimeter. Both figures are highly significant statistically. The tendency in general was for the heart to approach normal size under therapy. In the few cases that this was not fulfilled, usually some degree of hypertension persisted.

The decrease in size of the heart in myxedema under thyroid medication is a slow and progressive procedure, as indicated in table 3. Twelve patients had serial teleoroentgenograms

during the first year of treatment. Ten of these showed progressive shrinkage in size of the heart, reaching a maximum in three weeks to ten months after the beginning of treatment. Two cases reached their maximum in three weeks, six in three to five months, one in six months and one in ten months. The last had no examination in the interval between two months and ten months after treatment, so that the maximum change might well have occurred before ten months.

As indicated in table 3 the changes in the heart occurred in all diameters. However, measurements of the length and base of the heart are difficult to make and are subject to greater errors than the transverse cardiac diameter. Consequently the latter is used in judging the degree of cardiac shrinkage. As a matter of fact, the actual shrinkage in volume of the heart was greater in some instances than the decrease in transverse diameter indicated. Assuming that the surface area of the heart in the teleoroentgenogram is a more accurate measure of the volume of the heart than the transverse cardiac diameter, we measured the surface area of the heart of the first two cases (N. C. and R. M.) before and after treatment. In the first case (figure 1) the maximum change in surface area was from 161.6 sq. cm. to 77.6 sq. cm., a decrease of 52 per cent. The decrease in transverse cardiac diameter was 36 per cent. In the second case (figure 2) the maximum change in surface area was from 190.8 sq. cm. to 137.4 sq. cm., a decrease of 28 per cent. The transverse diameter decreased 26.6 per cent.

As mentioned above, the transverse

FIG. 1. Changes in the teleoroentgenogram of patient (N. C.), at intervals of two weeks and six months after thyroid medication. The level of basal metabolism was minus 28 per cent; two weeks later it was minus 4 per cent; and six months later it was minus 3 per cent.

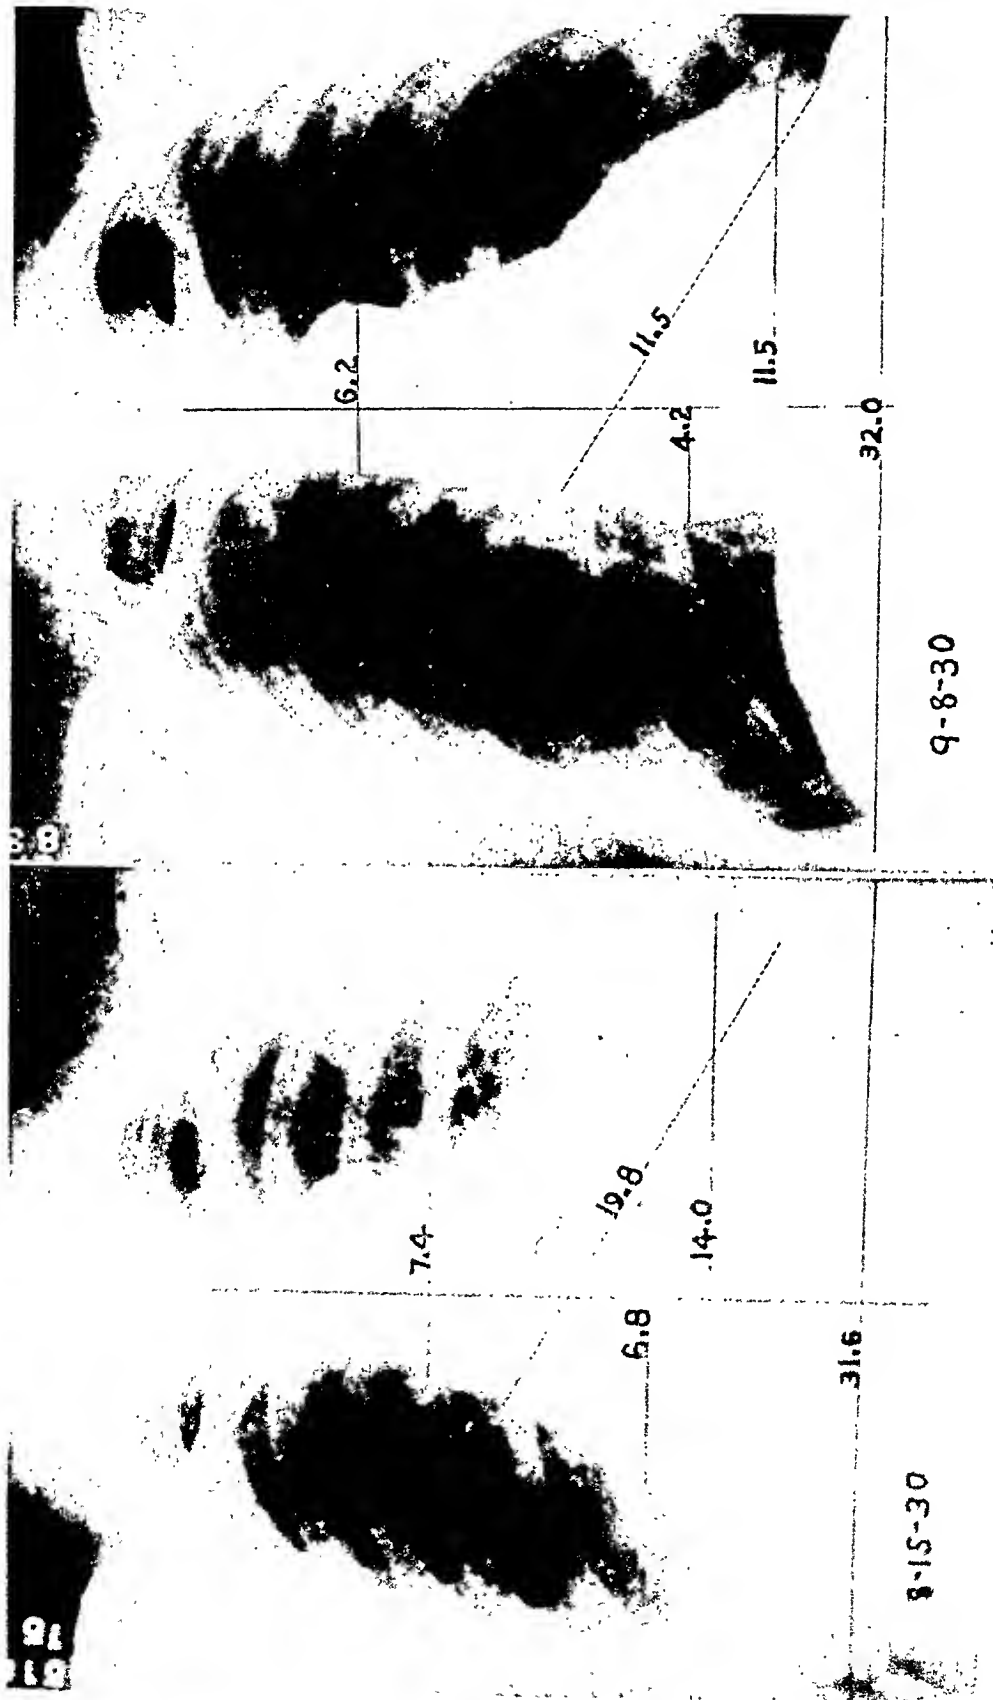

FIG. 2. Changes in the teleoroentgenogram of patient (R. M.), six weeks after thyroid medication. The level of basal metabolism was minus 37 per cent; and six weeks later it was plus 5 per cent.

diameter in ten cases decreased less than one centimeter or actually increased slightly under medication. The failure of these cases to show changes in the size of the heart may be explained for the most part by two factors. In the first place five of the patients (E. O., A. P., M. Mc., M. L., and J. C.) had persistent hypertension. Four of these had the first reëxamination of the heart one and one-half to three years after the beginning of treatment, and the fifth had the first reëxamination at three weeks and the second reëxamination at fourteen months. In these five cases, true hypertrophy might have been present at the beginning; or, if shrinkage of the heart had actually taken place, the cardiac hypertrophy due to hypertension during the long intervals between examinations might have masked it. The latter course of events was observed in one case (E. Mc.). This patient had a hypertension of 180 mm. of Hg systolic and 90-100 mm. diastolic. The transverse cardiac diameter was reduced from 14.6 cm. to 12.5 cm. in three weeks of treatment. At the end of nine months the transverse diameter was 13.0 cm. and at a year and one-half it was 13.4 cm.

The second explanation for the failure of this group of cases to show cardiac shrinkage is based on the above finding that the amount of shrinkage of the heart is proportional to the degree of cardiac enlargement. Consequently patients with normal hearts are not to be expected to show much change. Three (M. F., M. B., and E. D.) of the five remaining cases of this group had normal-sized hearts at the beginning of treatment. The fourth

case (E. S.) had a normal-sized heart after the slight reduction in size had taken place.

It may be said in passing that the more carefully one follows patients with myxedema the more often will one find cardiac changes under treatment. Thus, of the 15 patients followed from the beginning of treatment, with this matter in mind, nine showed a decrease in transverse cardiac diameter of more than 2 cm., four of 1 to 2 cm., one of 0.8 cm., and the other of 0.4 cm.

BLOOD PRESSURE

Under thyroid medication the blood pressure underwent changes in 23 cases, either systolic, diastolic, or both, no change in four cases and was not followed in three. The systolic pressure dropped 10 mm. or more in 13 cases, rose 10 mm. or more in seven cases and underwent an insignificant change in seven. The diastolic pressure dropped 10 mm. or more in 14 cases, rose 10 mm. or more in two, and underwent an insignificant change in 11. The net result was a slight increase in pulse pressure. The latter rose 10 mm. or more in 13 cases, dropped 10 mm. or more in six, and underwent an insignificant change in eight. The patients with hypertension showed more marked changes than the remainder. Of the 14 patients with hypertension that were followed, five developed a normal blood pressure after treatment and six reached a lower level of hypertension, particularly in diastolic pressure. Only one patient with normal blood pressure before treatment developed hypertension after treatment.

ELECTROCARDIOGRAMS

The matter of the electrocardiographic changes in myxedema appears to be on firm ground, but it was felt worth while to report the electrocardiograms in these patients both as adding to the evidence already at hand and for purposes of correlation with the roentgen-ray findings.

Electrocardiograms were obtained in 24 patients before and after treatment and are recorded in table 5. The most common abnormality in the electrocardiogram before treatment was flattening or inversion of the *T*-waves. This occurred 14 times in all leads, eight times in two leads and twice in one lead. The *T*-waves were abnormal in one or more leads in all 24 cases. The *T*-wave in Lead II was most commonly involved, i.e., in 23 cases; *T*₁ was involved in 22 cases and *T*₃ in 15 cases. In addition, nine electrocardiograms showed axis deviation, nine

showed small complexes, one showed auricular premature beats, and one showed intraventricular block. The *P*-waves were low or flat in all but one case.

Under thyroid administration, 11 of the patients showed normal electrocardiograms at varying intervals after the beginning of treatment. Nine of these belong in the group whose hearts shrank more than one centimeter. In some instances the return to normal was delayed. In addition six lost their *T*-wave abnormalities and one lost his small complexes. Thus a total of 18 patients showed a disappearance of one or more of these abnormalities from their electrocardiograms. Four of the remaining six patients showed partial improvement of *T*-wave changes. The *P*-waves increased in size in 22 of the 24 cases. In all, 17 patients showed a complete disappearance of *T*-wave abnormalities

TABLE V
THE ELECTROCARDIOGRAM IN 24 PATIENTS WITH MYXEDEMA BEFORE AND AFTER THYROID MEDICATION*

Initials	Electrocardiogram before Treatment	Electrocardiogram after Treatment Time Interval in Parentheses
Mrs. B. S.	Low <i>T</i> all leads; low voltage.	Normal (6 wks.). Slightly slurred <i>Q-R-S</i> ₂ and <i>Q-R-S</i> ₃ (8 mos.).
Mr. E. J.	Left axis deviation; slightly inverted <i>T</i> ₁ ; flat <i>T</i> ₂ and <i>T</i> ₃ .	Partial A-V block; low <i>T</i> -waves; slight left axis deviation (2 wks.). Slightly inverted <i>T</i> ₁ ; <i>T</i> ₂ and <i>T</i> ₃ + 3 mm.; slight left axis deviation (5 mos.).
Mrs. J. P.	Slightly inverted <i>T</i> ₁ ; low <i>T</i> ₂ and <i>T</i> ₃ ; slurred <i>Q-R-S</i> .	Inverted <i>T</i> ₁ and <i>T</i> ₂ ; slight slurring <i>Q-R-S</i> (3 wks.).
Mrs. A. P.	Low voltage; low <i>T</i> -waves.	Low voltage; low <i>T</i> -waves; slight left axis deviation (2 wks.). Left axis deviation; normal <i>T</i> ₁ and <i>T</i> ₂ ; inverted <i>T</i> ₃ (4 mos.).
Mrs. E. G.	Flat <i>T</i> ₁ ; inverted <i>T</i> ₂ and <i>T</i> ₃ ; low voltage; slight left axis deviation.	S-A tachycardia; small complexes (4 yrs.).

*The *T*-waves are not recorded here. They were small in all but one case. Under medication, the *T*-waves increased in size.

TABLE V—(Continued)

Initials	Electrocardiogram before Treatment	Electrocardiogram after Treatment Time Interval in Parentheses
Mrs. R. W.	Diphasic T_2 ; flat T_3 ; tendency toward right axis deviation; small complexes.	Normal (9 mos.).
Mrs. J. R.	Left axis deviation; T_1 inverted; T_2 flat.	S-A tachycardia; left axis deviation; flat T_1 and T_2 (1 wk.). S-A tachycardia; left axis deviation; T_1 and $T_3 + 3$ mm.; T_2 normal (4 mos.).
Mrs. E. Mc.	Slight intra-ventricular block; inverted T_1 ; flat T_2 .	Left axis deviation (10 mos.).
Mrs. A. F.	Flat T_1 and T_2 .	Normal (3 wks.). Normal (1 yr.).
Mrs. A. Mc.	Flat T_1 ; inverted T_2 ; left axis deviation.	Normal (5 mos.).
Mrs. A. G.	Low T -waves all leads; low voltage.	Flat T -waves all leads; slight left axis deviation (1 wk.). Normal (1 yr.).
Miss C. Mc.	Inverted T_1 ; diphasic T_2 ; left axis deviation.	Low T -waves; left axis deviation (2 wks.). Low T -waves; left axis deviation (3 wks.).
Mrs. E. M.	Low T -waves all leads.	Low T -waves all leads; T_2 slightly higher (15 mos.). Normal (7 yrs.).
Mrs. M. D.	All T -waves flat.	Normal (1 yr.).
Mr. J. W.	Flat T_1 ; diphasic T_2 ; flat T_3 ; small complexes.	Normal (5 yrs.).
Mrs. L. C.	Inverted T -waves all leads; small complexes.	Normal (1 mo.).
Mrs. E. S.	Rather low voltage; low T_1 and T_2 ; flat T_3 .	Normal T_1 ; Leads II and III not obtained (2½ yrs.).
Mrs. M. F.	Flat T_1 ; inverted T_2 and T_3 .	Slight left axis deviation; low T -waves all leads (2 mos.). Low T_1 and T_2 ; slight left axis deviation (8 mos.).
Mrs. M. B.	Flat T_1 ; inverted T_2 and T_3 ; slight right axis deviation.	T -waves normal; slight right axis deviation (7 mos.).
Miss A. P.	Slight left axis deviation; inverted T_1 .	Ventricular premature beats; left axis deviation; inverted T_1 (5 mos.). Slight slurring of Q - R - S ; diphasic T_1 and T_2 ; flat T_3 (1 yr.). Marked left axis deviation; inverted T all leads (3 yrs.).
Mrs. M. L.	Slightly inverted T_1 and T_2 ; slight left axis deviation.	Low T_2 (2 wks.). Slight left axis deviation (3 yrs.).
Mrs. J. C.	Auricular premature beats; inverted T_1 and T_2 .	Normal (3 yrs.).
Mrs. E. D.	Flat T -waves all leads; low voltage.	Inverted T_1 ; T_2 and $T_3 + 6$ mm.; slight left axis deviation; inverted Q - R - S ; (5 yrs.).
Mr. J. G.	Flat T_1 .	Moderate left axis deviation (5 yrs.).

whereas seven retained some abnormality. Small complexes were retained in only one of the nine cases. Six patients retained axis deviation and five additional patients developed this abnormality with treatment. However, six of these 11 patients had hypertension at the beginning of treatment, and six were in the group whose hearts decreased less than one centimeter. On the other hand the three patients who lost their axis deviation belonged in the group whose hearts decreased more than one centimeter. In general it would seem that the cases which showed the most marked shrinkage in the shadow of the heart were the ones whose electrocardiograms showed the most return to normal.

It has been suggested by Nobel, Rosenblüth and Samet²³ that resistance of the myxedema skin is the factor causing the abnormal electrocardiographic findings. By using needle electrodes to overcome skin resistance, they were able to change abnormal electrocardiograms to normal. The fallacy of this contention is that if the changes in the electrocardiogram are due to resistance of the skin, then all the complexes should be equally affected. On the contrary, in myxedema the T-waves show the most marked deviation from the normal. Dr. Paul D. White was good enough to test out the suggestion of Nobel et al by obtaining electrocardiograms with the usual electrodes and then with needle electrodes in two patients. The results are illustrated in figure 3. In one case the resistance was actually higher with needle electrodes than with the usual electrode, in the other the resistance

was about the same. With greater resistance a looser string was required so that overshooting and exaggerated complexes occurred but the character of these complexes was unchanged. Consequently electrocardiographic abnormalities are probably due to changes in the heart itself and not in the skin.

OTHER FINDINGS

Fourteen patients at time of entry into the hospital showed no abnormality on auscultation. Four showed systolic murmurs, two had extra systoles and the remainder presented sounds of faint or poor quality. Cardiac enlargement as gauged by physical examination was found in nine cases. The size of the heart was under-measured on physical examination in 15 cases and in eight of these the undermeasurement was great enough to cause the diagnosis of normal-sized heart, whereas the roentgen-ray showed an enlarged heart.

Several of the cases in the literature presented signs of definite cardiac decompensation. Fahr^{6,15} emphasizes cardiac failure as part of the picture of "myxedema heart". To be sure, many of our patients showed various degrees of peripheral edema but this may be accounted for on the basis of myxedema alone. Four patients showed evidence suggestive of cardiac failure, as follows: one (R. M.) showed crepitant râles at the lung bases and pitting edema over the extremities and sacrum; one (E. J.) showed a small amount of fluid in the right pleural cavity, palpable liver edge, and pitting edema of the extremities; and two (J. C. and E. O.) showed crepitant râles at the lung bases, palpable liver

FIG. 3. Illustration of the effect of needle electrodes on the electrocardiogram. In one case the skin resistance was the same with needle electrodes as with the usual electrodes; and in the other the skin resistance was greater with needle electrodes than with the usual electrodes.

edge, and pitting edema. The evidence for cardiac failure was not conclusive in any of these. All the signs disappeared on rest and thyroid medication. The blood pressure was moderately elevated in each of these cases, and the peripheral vessels sclerosed in three. The patient presenting the most evidence of congestive failure (R. M.) died suddenly seven months after leaving the hospital, cause undetermined.

DISCUSSION

One gathers the impression from a study of the literature that the cases reported by Zondek, Fahr, and others, in which roentgen-ray findings or photographs of the roentgenograms are given, are all thoroughly genuine. We believe that Fahr emphasizes the point of cardiac failure to a greater extent than his published findings warrant. In three of his cases,¹⁵ dyspnea and edema could well be part of the general picture of myxedema rather than due to cardiac failure. Our impression of the report by Willis and Haines⁶ is that their cases were not thoroughly worked up. The inclusion of patients with low metabolism but without myxedema may account for the finding of normal electrocardiograms in 54 per cent of their cases.

Moreover it is worth noting that Willis and Haines,⁶ and Christian,⁷ the two who are most emphatic in denying the existence of "myxedema heart" fail to mention roentgen-ray studies of the heart size. As indicated above, the heart in myxedema is frequently under-measured by physical examination before therapy is started. Consequently change in the size of

the heart might easily be missed, unless serial teleoroentgenograms are obtained.

Our studies lead us to believe that the heart in myxedema is usually enlarged and decreases in size when thyroid is administered and that the change in the size of the heart is of diagnostic importance. Cardiac failure due to myxedema is uncommon, and slight if present. It is practically always associated with hypertension and arteriosclerosis.

The nature of the decrease in heart size is difficult to understand, mainly because so little is known of the pathology of the heart in myxedema.* The best and most complete pathological description of myxedema cases is to be found in the report of the Clinical Society of London published in 1888.²⁶ The findings in 20 cases are reviewed. The left ventricle of the heart was hypertrophied in a third of the cases. In more than half there was atheroma of the arteries. Microscopic descriptions are given in only nine cases. Three of these showed evidence of interstitial myocarditis.

At the Massachusetts General Hospital we have been able to trace the records of five autopsies on myxedema patients. Three died as a result of complicating infections, one died of an unknown cause, and one died of hypertensive and arteriosclerotic heart disease before the myxedema could be treated. Four showed interstitial edema with more or less fibrosis of the heart muscle, and the fifth showed fibrosis only. Two of the patients had not

*The nature of the heart in myxedema is discussed by one of us (J. H. M.) in a recent article.

received any thyroid medication. It seems likely that the edematous condition present in other tissues in myxedema is also present in the heart muscle. Therefore the changes in the heart should be regarded as part of the picture of myxedema and not as a separate entity.

Experimentally, the removal of thyroids in animals causes gross alterations in the cardiovascular system. Among others, Goldberg²⁶ showed that sheep and goats made cretinoid by removal of their thyroids, developed cardiac dilatation and a flabby myocardium.

On the basis of the above facts, one is justified in making the tentative assumption that administration of thyroid extract decreases the size of the heart in myxedema by causing the loss of interstitial edema and by increasing the muscle tonus.

It has been suggested that pericardial effusion may account for the size of the heart and that disappearance of fluid with thyroid medication may account for the apparent cardiac shrinkage. This is of interest in view of the finding of the London Committee²⁷: "Anasarca to a slight degree was not uncommon, though in no instance was it excessive. On the other hand, passive effusions into serous cavities, sometimes to a considerable amount, were frequently noted." While they do not specifically report any case with pericardial effusion, their findings suggest that this condition may occur. Both of our autopsied patients who did not receive thyroid before death had fluid in the pericardial sac—one a small amount (150 c.c.) and the other a large amount (1+ liters). The latter pa-

tient possessed the complicating factors of hypertension and arteriosclerosis. Moreover, Goldberg²⁶ found pericardial fluid in seven of 18 sheep with experimental myxedema. In most cases, however, neither the clinical findings nor the roentgen-ray picture of the heart are consistent with significant amounts of pericardial fluid.

CONCLUSIONS

The heart is generally enlarged in myxedema. After thyroid medication, the size of the heart, in most cases, undergoes a progressive shrinkage, which reaches its maximum as a rule in three to six months. This decrease is of diagnostic value. The amount of reduction in the size of the heart is proportional to the degree of cardiac enlargement. The failure of some patients to show cardiac change after thyroid medication may be explained on the basis either of long standing hypertension or of the fact that the heart is not enlarged before treatment.

The blood pressure in myxedema is often elevated above normal. With treatment there is a tendency for both systolic and diastolic pressures to fall, particularly the latter. The net result is a slight increase in pulse pressure. The most marked reductions in blood pressure occur in patients with hypertension.

The electrocardiogram in myxedema is always abnormal. The most common abnormality is a flattening or inversion of the *T*-waves, particularly in Lead II. In addition, abnormal axis deviation and small *P* and *Q-R-S* complexes are common. On thyroid treatment, many of the abnormalities disappear wholly or in part. The greatest

return to normal occurs in those patients with the most marked shrinkage in the size of the heart. The abnormalities in the electrocardiograms are probably not due to increased skin resistance but to changes in the conduction system of the myocardium.

"Myxedema heart" in the sense of cardiac enlargement which undergoes shrinkage on thyroid medication is common; in the sense of Zondek and Fahr, i.e., cardiac enlargement in association with congestive failure, it is rare. The heart changes are to be

regarded as part of the picture of myxedema, not as a separate cardiac entity. The patients with findings suggestive of cardiac failure usually have hypertension and arteriosclerosis.

The change in the heart with thyroid treatment is probably due to increased muscle tonus and loss of interstitial edema. In an occasional case the loss of pericardial fluid may account for this change.

We are indebted to Dr. P. D. White for his valuable assistance during the course of this work.

Heredit^y in Diabetes*

By WILLIAM ALLAN, M.D., ^{Charlotte, North Carolina}

THE impression prevails that diabetes mellitus is in some degree hereditary. In discussing this matter Joslin¹ cites the frequency of a history of diabetes in grandparents, parents, uncles, aunts, and children as the group of relatives indicating hereditary tendencies, and the frequency of diabetes in siblings and cousins as indicating familial occurrence of diabetes. In two series of diabetic persons numbering 2,800 and 2,646 he finds the frequency of a history of diabetes in the "hereditary group" to be 15 per cent and 17 per cent respectively. His figures for the familial occurrence of diabetes in his two series are 7 per cent and 12 per cent respectively, while I secured a history of diabetes in sibs and cousins in 25 per cent of 143 diabetics. If his patients belonged to separate families the number of "hereditary group" relatives would be 108, 920 giving a diabetic incidence of approximately .8 per cent, which as he points out is not far from the incidence of diabetes in the general population at any time.

This method of evaluating the hereditary factor in diabetes seems unlikely to lead to anything definite. Would it not be better to take the incidence of diabetes in the general population, determine the expected incidence of diabetes in parents, siblings, and children? and compare these figures with our

actual findings? Joslin (page 131) estimates the incidence of declared and potential diabetes were inherited as a dominant unit character. Points in 100 per cent of instances: the actual finding of 10 per cent to 15 per cent of parental diabetes is so far from the expected incidence that it seems useless to consider further the inheritance of diabetes as a dominant character.

If diabetes were a unit recessive trait, Let D = gene for normal or non-diabetic condition

d = gene for diabetes

p = frequency of D

q = frequency of d

Then $p + q = 1$

The possible combinations of these factors are expressed by the equation $(p + q)^2 = 1$, and the chance association of genes is shown in figure 1.

	D (p)	d (q)
D (p)	DD (p ²)	Dd (pq)
d (q)	Dd (pq)	dd (q ²)

FIG. 1.

$$p^2 + 2pq = \text{non-diabetics}$$

$$q^2 = \text{diabetics}$$

$$q = \sqrt{\text{diabetics}}$$

Substituting Joslin's figure for the incidence of diabetes, 1.4%

$$q = \sqrt{.014} = .1185$$

$$p = 1 - q = .8815$$

Substituting the values of p and q in the foregoing equations

$$p^2 = \text{pure or homozygous non-diabetics} = 77.7 \text{ (DD)}$$

$$2pq = \text{hybrid or heterozygous non-diabetics} = 20.9 \text{ (Dd)}$$

$$q^2 = \text{diabetics} = 1.4 \text{ (dd)}$$

Within the non-diabetic group are the following ratios:

Homozygous non-diabetics = 78.8%

Heterozygous non-diabetics = 21.2%

The incidence in the general population if diabetes were recessive is shown in figure 2.

	DD .777	Dd .209	dd .014
DD .777	1 .6037	2 .1624	3 .0109

100.00%

FIG. 2

If diabetes were a recessive unit character with an incidence of 1.4%:

(1) One or both parents should have it in 22% of instances.

(6) If one parent has diabetes, 10.6% of the children should have it.

	DD .788	Dd .212		Dd	dd
dd	1	2	1=Dd Dd Dd Dd=78.8%	78.8%	
1.00	.788	.212	2=Dd Dd dd dd=21.2	10.6%	10.6%

I have not been able to find in the literature any figures on the percentage of children with diabetes when either one or both parents have it.

(7) If neither parent has diabetes, 1.125% of the children should have it.

	DD .788	Dd .212		DD	Dd	dd
DD	1	2	1=DD DD DD DD=62.10			
.788	.621	.1670	2=DD DD Dd Dd=16.70			
Dd	3	4	3=DD DD Dd Dd=16.70			
.212	.1670	.045	4=DD Dd Dd dd=4.50			
	DD	Dd	dd			
	62.10%					
	8.35	8.35%				
	8.35	8.35				
	1.125	2.25	1.125%			

(8) If diabetes is recessive with an incidence of 1.4%, then 31.3% of the sibs of diabetics should have it.

One-fourth mating 5 = 1.09 : diabetic sibs 25% = .273
 One-half mating 6 = .145 : diabetic sibs 50% = .0725
 One-half mating 8 = .145 : diabetic sibs 50% = .0725
 Mating 9 = .02 : diabetic sibs 100% = .02

1.4 Total inc. 1.4) .4380 (31.29

One-half of mating 6 = Dd×dd = .145

One-half of mating 8 = dd×Dd = .145

Mating 9 = dd×dd = .02

Total incidence 1.4) .310 (.22

In 143 cases I secured a history of diabetes in one parent in 17 instances, or 12%.

(2) Both parents should have it in 1.4%

Mating 9 = .02

1.4% = 1.4%

Total Inc. 1.4

Only twice have I encountered diabetes in both parents, but Joslin reports diabetes in both parents 42 times in 4675 cases, giving an incidence of .9%.

(3) One parent should have it in 20.7%

One-half mating 6 = Dd×dd = .145

One-half mating 8 = dd×Dd = .145

Total incidence 1.4) .290 (.207

My figures show 12%.

(4) Neither parent should have it in 78%

One-fourth mating 5 = Dd×Dd = 1/4 × 4.37

1.4

In 88% of 143 cases I failed to obtain a diabetic history in either parent.

(5) If both parents have diabetes, then 100% of the children should have it. I have encountered diabetes in both husband and wife only twice; in one instance there were no children and in the other the number of diabetic children was unknown.

I have only 24 separate families in which there was a history of diabetes in the sibs. These 24 diabetics had 36 sibs with diabetes, but the total number of sibs was not recorded. Taking 4.3 per cent as the average number of sibs there should thus be a total of 103 sibs in these 24 families, 36 or 35 per cent of whom have diabetes. As an actual fact in 15 of these families there were 101 children, that is, 86 sibs among whom there were 25 diabetic sibs which gives 29 per cent. But 143 diabetic patients would theoretically have 615 sibs and, as I secured a history of diabetes in only 36, this is only about 6 per cent.

(9) If diabetes is recessive with an incidence of 1.4%, then .98% of the sibs of non-diabetics should have it.

Three-fourths	mating 5 = 3.28	with diabetic sibs 25% = .82
One-half	mating 6 = .145	with diabetic sibs 50% = .0725
One-half	mating 8 = .145	with diabetic sibs 50% = .0725

Total incidence 98.6) .9650 (.98

I have no data on the frequency of diabetes in the sibs of non-diabetics.

SUMMARY

The data available at present are much too meager to warrant drawing any conclusions, but it seems possible that diabetes may be transmitted as a recessive unit character.

DISCUSSION

Since these notes were written about eighteen months ago, Wright³ has published an interesting discussion of "hereditary and familial diabetes mellitus", illustrated by nine charts of diabetic family pedigrees. He considers diabetes to be the product of two factors, an hereditary factor plus an acquired factor such as infection or obesity. Although none of his charts shows diabetes in more than two successive generations, he apparently follows Cammidge in believing that diabetes is sometimes a recessive trait (when severe in the young) and sometimes a dominant trait (when mild in the old).

Howard and Cammidge⁴ found that high fasting blood sugar in mice is transmitted as a unit recessive Mendelian trait, and Cammidge⁵ states "since the abnormality of carbohydrate metabolism giving rise to a high fasting blood sugar in animals is un-

doubtedly a recessive character, it is not unlikely that similar defects in the chemistry of the body of human beings may be transmitted in the same way, and that some forms at least of hyperglycemia and glycosuria, or the conditions predisposing to their development, may consequently run in families like a high fasting blood sugar in mice."

Cammidge discounts statistical studies and undertakes to illustrate the inheritance of human diabetes by family pedigrees of two or three generations, with half a dozen members in each generation, and promptly encounters the dilemma of pedigrees that correspond to both dominant and recessive traits, or to neither. In addition since his cases are not controlled by blood sugar reports, alimentary glycosuria, which is hereditary, may be a confusing element. Hence it seems wiser to stick to statistical studies, unless much more extensive family surveys can be made.

Undulant Fever: A Fatal Case*†

By R. C. ROTHENBERG, M.D., *Cincinnati, Ohio*

THERE have recently been numerous clinical publications on undulant fever. Kern,¹ in 1928, summarized the 36 abortus strain cases previously cited in the American literature and added two more. Simpson and Fraizer² in 1929, and Simpson³ in 1930, recorded the findings in a group of cases near Dayton, Ohio. In the latter year Giordano and Senenich⁴ reported a clinical analysis of 35 cases in Indiana. In the same year (1930) Hardy's⁵ extensive study in Iowa mentioned ten fatal cases, with gross and microscopic autopsy findings in two.

While the mortality rate has been placed by Hardy at 3 per cent, there are relatively infrequent references in the literature to fatal instances of the disease. The following case is reported because of the unusual opportunity to study the patient for a long time, and to follow him to the necropsy table.

CASE REPORT

W.J., aged 57, a farmer, who had lived in Michigan all his life, entered the University Hospital December 2, 1930, in the fifth month of an illness that had begun suddenly on July 6, 1930. The onset had been marked by cough, expectoration of large quantities

of tenacious sputum, chills and fever, drenching night-sweats, soon followed by generalized arthralgia, and by moderate dyspnea accompanying his usual activities. On July 15 a diagnosis of undulant fever had been made as a result of agglutination studies in a nearby laboratory (titer: Br. abortus 1:100). In the same laboratory one month later the titer was again significantly positive (Br. abortus 1:250).

Treatment with "convalescent serum" had produced a remission of symptoms for two weeks soon after the onset; then all symptoms had recurred and two more treatments with serum had afforded no improvement. In August, a series of rectal instillations of a "blue dye" had been of no avail. All symptoms had persisted until the time of admission to the hospital, although the arthralgia had become much less severe and the dyspnea more pronounced. The patient had been confined to bed since the exacerbation, about August 1, a period of four months. For three weeks before entrance there had been gradual swelling of the abdomen and slight edema of the ankles, accompanied by oliguria. The temperature had risen to 101° or 101.5° every afternoon since the onset.

The patient had been married for thirty-two years; there were no offspring. The remainder of the history was irrelevant. There had been no other illness with the exception of mild scarlatina in childhood. The man had been actively engaged in tending his farm, assisting in strenuous manual tasks until the sudden onset of this disease.

A possible source of infection existed in the patient's herd of cattle, three cows recently purchased having aborted. The patient stated that he drank raw milk only in hot coffee. No similar infection had occurred

*Received for publication March 5, 1932.

†From the Department of Internal Medicine, University of Michigan, Ann Arbor, Mich.

in any member of the patient's household. Agglutination of his wife's blood was negative. Subsequent bacteriological examination of milk samples in our laboratory failed to demonstrate brucella organisms.

The essential features of the physical examination were evidence of general weakness, moderate loss of flesh, ascites, and bilateral pretibial edema. The lungs showed only slight congestion at the right base. The heart was normal in position, size, and action; there was electrocardiographic evidence of small complexes and slight left ventricular preponderance. The palpable peripheral arteries were moderately sclerosed. The blood pressure was 114/72. A smooth liver edge could be felt 3.5 centimeters below the right costal margin. The spleen extended one finger's breadth below the ribs on the left.

The urine showed a trace of albumin at a few examinations. There were usually a few white blood cells in the sediment and occasionally a red corpuscle. A Lashmet-Newburgh² concentration test for kidney function gave a maximum value of 1.022, a reading slightly below normal for the method employed. The red blood cell count varied from 4,100,000 to 5,300,000, and the hemoglobin from 75 to 87 per cent on the Sahli scale. A leukopenia was a rather constant feature. The white cells averaged 4200 on ten examinations, with a range between 3200 and 7000. A terminal rise to 17,000 occurred. The average polymorphonuclear percentage was 53, and there was a slight relative lymphocytosis, with an average of 42 per cent. The character of cells and platelets was normal at all times.

The stool was normal. The sputum was clear, of unaltered consistency, and contained no organisms. Two examinations of the ascitic fluid showed it to be colorless, clear, neutral to litmus, with specific gravity of 1.007 to 1.010, and containing an average of 7000 cells per cubic millimeter, chiefly lymphocytes. There were also mononuclear cells, but no eosinophilic cells.

The Kahn test on the blood serum was negative. Blood nitrogen, nitrogen and creatinine, and urea on the day after admission were 10.0, 1.0, and 0.25, respectively. 34.2 milli-

grams per cent, and 6 milligrams per 1000 c.c. (indirect reaction).

Four blood cultures were negative. Cultures of the urine and ascitic fluid, and of the stool by the technic of Amoss and Poston⁷ gave no growth.

Agglutination values were as indicated in the table. The titer remained at a significantly high level throughout the period of observation, being always highest for the melitensis strain. The variation between melitensis agglutination and that for abortus, while usually a difference of only one dilution, was occasionally more marked, a finding of interest which is at variance with the reported studies of some authors.* The absence of any cross-agglutination with members of the typhoid group is worthy of mention. The presence of agglutinins for brucella organisms in the ascitic fluid confirms the previously recognized fact that secretions from the serous cavities can agglutinate various bacteria in the presence of infection with those bacteria.

The clinical course of the disease during 133 days in the hospital is shown on the chart. The temperature was of intermittent character, with several short apyrexial periods. These give to the curve an irregularly undulant appearance, somewhat like some of the temperature types illustrated in the reports of the Mediterranean Fever Commission in 1905.⁸ Similar findings have been recorded by Craig,⁹ Giordano,⁴ and other writers in their more chronic cases.

The pulse and respiration showed ranges generally proportional to the temperature, although at times the heart rate was relatively slow.

Loss of weight was progressive, associated with increasing weakness. The cough and sputum disappeared soon after admission and under maintenance doses of digitalis there was no longer dyspnea at bed rest. The use of a neutral diet with ammonium chloride,

*Additional unpublished data are at hand which show a similar variation in undulant fever cases. In these, agglutination for *Brucella* was also studied, and the results likewise showed no consistency in values in relationship to the others.

and, in addition, the intravenous administration of Salyrgan failed to control the accumulation of ascites, necessitating several paracenteses, as illustrated.

Two courses of brucella vaccine were given according to the method recommended by Simpson.^{3,10} The second saline suspension contained twice as many brucella organisms (*abortus* and *melitensis* strains) as the first. Although no specific *intradermal* test was tried with these preparations, which were given subcutaneously, after the first injection with the stronger solution there appeared a localized red area which became indurated, in a manner entirely comparable

was flabby, with a moderate excess of overlying fat. Microscopically, it showed brown atrophy, and slight endocardial sclerosis with fibrosis extending into the myocardium. Bilateral basal confluent lobular pneumonia was evident as were also chronic passive congestion and chronic edema of the lungs. The liver was atrophic, with moderately sharp and pointed edges. The capsule was of normal thickness, and showed numerous small grayish nodules over its surface. The organ cut with increased resistance. There was marked increase of connective tissue, chiefly perilobular in distribution. Occasional yellowish-gray areas of lipid deposit

to the reaction obtained with saline intradermal brucella antigens.

No appreciable result was obtained by either course of vaccine therapy. The clinical progression was steadily downward. Erysipelas of the face developed about a week before death, but cleared completely under treatment with continuous magnesium sulfate dressings. There was evidence of terminal pneumonia in both lower lobes. Exitus occurred on April 13, 1931, the 283rd day of disease.

The significant autopsy findings were as follows: 3400 c.c. of ascitic fluid were recovered and 200 c.c. of effusion were present in each pleural cavity. The pericardial sac was under slightly increased tension due to the presence of 150 c.c. of fluid. The heart

and moderate congestion were seen. Under the microscope, chronic passive congestion, patchy fatty infiltration, and irregularly distributed chronic parenchymatous hepatitis of the type of atrophic cirrhosis were distinguished. Chronic interstitial pancreatitis was noted. There was atrophy, passive congestion, and parenchymatous degeneration of all organs.

The spleen and testes were of prime interest, the former because of its important place in all references since the earliest writings about undulant fever, the latter particularly because of its association as a complication in the disease, orchitis being prominently mentioned by Simpson,³ Hardy,⁵ and others.

Grossly, there were diffusely scattered pin-

in any member of the patient's household. Agglutination of his wife's blood was negative. Subsequent bacteriological examination of milk samples in our laboratory failed to demonstrate brucella organisms.

The essential features of the physical examination were evidence of general weakness, moderate loss of flesh, ascites, and bilateral pretibial edema. The lungs showed only slight congestion at the right base. The heart was normal in position, size, and action; there was electrocardiographic evidence of small complexes and slight left ventricular preponderance. The palpable peripheral arteries were moderately sclerosed. The blood pressure was 114/72. A smooth liver edge could be felt 3.5 centimeters below the right costal margin. The spleen extended one finger's breadth below the ribs on the left.

The urine showed a trace of albumin at a few examinations. There were usually a few white blood cells in the sediment and occasionally a red corpuscle. A Lashmet-Newburgh⁶ concentration test for kidney function gave a maximum value of 1.022, a reading slightly below normal for the method employed. The red blood cell count varied from 4,100,000 to 5,300,000, and the hemoglobin from 75 to 87 per cent on the Sahli scale. A leukopenia was a rather constant feature. The white cells averaged 4200 on ten examinations, with a range between 3200 and 7900. A terminal rise to 17,000 occurred. The average polymorphonuclear percentage was 53, and there was a slight relative lymphocytosis, with an average of 42 per cent. The character of cells and platelets was normal at all times.

The stool was normal. The sputum was clear, of mucoid consistency, and contained no organisms. Two examinations of the ascitic fluid showed it to be cider-colored, clear, neutral to litmus, with specific gravity of 1.007 to 1.010, and containing an average of 7000 cells per cubic millimeter, chiefly lymphocytes. There were also mesothelial cells, but no neoplastic cells.

The Kahn test on the blood serum was negative. Blood non-protein nitrogen and blood bilirubin values the day after admission to the hospital were respectively 34.2 milli-

grams per cent, and 6 milligrams per 1000 c.c. (indirect reaction).

Four blood cultures were negative. Cultures of the urine and ascitic fluid, and of the stool by the technic of Amoss and Poston⁷ gave no growth.

Agglutination values were as indicated in the table. The titer remained at a significantly high level throughout the period of observation, being always highest for the melitensis strain. The variation between melitensis agglutination and that for abortus, while usually a difference of only one dilution, was occasionally more marked, a finding of interest which is at variance with the reported studies of some authors.* The absence of any cross-agglutination with members of the typhoid group is worthy of mention. The presence of agglutinins for brucella organisms in the ascitic fluid confirms the previously recognized fact that secretions from the serous cavities can agglutinate various bacteria in the presence of infection with those bacteria.

The clinical course of the disease during 133 days in the hospital is shown on the chart. The temperature was of intermittent character, with several short apyrexial periods. These give to the curve an irregularly undulant appearance, somewhat like some of the temperature types illustrated in the reports of the Mediterranean Fever Commission in 1905.⁸ Similar findings have been recorded by Craig,⁹ Giordano,⁴ and other writers in their more chronic cases.

The pulse and respiration showed ranges generally proportional to the temperature, although at times the heart rate was relatively slow.

Loss of weight was progressive, associated with increasing weakness. The cough and sputum disappeared soon after admission and under maintenance doses of digitalis there was no longer dyspnea at bed rest. The use of a neutral diet with ammonium chloride,

*Additional unpublished data are at hand which show a similar variation in undulant fever cases. In these, agglutination for *Brucella suis* was also studied, and this titer likewise showed no constancy in value nor in relationship to the others.

and, in addition, the intravenous administration of Salyrgan failed to control the accumulation of ascites, necessitating several paracenteses, as illustrated.

Two courses of brucella vaccine were given according to the method recommended by Simpson.^{3,10} The second saline suspension contained twice as many brucella organisms (abortus and melitensis strains) as the first. Although no specific *intra*dermal test was tried with these preparations, which were given subcutaneously, after the first injection with the stronger solution there appeared a localized red area which became indurated, in a manner entirely comparable

was flabby, with a moderate excess of overlying fat. Microscopically, it showed brown atrophy, and slight endocardial sclerosis with fibrosis extending into the myocardium. Bilateral basal confluent lobular pneumonia was evident as were also chronic passive congestion and chronic edema of the lungs. The liver was atrophic, with moderately sharp and pointed edges. The capsule was of normal thickness, and showed numerous small grayish nodules over its surface. The organ cut with increased resistance. There was marked increase of connective tissue, chiefly perilobular in distribution. Occasional yellowish-gray areas of lipoid deposit

to the reaction obtained with saline intra-dermal brucella antigens.

No appreciable result was obtained by either course of vaccine therapy. The clinical progression was steadily downward. Erysipelas of the face developed about a week before death, but cleared completely under treatment with continuous magnesium sulfate dressings. There was evidence of terminal pneumonia in both lower lobes. Exitus occurred on April 13, 1931, the 283rd day of disease.

The significant autopsy findings were as follows: 3400 c.c. of ascitic fluid were recovered and 200 c.c. of effusion were present in each pleural cavity. The pericardial sac was under slightly increased tension due to the presence of 150 c.c. of fluid. The heart

and moderate congestion were seen. Under the microscope, chronic passive congestion, patchy fatty infiltration, and irregularly distributed chronic parenchymatous hepatitis of the type of atrophic cirrhosis were distinguished. Chronic interstitial pancreatitis was noted. There was atrophy, passive congestion, and parenchymatous degeneration of all organs.

The spleen and testes were of prime interest, the former because of its important place in all references since the earliest writings about undulant fever, the latter particularly because of its association as a complication in the disease, orchitis being prominently mentioned by Simpson,³ Hardy,⁵ and others.

Grossly, there were diffusely scattered pin-

head sized, reddish, translucent nodules on the splenic surface, somewhat resembling tubercles. These proved microscopically to be localized areas of perisplenitis with hyaline change. The spleen was slightly enlarged with rounded edges. The capsule was thickened. There was lymphoid hyperplasia throughout. The sinuses were dilated and contained numerous macrophages in which red blood cells and blood pigment were engulfed. A few multinucleate giant cells were also present in the sinuses.

The testes revealed complete aspermatogenesis, with evidence of active interstitial orchitis, and scattered areas of fibroid atrophy. Vacuolar degeneration of the epithelium was noted. The prostate and seminal vesicles were normal.

DISCUSSION

Whether these pathological changes may be considered specific of undulant fever is open to question. The patient

died because of arteriosclerotic heart disease and cirrhosis of the liver. It is unlikely, however, that without the concomitant undulant fever impaired function of these organs would have been manifested when it was, or that death would have ensued when it did. On the other hand, it is entirely possible that without the hepatic damage and cardiac weakness the undulant fever would have run a shorter and more favorable course.

The precedent history of sterility does not permit an opinion that the aspermatogenesis was due to undulant fever. The active orchitis, however,

can be more justifiably related to this disease.

It is interesting that both of Hardy's⁵ cases showed hepatic damage and cardiac involvement at autopsy after a rather chronic course of illness.

In the present instance it seems at least highly suggestive, in view of the previous vigorous health, that the visceral damage resulted from the prolonged brucella infection.

SUMMARY

A prolonged fatal case of undulant fever is presented and discussed with reference to its clinical, laboratory, and pathological considerations.

Subacute Yellow Atrophy of the Liver Following Ingestion of Cinchophen and Allied Compounds*†

By WALTER K. GRIGG, M.D., and VICTOR C. JACOBSEN, M.D.,
Albany, New York

CASE REPORT

CINCHOPHEN was first introduced to therapeutics in 1908 by Nicolaier and Dohrn for the treatment of gout. Since then its use has been extended to arthritis in general and as an analgesic. Various closely allied chemical compounds and derivatives have been brought out from time to time until now there are many similar drugs on the market, and with the multiplicity of trade names it is doubtful whether persons using or prescribing them are fully acquainted with the toxicity which they possess. Rabinowitz¹ has listed twenty in this group of remedies, and there are probably others.

The toxicity of these preparations has obtained considerable notoriety in the past few years. The occurrence of fatalities and of less serious complications has been so frequent that recently it has drawn editorial comment in the *Journal of the American Medical Association*.² The data of carefully studied cases of such poisoning should be published in order to stimulate the development of proper safeguards.

*Received for publication May 7, 1932.

†From the Departments of Medicine and Pathology of Albany Medical College and Albany Hospital.

The case we wish to describe is that of a feeble white woman, aged 68 years. For many years she had been troubled with arthritis, involving especially the shoulders and hands. She had used many different remedies, the names of which could not be learned. It was noted by the family that for the two years prior to death, she had been growing weaker, was unable to accomplish her housework in a satisfactory manner, and had nervous manifestations, such as incoördinated twitchings of various muscle groups. She had lost from ten to fifteen pounds in the past year, although her appetite was good and she ate well without complaining of gastrointestinal symptoms.

During the three months she had been under our observation her chief symptoms were extreme weakness, slight incoördination of muscular movements accompanied by twitching, insomnia, arthritis of shoulders and hands, and loss of weight. Examination of heart, lungs, and kidneys showed nothing abnormal.

She was given occasional doses of luminal ($\frac{1}{2}$ gr.) for nervousness and insomnia with good results. Occasionally she would take two or three teaspoonfuls of whiskey in warm milk at bedtime. For arthritis she was given cinchophen intermittently—averaging two tablets daily for a few days and then stopping for a few days. She took about 35 tablets (262.5 grains) in the last two months. She was also given at other times oxyl-iodide, about two capsules daily for a few days, the drug then being discon-

tinued for several days. Of this she took about 25 capsules (75 grains). It was learned that prior to coming under our observation she had used atophan for various periods, the amounts or rate not being known.

About two months previous to death she had two acute spells of chills and fever, lasting about one and a half days each, about two weeks apart. The temperature reached 101°-102°. The symptoms each time cleared up entirely on rest in bed for a day. Leukocyte counts were within normal limits on both occasions.

On March 31, jaundice was noted. About two days before this she had taken one capsule of oxyd-iodide, but this had caused nausea, and no more of the drug had been used. The jaundice rapidly became very intense. There was no apparent diminution in the intensity of the jaundice, either clinically or by observation of urine. The urine showed albumin, hyaline, and finely granular casts, and an occasional red cell. Bile was present.

The jaundice continued for about four weeks, until death intervened. The stools were clay colored for the most part, although occasionally a small amount of bile coloration could be seen. About a week before death, toxic symptoms became more prominent. Her speech was somewhat thick, and she was quite drowsy, and finally two days before her death she lapsed into a semicomatose condition from which she would arouse only momentarily. The forcing of fluids was followed by edema of the legs, but this subsided somewhat when she was put on a Karrell diet. Toward the end there was marked tympanites, but ascites was not noted until about two days before death. Her temperature was normal throughout this later period. It is worthy of note that after the appearance of jaundice she had no subjective symptoms of arthritis.

Necropsy was performed one and a half hours post mortem.

Anatomical Diagnosis: Subacute yellow atrophy of the liver; jaundice; dilatation of the mesenteric veins; bronchopneumonia.

The body is fairly well developed and nourished, 61 inches long. There is slight edema of the ankles. The skin is markedly jaundiced and the sclerae are deep yellow.

No teeth are present. There is a small pigmented mole at the right external canthus and numerous small pigmented moles on the chest and back. Varicosities of the veins of both legs are present.

The abdominal fat is deep yellow, 3 cms. thick. Throughout the body the tissues are markedly jaundiced.

Peritoneal Cavity: Contains about 400 c.c. of clear, bile-stained fluid. There are firm adhesions about the spleen, gall-bladder, and appendix. In the area of the gall-bladder and the under surface of the liver the tissues are very edematous.

Pericardial Cavity: Contains a normal amount of bile-stained fluid.

Heart: Normal in size. Pericardial fat is normal in amount but is deeply bile-stained. The coronary arteries are very slightly thickened and on section the myocardium presents numerous grey plaques and streaks. The endocardium is smooth and glistening throughout. The edges of the mitral valve are slightly thickened.

Lungs: The external surface of the right lung is mottled grey. The lower lobe is slightly more firm and deeper in color. There is a scar at the apex. On section there is congestion and edema of the lower lobe. The left lung resembles the right.

Spleen: Is light grey and presents several irregular, deeply pigmented areas. On section the cut surface is firm and deep red.

Gastrointestinal Tract: Normal except for a few small areas of injection in the mucosa.

Pancreas: Is normal but the tissues about the pancreas present marked edema and bile staining.

Liver: Is small, firm, and nodular. Weight 650 gms. The external surface is bile-stained and marked by numerous small nodules. It cuts with considerable resistance, and the cut surface is bile-stained, hard and fibrous and irregularly lobulated. In the upper posterior part of the right lobe is an area about 8 by 5 cms., smooth and practically normal. The middle of the left lobe on its anterior surface is also quite smooth and lies below the level of the nodular tissue. The veins of the falciform ligament are markedly dilated.

Gall-Bladder and Ducts: There is much

edema and bile staining in the tissues about the gall-bladder. The ducts are patent but there is a very little bile in the gall-bladder. The mucosa of the gall-bladder is grossly normal. No stones are found.

Kidneys: Right is of normal size. There are numerous small subcortical cysts. On section the cut surface is markedly bile-stained. The cortex averages 5 mms. and

Lungs: Scattered foci of acute pneumonitis.

Spleen: Normal.

Pancreas: Normal except for a rare focus of acute interstitial pancreatitis.

Adrenal: Normal.

Stomach: Normal.

Duodenum and Jejunum: Perivascular lymphoid cells and eosinophiles are seen in

FIG. 1. Photograph of anterior surface of liver showing irregular type of nodular cirrhosis following destruction of most of parenchyma. A portion of the right lobe, upper zone, is practically uninvolved.

the capsule strips with ease, leaving a smooth surface marked by small cysts. The left kidney resembles the right. The vessels and ureters are normal.

Adrenals: Normal.

Bladder: Is filled with dirty mud-colored urine. The mucosa is slightly injected.

Genitalia: Cervix is senile in type, endometrium is hemorrhagic and there is a small leiomyoma in the posterior wall.

Aorta: Presents numerous atheromatous plaques in the abdominal portion.

MICROSCOPIC EXAMINATION

Heart: A section of left ventricle is normal.

the muscularis and beneath a thickened serosa. No ulceration.

Kidneys: Many bile-stained hyaline and granular casts in the cortex. Glomeruli slightly thickened.

Uterus: Many large hemorrhages in endometrium and upper layer of myometrium which also shows much myofibrosis.

Ovary: Senile type.

Gall-Bladder: Marked chronic inflammation of mucosa and submucosa with heteroplasia of mucosal epithelium.

Liver: Widespread destruction of lobules with loss of architecture. Many sections contain no parenchyma but only proliferating bile ducts, mononuclear cells, stroma,

and blood vessels. Certain parts show regenerating liver cells in pseudo-lobule formation. The bile canaliculi are dilated with bile thrombi. The capsule of the liver is much wrinkled due to loss of substance beneath. The picture is typical of subacute "yellow atrophy" or necrosis of toxic origin with some repair.

2-phenyl-quinolin-4-carboxylic acid. They prepared it by warming together pyrrolic acid, benzaldehyde and anilin in alcoholic solution.

Action. It stimulates the kidneys in such a way as to have a selective effect on the excretion of uric acid, which is

FIG. 2. Photomicrograph showing the loss of liver parenchyma, infiltration of lymphoid cells and proliferation of bile duct epithelium.

Microscopic Diagnosis: Subacute yellow atrophy of liver; chronic cholecystitis; acute pancreatitis; acute pneumonitis; endometrial hemorrhage.

DISCUSSION

Cinchophen. Cinchophen is phenyl-quinolin-carboxylic acid. It was introduced in therapeutics under the proprietary name "atophan" and is derived from quinolin carboxylic acid. Doebner and Giesecke in 1887 described

increased considerably. The amount of ammonia and of total nitrogen in the urine is slightly increased during the action of cinchophen. Cinchophen does not increase the leukocytes, purin bases or the phosphoric acid. There is no evidence of increased formation of uric acid nor of any effect on deposited urates.

The above two paragraphs are taken from *New and Nonofficial Rem-*

edies, 1924 edition, published by the American Medical Association.

The clinical use of cinchophen has been based largely upon the fact that there is an increase in uric acid output after its administration. While the mechanism of this effect is not entirely clear there seems to be a selective action on renal epithelium since a diuresis is also produced. It has become, next to diet, the chief weapon in the treatment of gout. The drug and its derivatives have also an important analgesic effect and are antipyretics as well, features likely to attract clinical interest towards any therapeutic agent.

According to Rabinowitz¹ toxic jaundice and hepatolysis may result not only from atophan (cinchophen), but also from atophanyl and diiodoatophan. Atophanyl is a combination of the sodium salt of atophan and salicylic acid, while diiodoatophan contains 50.7 per cent iodine and has been used in Austria and Germany for cholecystography.

The toxic action of cinchophen has been thought due to the quinolin nucleus, consisting of the benzol and pyridin rings which yield the toxic, free benzol ring. Most individuals, fortunately, are not susceptible to the toxic effect of the drug. It is undoubtedly true that toxic jaundice will result only in the case of individual idiosyncrasy, but the fact remains that in spite of supposedly careful use of these compounds fatalities do occur. It is also true that serious symptoms may develop after withdrawal of the offending drug. Contraindications to use, such as nausea, vomiting or gastrointestinal symptoms, may not be

present at all or come so late that they cannot be used as criteria of toxicity. Because of these facts cinchophen and its derivatives must be regarded as sources of danger and it would seem best to restrict their use when possible in favor of drugs which are less toxic.

Great importance must undoubtedly be given to the amount of glycogen in the liver cells at the time of cinchophen administration. There is undoubtedly a greater tendency to liver degeneration where there is malnutrition and a decrease in the glycogen content of the liver cells. As a result of this depletion, intoxications tend more readily to cause degeneration of the liver cells. Especially predisposed are alcoholics, pregnant women, and those who in the past have suffered from liver diseases associated with jaundice. It is important to remember that cases of chronic liver atrophy may suddenly present a picture of acute yellow atrophy, leading rapidly to death.

The dose or the duration of use of the drug will vary in individual instances—one developing toxic jaundice after as small a dose as 7 grains, others having a tolerance of several thousand grains taken during a period of years before intoxication occurs.

In 1922, Schroeder² described jaundice resulting from the use of cinchophen and published a review of seventeen cases. Since then the literature has shown many examples of fatalities from its use.

In 1929, Reichle⁴ described two cases of toxic cirrhosis due to cinchophen resulting in death, and gave an excellent review of the literature since

1922. He found 47 reports of poisoning with 10 deaths.

Hitzenberger⁵ cites the case of a young woman who died 10 days after diiodoatophan, administered for cholecystography. She had suffered from diabetes insipidus and occasional febrile attacks. A slight tenderness under the ribs suggested the possibility of gall-bladder disease, and cholecystography was undertaken.

Singer⁶ also reported the case of a 50-year-old woman whose death took place after the use of diiodoatophan for cholecystography. Definite jaundice occurred the following day.

Langdon-Brown⁷ observed fatalities after the use of atophan for rheumatism and stated that he knew of several others.

Anderson and Teter⁸ reported a fatality in a woman of 48 years who had been taking oxyl-iodide capsules for arthritis.

Stacy and Vanzant⁹ recorded the case of a woman of 52 years who took from one to three tablets of cinchophen daily for pain. She finally discontinued its use because of nausea and vomiting, but evidently too late, as she died one week later from acute yellow atrophy of the liver.

Rabinowitz¹⁰ has recently reported seven additional cases of cinchophen poisoning, four of which were fatal. He quoted Dr. Leo Kessel as having seen thirteen cases of atophan poisoning. From conversations with various practitioners in eastern New York we have concluded that in the use of this group of drugs untoward symptoms are very frequently observed, and that there are many unreported fatalities.

A striking fact is the high propor-

tion of fatal cases in women. Twelve of fourteen deaths occurred in females. The ages vary from 20 to 63. The influence of pregnancy and its frequent toxemias on the liver, the higher incidence of gall tract disease in women, and the more general tendency in women to disturbances of metabolism in later adult life, may all be factors in producing this sex preponderance.

The incidence of diffuse toxic necrosis of the liver—or, as it is more commonly but less properly called, acute yellow atrophy—has apparently increased in recent years, a fact attributed to the increasing use of various cyclic organic compounds, among which is the group concerned in our case.

The etiology is quite unknown but probably there is no specific cause since various forms of intoxication may closely simulate acute yellow atrophy, i.e., puerperal eclampsia, streptococcus septicemia, also poisoning with phosphorus, arsenic, nitrophenols, and even mushrooms. It is probably true, as Wells and Bassoe¹¹ state, that *any poison which does not directly cause death, but which causes a severe injury to the liver cells without at the same time destroying the autolytic enzymes, so that the cells die and undergo rapid autolysis, may produce a condition identical with or similar to acute yellow atrophy.*

Intracellular oxidations are probably affected in diffuse toxic necrosis, although fatty infiltration is more evident in the liver of phosphorus, chloroform and other poisonings. The fatty change is taken to be evidence of inhibition or destruction of oxidizing enzymes, the autolytic enzymes

being left free to act.¹² The ability of sugar to protect the liver from poisons such as phosphorus and chloroform seems to depend on its furnishing easily oxidizable material to cells with lessened oxidative capacity (Simonds¹³). Ervin,¹⁴ however, regards the protective action of carbohydrate as due to the liver glycogen which protects the protein-fat emulsion of the protoplasm from the action of acids. Nevertheless with the liver destruction carbohydrate tolerance is reduced (Bodansky¹⁵).

Stewart, Vining and Bibby¹⁶ emphasize the fact that acute yellow atrophy occurs more often after poisoning with picric acid, trinitrotoluene, dinitrobenzene, and aromatic arsenicals, and since the benzol ring is the only common component in these compounds, and is also present in cinchophen, its responsibility is strongly suggested.

In the literature dealing with poisonings of various kinds the word idiosyncrasy is frequently encountered. This term implies that a person has some peculiar constitutional susceptibility to the substance in question, a condition incapable of more concrete definition and hence probably covering a multiplicity of contributing factors. Minute analysis of clinical and pathological data may often give a more objective basis for the toxic state. In our case, for instance, at necropsy a very marked chronic cholecystitis was present although no gall-stones were found. This condition may have been present for years and possibly was responsible for the use of drugs for the "shoulder" pains which she had experienced. There is no definite evidence that gall-bladder disease per se

affects liver function, but it is conceivable that such contiguous lesions may render the liver less resistant to toxins which have an affinity for it.

Cinchophen or atophan and its related compounds are sold in most drug stores. Theoretically they are supposed to be procurable only by prescription but it is quite feasible for any one to purchase them without a physician's written order. This of course leaves open the possibility of abuse of the drug by the laity, especially since the bottles in which the powders or tablets are put up have no precautions printed on the labels. The physician is probably to blame in large measure for most cases of cinchophen poisoning since he is the proper person to warn his patients about the dangers of any form of medication he prescribes.

One manufacturer of this group of remedies gives ample warning to the profession about their contraindications. In a pamphlet¹⁷ sent out to physicians at regular intervals by this company the following cautions are given: "Discretion should be exercised in the use of this drug with individuals suffering from hepatic and biliary dysfunction, especially as it is evidenced in the elderly and poorly nourished patient; yet, if progressive degeneration of these organs is neither known to be present nor reasonably to be suspected, clinical observers believe that this form of medication need not be withheld, more especially if a diet rich in carbohydrates be provided and maintained paralleling the treatment. The use of oxyl-iodide compound is not recommended during pregnancy or for alcoholics. The drug should be at

once discontinued if any of the following symptoms are observed: loss of appetite, nausea, vomiting, tenderness over the liver or in the gall-bladder region, icteroid tint to the sclera or skin, urticarial rash, itching of the skin, swelling of the lips, tongue or face. The appearance of albumin, casts, or bile in the urine should be an indication for the interruption of the administration of the drug."

It would seem that the above constitutes a very genuine effort upon the part of the manufacturer to make the physician realize the dangers of the cinchophenic compounds. Certainly it behooves the latter to acquaint himself thoroughly with their powers for evil before prescribing them for his patients. The dispenser, on the other hand, should be required to indicate on the labels of the containers the dangers of the unguided use of the contents.

SUMMARY ·

1. Cinchophen or atophan and its related compounds are capable in susceptible individuals of causing toxic symptoms which may eventuate in the so-called yellow atrophy of the liver.

2. A case is reported of subacute yellow atrophy in a woman aged 68 years, who in the previous two months had taken for arthritic pains about 263 grains of cinchophen and 75 grains of oxyl-iodide-phenylcinchoninic acid.

3. The benzol ring is a common component of this group of remedies and its responsibility for the toxicosis is strongly suggested.

4. Physicians prescribing these drugs should become familiar with their dangers and warn patients against using them without direction.

5. A large majority of the cases of poisoning occur in women.

6. In our case a concomitant cholecystitis of marked degree was present.

Migrating Pneumonia*†

Certain Mechanical Factors in Its Production, Prevention, and Treatment

By WILLIAM B. FAULKNER, JR., M.D., AIME N. FREGEAU, M.D., and
EDWARD C. FAULKNER, M.D., *San Francisco, California*

A CLOSE study of postoperative massive collapse of the lung (pulmonary atelectasis) indicates its marked similarity to pneumonia. These two conditions have many characteristics in common and, from the study of atelectasis, we may draw certain deductions relative to pneumonia.

As observed by Norris and Landis,¹ "practically every case of pneumonia spreads to some extent. In some cases it slowly extends spreading from lobe to lobe by contiguity; in others the process apparently develops afresh at different points in the same or the opposite lung", and, "in double pneumonia, both bases may be affected simultaneously or the apex of one lung and the lower lobe of the opposite lung may be involved". This migrating or wandering pneumonia, which moves from place to place within the same or the opposite lung, also has been

designated as "creeping", "progressive", and "extending" pneumonia.

We believe that migrating atelectasis and migrating pneumonia are attributable to the same factors. This conclusion is reached by studying the changes in the position of the abnormal signs after the patient has changed from one posture to another. Pneumonia, as well as atelectasis, migrates to definite areas, in accordance with the principles of "internal drainage",² i.e., the spilling of pus or secretion from place to place within the same or the opposite lung, plugging bronchi, obstructing air flow, and causing infection of previously uninvolved areas. The spilling is on a mechanical basis. It depends upon the amount and viscosity of the intrabronchial pus, the posture of the patient, the course of the bronchial stems, and the relative position of the various bronchial openings. (Figures 1, 2, and 3)

The changes within the bronchi are influenced further by the virulence of the organisms within the intrabronchial exudate; but there will be no spilling or migration in the absence of excess intrabronchial secretion.

Bronchoscopic examinations support these deductions and show that thick

*Read before the American College of Physicians, San Francisco, California, April 8, 1932.

†From the Department of Surgery, University of California Medical School, San Francisco; Department of Medicine, French Hospital, San Francisco; and Department of Thoracic Surgery, St. Mary's Hospital, San Francisco.

pus gravitates less readily than thin watery material. Should thick sticky pus be dislodged from the original site of a pneumonic area, it is likely to plug a large bronchus, shut off air flow from a great portion of a lobe or an entire lung, and give signs of lobar pneumonia over a new site.

Thinner material spills with greater ease, runs deeply into the lung, and either plugs or fills one or several small minor bronchi to produce signs of bronchopneumonia. Such migrations of both bronchopneumonia and lobar pneumonia owe their origin to the same cause, namely, internal drain-

age. Any apparent difference in the two is attributable to the varying viscosity of the intrabronchial secretion and the size of the plugged and infected bronchi. One can predict even

lobe. When the patient lies flat upon the affected side, there is little opportunity for spilling or migration to other lobes. (Figure 4) If he is flat upon his back instead of upon his side,

FIG 2 Iodized oil roentgenogram to illustrate the facility with which intrabronchial material can migrate by "internal drainage". The oil was introduced without the use of any type of anesthesia with the patient leaning slightly towards the left. Note the absence of oil in the right lung. Compare with plate 3.

the sites to which pneumonia will migrate for these are determined by the posture of the patient.

For example, let us consider the probable sites of migration of a pneumonia beginning in the right upper

lobe. When the patient lies flat upon the affected side, there is little opportunity for spilling or migration to other lobes. (Figure 4) If he is flat upon his back instead of upon his side,

to the other. (Figures 5 and 6) Should the patient be placed in the semi-Fowler or sitting position, the spilling of pus from the upper lobe is facilitated. This material gravitates along the floor of the right main bronchus to the first available opening.

small amount of secretion plugging the bronchus and the comparatively large area over which the abnormal physical findings are elicited. Every change in the position of the patient leaves him liable to the spilling of pus and the consequent migration of the pneumo-

FIG. 3. Same patient as in figure 2. The oil spilled from the left lung into the right when the patient lay upon the right side. There was no cough associated with this spilling. It was caused by the change in the posture of the patient.

which is the posterior minor bronchus of the lower lobe. By plugging or filling this small bronchus, it produces abnormal findings at the area below the angle of the right scapula.

All clinicians are familiar with the frequency of pneumonia at this site, but attention should be called to the striking disproportion between the

pneumonia. The progression of the disease into the sound lung when a position on the unaffected side is assumed, should be sufficient evidence of the influence of posture upon migration. The high position of the right upper lobe bronchus almost directly opposite the bifurcation accounts for the spread of pneumonia from the right upper to the

left lower lobe and vice versa. (Figure 7)

We have observed very closely the changes in the physical findings following alterations in the posture of

quently there is hyperresonance over the area to which the pus has spilled but the breath sounds are markedly reduced or completely absent. This is exactly what one finds in the case of

FIG. 4. Iodized oil injection of the right lung demonstrating the horizontal course of the right upper lobe bronchus (RU) and the difficulty of pneumonia migrating from this area to new sites when the patient lies upon the affected side

patients who have pneumonia. Râles occasionally appear at new areas and there is an interference with the inflow and outflow of air at this particular region. Later there is a change in the percussion note. More fre-

an intrabronchial foreign body. The signs are caused by the obstruction of the bronchus and the trapping of air resulting in the production of an obstructive emphysema. The strongest argument in favor of the mechanical

production of this migration is that the signs change with a rapidity equal to those produced by an intrabronchial foreign body. Following the absorp-

tion of the air which is trapped beyond the plug of pus, an atelectasis ensues, infection sets in, and if the condition is not corrected, a true pneumonia of the migratory type becomes established at this site.

The acceptance of this mechanical factor in the production of migrating pneumonia enables us to adopt measures not only to prevent but also to treat the condition. The patient can be kept in such a position as to lessen the likelihood of spilling to new areas. Nevertheless, even in these instances, there may be a welling up of pus to such an extent that there is some overflow to the dependent and accessible regions.

Prevention of migration really rests

upon the removal of the intrabronchial pus. This often can be attained through expectoration. It is facilitated by the administration of expectorants and a saturated solution of potassium iodide which lessens the viscosity of the secretion. Steam inhalations serve the same purpose, while inhalations of pure carbon dioxide gas so widen the bronchi that the evacuation of the intrabronchial material is possible.

With all these methods of removal, the posture of the patient should be such that the material will drain out of the lung rather than deeper into it. These postures are extremely variable and depend on the site of the pneumonia. Atropin, which tends to thicken secretions, is contraindicated for these patients because it interferes with expectoration.

Should it be noted that secretions are spilling and are not evacuated following cough and postural exercises, bronchoscopic removal of the secretion, and bronchoscopic treatment of the affected regions should be instituted before the onset of atelectasis and subsequent pneumonia. In trained hands, the bronchoscopy can be done in from one to two minutes under local anesthesia without particular discomfort to the patient.

These mechanical principles are offered as adjuncts in the management of patients with pneumonia without any intention of minimizing the value of the other general therapeutic measures of proven worth.

CONCLUSIONS

1. Postoperative massive collapse of the lung (pulmonary atelectasis) has many characteristics in common with bronchopneumonia and lobar

FIG. 6. Iodized oil injection of the right lung to demonstrate the close relationship of the branches of the upper lobe bronchi. RU- right upper lobe bronchus dividing into its anterior (A), posterior (P), and lateral branches (L). M- middle lobe; C- carina (bifurcation of the trachea); D- point of origin of the middle and lower lobes.

pneumonia. Both show strong tendencies to migrate to identical areas following similar changes in the posture of the patient.

2. Evidence is offered to show that

3. This whole problem is intimately connected with the mechanism of "internal drainage", i.e., the spilling of secretion from place to place within the same or the opposite lung.

FIG. 7. Iodized oil introduced into a left lower lobe bronchial fistula (F) without the use of any type of anesthesia spilled across the bifurcation into the right upper lobe when the patient lay upon the right side. The facilities for the migration of secretion from the left lower to the right upper lobe are demonstrated also in figure 1.

the migrations in pneumonia are on a mechanical basis. They are dependent on the original site of the pneumonia, the posture of the patient, the intra-bronchial anatomy, and the amount and viscosity of the intrabronchial pus.

4. Thin secretion spills deeply into the lung, plugs small scattered bronchi and produces a migratory bronchopneumonia. More viscid material gravitates less readily. It leads to obstruction and infection of the major

bronchi resulting in a migratory lobar pneumonia.

5. The administration of expectorants, the use of saturated solution of potassium iodide to lessen the viscosity of the secretions, and the adoption of proper postures offer a means of evacuating the bronchi and preventing the

internal drainage which is responsible for the production of migrating pneumonia.

6. The bronchoscopic removal of the intrabronchial exudate is to be recommended whenever the patient fails to respond promptly to the other therapeutic measures.

Maintenance Dosage of Liver Extract in the Treatment of Pernicious Anemia*†

By PAUL J. FOUTS, M.D., and L. G. ZERFAS, M.D., *Indianapolis, Indiana*

IN presenting data relative to the maintenance dosage of liver extract or other substances potent in the treatment of pernicious anemia, it is necessary to define and state the requirements which this term implies. Beebe and Lewis¹ have clearly defined these requirements in a recent report of a large series of cases observed at the Thorndike Memorial Laboratory and at the Boston City Hospital. They stated that, "although the level of the red blood cells and hemoglobin serves as one important guide to the amount of therapeutic material necessary for the maintenance of health, there are other aspects of each case that should be recognized as important criteria in determining the amount of liver or potent substitute that should be taken. These other matters pertain to the patient's habits, symptoms and physical signs, the presence or absence of complications, and the detailed histology of the blood itself."

There is much information relative to the course of this disease before the advent of liver, kidney, and stomach therapy with which to compare the re-

sults obtained following the administration of effective therapeutic substances over prolonged periods of time. It is essential that "prolonged periods of time" be emphasized, because of the occurrence of spontaneous remissions, the duration of which is known to vary considerably in the same and in different patients.

It has been a common experience to see patients attempt to regulate their own dosage. Many times both patient and physician are misled as to the determination of the proper maintenance dosage, because prolonged periods are often required to determine the effects of an increased or decreased daily amount of potent substance. The psychology of these patients under treatment and the insidious nature of the disease are other factors that constitute serious obstacles in their proper treatment. It is obvious that frequent observations relative to the clinical aspects of the disease and to the state of the blood are imperative at frequent intervals for the proper management of the patient.

We have selected, from a series of 150 cases treated, fifty-nine patients with typical pernicious anemia, on the basis of the duration of treatment (none less than one year), frequency of observations, and consistency with

*Received for publication March 5, 1932.

†From the Lilly Laboratory for Clinical Research, Indianapolis City Hospital, and the Department of Medicine, Indiana University School of Medicine.

which they ingested the prescribed amount of liver extract. The average duration of treatment of these patients was thirty-six months, ranging from twelve months (two cases) to fifty-seven months. At the beginning of treatment, fifty-seven of the fifty-nine patients were admitted to the hospital in severe relapse, and afterwards were released to the "Out-Patient Department", where they have continued treatment under our personal observation and management. The two remaining patients were admitted to the "Out-Patient Department" while in a remission. As a rule these patients were regular in attendance, reporting at monthly intervals, at which time they were supplied gratis with a sufficient amount of Liver Extract No. 343* to last until their next visit. Under these circumstances, the regularity of their visits was quite imperative. Occasionally certain patients attempted to make the monthly quota of extract do for two months or longer and others omitted therapy altogether until it became obvious to them that they needed further treatment.

The average red blood cell counts, percentages of hemoglobin, and daily amounts of extract which they consumed were computed in each case studied, beginning with the time that the red blood cell count and hemoglobin reached normal levels. It is regrettable that each individual case cannot be presented in full detail as to the blood determinations and clinical findings, as there are many points of interest which are not recorded or

which are obscured by the general averages. The daily amount of potent extract to maintain the blood at normal and to keep the health of the patient in a satisfactory state was calculated over a period of not less than one year. In the majority of instances, either smaller daily amounts had been taken previously for a year or more and found insufficient, or larger daily amounts were reduced for a similar period of time without appreciable changes in the blood or in the health of the patients. The average maintenance dose of potent liver extract, so computed, represents the minimum daily amount as determined in this series of patients during an average period of thirty-six months. We have used the same lower limits of normal as those stated by Beebe and Lewis—4,500,000 red blood cells per cubic millimeter and 85 per cent hemoglobin. The hemoglobin was determined by the Newcomer method. There were a few cases in which the average percentage of hemoglobin was slightly less than 85 per cent which were included in the normal group, since the red blood cell counts and the general health of the patients were satisfactory.

An analysis of the series of fifty-nine patients treated showed that thirty-eight (64.4 per cent) maintained normal red blood cell counts and hemoglobin percentages while taking the daily amount of extract derived from three hundred grams of liver, or less. These patients were classified as Group I. The twenty-one remaining cases (35.6 per cent) did not maintain normal red blood cell counts and hemoglobin percentages while taking the

*The liver extract was supplied by Eli Lilly and Company.

daily amount of extract derived from three hundred grams of liver and were classified as Group II.

In table 1 the patients composing Groups I and II have been further subgrouped as to the average daily amount of extract taken. The average

tract derived from 400 and 600 grams of liver. These patients had previously been given the amount of extract derived from 300 grams of liver, but their blood and hemoglobin either did not reach normal or was not maintained at normal for any length of time

TABLE I

The data in table 1 show the number of patients who did or did not maintain normal red blood cell counts and hemoglobin percentages while taking various daily amounts of potent liver extract. The amount of liver extract is expressed in terms of the number of grams of whole liver from which it was derived, as it is generally considered that 25 to 30 per cent of the active principle contained in liver is lost by fractionation.

	GROUP I				GROUP II		
	LESS THAN 100 GRAMS	100 GRAMS	200 GRAMS	300 GRAMS	400 GRAMS	600 GRAMS	300 GRAMS†
Number of cases	3	6	10	19	4	3	14
Average age in years	57	55.1	53.7	55.5	58.2	44.3	59.5
Average number of red blood cells per cubic millimeter (in millions)	5.32	4.85	5.01	4.84	4.92	4.83	3.92
Average hemoglobin percentage	89.2	82.5*	86.7	85.6	86.2	88.9	77.2
Average amount of liver extract (in grams)	60	100	200	300	400	600	328

*Three patients who had normal red blood cell counts, but whose hemoglobin percentages were below 85 per cent, were considered essentially normal, since their general health was in a satisfactory state.
†Two patients in this group received the daily amount of liver extract derived from six hundred grams of liver.

red blood cell count, percentage of hemoglobin, and the average age of the patients in each subgroup have been determined. It can readily be seen from an examination of this table that there is a great variation in the daily amount of extract ingested capable of maintaining the blood and hemoglobin at normal levels over a period of time greater than that usually observed in spontaneous remissions. Seven of the patients in Group II reached and maintained normal red blood cell counts and hemoglobin levels while taking the daily amount of ex-

on this dosage. The remaining fourteen patients in Group II ingested inadequate daily amounts of the extract when they took regularly the amount derived from 300 grams of liver. Seven of the fourteen patients still living are receiving large daily amounts of the extract, but sufficient time has not elapsed to evaluate the dosage for inclusion in this paper. Since thirty-eight of the patients (64.4 per cent) maintained normal blood counts and hemoglobin percentages on the daily amount of extract derived from 300 grams of liver and less, it is still neces-

sary to question why twenty-one (35.6 per cent) were unable to reach or maintain normal blood levels while taking regularly the daily amount of extract derived from 300 grams of liver.

extract derived from 223 grams of liver. This average daily amount we consider to be the minimum. The twenty-one patients in Group II maintained an average red blood cell count of 4.19 million and percentage of hem-

TABLE II

The data presented in this table correlate the blood and the clinical aspects of the fifty-nine patients treated with liver extract for an average period of thirty-six months, as separated into Groups I and II.

	GROUP I	GROUP II
Number of patients	38	21
Average age in years, on admission	55.1	58.1
Average red blood cell count in millions per cubic millimeter	4.92	4.19
Average hemoglobin percentage	85.6	80.9
Average daily amount liver extract (in grams liver)	223	381
Percentage of patients with moderate to advanced arteriosclerosis	47.2	71.4
Percentage of patients with chronic infections	2.6	28.6
Percentage of patients with noninfectious complications	18.4	52.4
Percentage of patients who had moderate to advanced central nervous system involvement at the onset of treatment	34.2	66.6
Number of patients who developed central nervous system involvement while on liver extract treatment	3	2
Number of patients who developed central nervous system involvement and later improved	1	0
Number of patients with moderate to advanced central nervous system involvement who improved during treatment	4	1
Number of patients with moderate to advanced central nervous system involvement who had an increase in this involvement during treatment	1	10
Number of patients who died during treatment	0	7

In table 2, the average red blood cell count, hemoglobin percentage, and the daily amount of liver extract ingested have been correlated with the clinical aspects of the patients as previously classified (Groups I and II). The thirty-eight patients in Group I maintained an average red blood cell count of 4.92 million and percentage of hemoglobin of 85.6 per cent, while taking an average daily amount of

oglobin of 80.9, while taking daily the average amount of extract derived from 381 grams of liver. While this average daily amount was much greater than that recorded for Group I, it is still far below the minimum for this group and, therefore, inadequate. The average age of the patients in Group II was only slightly greater than that of Group I. In comparing the clinical aspects of these two groups, it is inter-

esting to note that, despite the slight difference in the average ages, the patients of Group II showed a much higher incidence of arteriosclerosis. The usual clinical means for determining arteriosclerosis were employed, such as digital palpation of the peripheral arteries, ophthalmoscopic examination of the retinal vessels, and blood pressure determinations.

The percentage of complications of an infectious and a noninfectious nature, separate and apart from the central nervous system involvement, was much greater in Group II than in Group I. These facts are significant, as the noninfectious complications include those degenerative conditions commonly seen in cases with advanced arteriosclerosis. In many instances the infectious processes involved the urinary tract, and some of these complications were secondary to the bladder disturbances resultant from advanced central nervous system involvement.

The incidence of central nervous system involvement on admission to the hospital was 34.2 per cent for Group I and nearly twice this percentage (66.6 per cent) for Group II. Therefore, it cannot be said that the greater incidence of central nervous system involvement in Group II occurred because of an insufficient amount of liver extract ingested while under treatment or because of a failure of the blood to reach or maintain a normal level. It can be said, however, that the number of patients whose central nervous system involvement advanced while under treatment was much greater in Group II (ten patients) than in Group I (one patient). Three patients in Group I and

two patients in Group II developed central nervous system involvement for the first time while under treatment, and only one of these patients improved (in Group I) while under treatment.

Four of the total number of patients in Group I, who had central nervous system involvement present at the onset of treatment, improved during liver therapy, in contrast to one patient in Group II. Many patients showed improvement of the minor signs and symptoms of central nervous system involvement while taking potent fractions of liver, but in this series we have considered only those cases showing moderate to advanced lesions, as interpreted by the clinical findings. Repeated clinical observations indicate that there are quiescent and actively progressive phases of the central nervous system involvement which may be recognized from time to time. During one of these active phases it is common to see the level of the red blood cells decrease; usually the decrease in the percentage of hemoglobin is much less, proportionately. Often large amounts of liver extract ingested daily (that derived from 1000 to 1200 grams of liver) will not be sufficient to cause the blood to return to normal or to prevent the progress of the central nervous system involvement at that time. During the entire period of observation, seven of the fifty-nine patients died while under treatment. These deaths occurred in Group II, while there were no deaths in Group I. All of the seven patients who died had advanced central nervous system involvement.

The data in table 2 indicate that

those patients with a higher incidence of complications, arteriosclerosis, and moderate to advanced central nervous system involvement (Group II) required, on the average, a greater daily amount of the active principle in liver to keep the blood and color index near normal. These findings are in accord with those reported by Beebe and Lewis.

An examination of the individual patients shows that an acute exacerbation of any or all of the above complications may lead to a severe relapse, even though the blood has been maintained at normal levels for a prolonged period of time while they are taking a given daily amount of liver extract. Occasionally, and for no apparent reason, relapses develop while they are taking the daily amount of potent extract which has maintained the blood and the state of their health at normal for as long as four and one-half years. Fourteen of the fifty-nine patients developed relapses some time during the period of observation, because of the omission of therapy or because of a reduction in the daily amount of liver extract. The time required to develop a relapse under either circumstance varied from two to eighteen months. In three cases more than one relapse occurred because of the omission of therapy. The length of time required to develop a relapse in the same patient varied from two to twelve months. Often a decrease in the hemoglobin percentage preceded, by several months, a reduction in the number of red blood cells previous to a relapse. However, a decrease in the number of red blood cells does not always follow, as the percentage of hemoglobin has

been observed to return to normal while the patient was taking the same amount of potent extract. It would seem advisable, under such circumstances, to administer large doses of iron, as recommended by Minot and his associates.

It is reasonable to believe that a relapse is conducive either to the development of or to the exacerbation of already existing complications seen in this disease, thereby establishing a vicious cycle. Therefore, it is imperative that the blood and the clinical condition of the patient be observed closely at frequent intervals. In the presence of or at the onset of such a cycle, the daily amount of liver extract should be increased sufficiently to, at least, maintain the blood of the individual patient at a normal level. If for any reason the daily administration of large amounts of liver extract by mouth is not feasible during this time, the parenteral use of liver extract is indicated.

CONCLUSIONS

1. Fifty-nine patients with pernicious anemia were treated with Liver Extract No. 343 by mouth for an average period of thirty-six months.
2. In Group I, thirty-eight patients (64.4 per cent) maintained normal red blood cell levels and percentages of hemoglobin, while taking the daily amount of extract derived from 300 grams of liver or less (average 223 grams).
3. In Group II twenty-one patients (35.6 per cent) did not maintain an average normal red blood cell count or hemoglobin percentage, while taking the daily amount of potent extract derived from 381 grams of liver.

4. The maintenance dosage of liver extract varied in different patients and in the same patient at different times.

5. The incidence of infectious and noninfectious complications, arteriosclerosis, and moderate to advanced central nervous system involvement was greater in Group II than in Group I.

6. The number of cases which showed an increase of the central nervous system involvement while under treatment was greater in Group II than in Group I.

7. Seven patients with advanced

central nervous system involvement in Group II died while on treatment, and no patients in Group I died.

8. In the presence of complications, both the blood and the clinical aspects of the patient should be observed closely, and, under any circumstances, amounts of potent material sufficient to maintain the blood at a normal level should be administered.

Cardiospasm with Associated Arthritis*

By JOHN H. FITZGIBBON, M.D., F.A.C.P., *Portland, Oregon*

MANY etiological and contributing factors have been mentioned in the literature of arthritis, but cases in which the condition is associated with esophageal obstruction must be relatively rare. For five years, I have had under observation and treatment a patient in whom cardiospasm and arthritis are intimately associated. As symptoms of arthritis have at times accompanied the appearance of difficulty in swallowing and have improved after dilatation of the stenosis, it seems worthwhile to report the case as one in which there appears to be an intimate etiological relationship between esophageal obstruction and arthritis.

CASE REPORT

Mrs. L. S. B., age thirty-one, was first seen May 4, 1927, in consultation with Dr. Frank McCauley and Dr. Wilson Johnston. She gave a history of cardiospasm of twenty years' duration. The stricture had not been dilated since 1919. As the result of marked obstruction and difficulty in swallowing, she had lost a great deal of weight. Her chief complaint, however, was generalized arthritis, on account of which she was confined to bed.

In June 1926, she had been very ill with pneumonia, and had been in bed for several weeks. Painful swelling of the feet and ankles appeared at that time. Following a diagnosis of pulmonary tuberculosis, she went to Arizona, where her chest condition

improved and the lesion was pronounced arrested. Arthritis of the finger joints and wrists developed in October and November 1926. Four infected teeth were extracted at that time. In January and February 1927, swelling and pain in the joints increased and she returned to Oregon in March with her shoulders, knees, hips, wrists, ankles, and finger joints involved. She was unable to walk and was confined to bed. Her tonsils had been removed in 1919, but a small amount of tonsillar tissue remained and was removed by Dr. Johnston, May 5, 1927.

Difficulty in swallowing had gradually increased over a long period of time and she was extremely weak. A large amount of mucopurulent, blood-streaked material mixed with food was frequently regurgitated. Physical examination was negative except for generalized arthritis with swelling.

Laboratory findings were as follows: Urinalysis, negative. Hemoglobin, 89 per cent. Red blood cells, 4,704,000. White cells, 8,700. Polymorphonuclears, 64 per cent. Small lymphocytes, 24 per cent. Large lymphocytes, 2 per cent. Coagulation time, 7 minutes. Blood Wassermann, negative. X-ray examination of the esophagus showed a markedly dilated esophagus with obstruction at the cardia. (Figure 1)

It was hoped that her general condition could be improved by relieving the esophageal obstruction. Several attempts were made, using the Sippy air bag dilator introduced over a piano wire guided by a previously swallowed silk thread. It was possible to introduce the bag into the stricture, but inflation was not followed by improvement, for the bag tended to slip out of position. Fluoroscopic examination while the bag was being inflated showed that as the

*Received for publication July 13, 1932.

bag filled with air from the upper end it slipped upward into the esophagus and out of the stricture. As the esophagus was greatly dilated, there was room for the flexible shaft of the instrument to bend lat-

brought to the office for treatment and did not wish to make the trips often because of the inconvenience and the pain in the joints. It was necessary to carry her to and from the automobile. During this period she re-

FIG. 1. Dilated esophagus due to cardiospasm.

erally and permit the bag to slip upward. The instrument was then modified¹ so that air entered from both ends simultaneously, and no difficulty was experienced in successfully dilating the stricture.

The failures with the original dilator consumed a great deal of time. She was

ceived quartz light and diathermy treatments from Dr. W. D. Lockwood. The esophagus was lavaged each evening, in the hope of relieving the local inflammation due to retention of food and secretions.

After successful dilation with the modified dilator, July 6 and 15, 1927, there was very

little difficulty in swallowing, and improvement in the arthritic symptoms began. Improvement continued and in September she was able to walk without pain. Her weight and general condition improved at the same time. She has experienced very little difficulty since. She has reported for treatment off and on, especially when difficulty in swallowing develops.

In January 1931, swelling and pain in the joints of the right hand and foot, reappeared, associated with difficulty in swallowing. Following satisfactory dilation of the cardia, these symptoms cleared up.

On November 3, 1931, she reported that she was four months' pregnant. As there was some difficulty in swallowing, and it was feared that this might increase during the remaining months of her pregnancy, her physician was consulted and the cardia was dilated with moderate pressure. On March 25, 1932, she returned, having passed through a normal pregnancy and delivery, but complained of a return of her difficulty in swallowing, associated with pain in the metacarpophalangeal joints of the right hand and the ankle and wrist joints. There was also a ganglion of the extensor tendon sheath of the index finger of the right hand.

The esophagus was dilated on April 26,

1932 and her joint symptoms have responded as usual.

COMMENT

From the course of this patient's arthritis, it seems reasonable to assume that improvement was the result of relieving the stricture of the esophagus. Previous to dilatation, she had regurgitated large amounts of mucopurulent, blood-streaked material from the esophagus and showed signs of having rather marked esophagitis due to retention above the stricture. Would it not be fair to draw the conclusion that the inflammatory lesions in the esophagus have acted as foci of infection which have activated the arthritis, and that drainage resulting from relief of the stenosis has permitted healing of these lesions with improvement in arthritic symptoms?

A Study of 800 Abnormal Electrocardiograms and Associated Clinical Conditions*

By M. A. MORTENSEN, M.D., F.A.C.P., *Battle Creek, Michigan*

THE purpose of this communication is to emphasize the practical value of the electrocardiogram for the study of cardiovascular diseases. The tracing is based on the electrical reactions of the heart muscle during each complete cycle of action and rest. The evolution of our knowledge of the cardiogram dates back to Matteuci, who in 1843 reported the existence of reactions or currents originating in the heart muscle. The studies of Engelman, Marey, Burdon, Sanderson and Page, Gaskell, Kölliker and Mueller, and Waller, led up to the development of the string galvanometer by Einthoven in 1903. Since then there has been a rapid increase in the use of string galvanometers for research and clinical studies of the various abnormal cardiac mechanisms. The work of Wenckebach, McKenzie, Lewis, and Nicolai in Europe, and Cohn, Herrick, Smith, Wilson, Pardee, and White in this country must be mentioned as taking a leading part in the development of our present knowledge of electrocardiography.

Today the internist must realize that cardiovascular disease forms perhaps

the most important group in his field to be studied and mastered. From the standpoint of morbidity and mortality it heads the list, and our program at this clinical session emphasizes this fact by devoting eighty-five periods to various phases of this group of diseases. In many diseases, such as smallpox, typhoid fever, diphtheria, scarlet fever, and tuberculosis, prophylaxis and therapeutic management have been well standardized, and as a result the physician and the laity are in a position to coöperate in the care and control of these diseases. In circulatory diseases, either acute or chronic, these phases are not so generally understood.

In the study of 800 abnormal cardiograms, we find all groups of cardiac diseases represented. They may be classified into three main groups: (1) those that are supposedly due to irritation of the myocardium; (2) the infections; (3) the degenerative processes.

IRRITATION OF THE MYOCARDIUM

In the first group we include the arrhythmias, represented by premature beats, paroxysmal tachycardia and simple tachycardia. The etiology may be toxic, directly affecting the myocardium, as occasionally seen in excessive use of tobacco, tea or coffee; or it

*Read at the meeting of the American College of Physicians, San Francisco, California, April 7, 1932.

may be temporarily produced by some acute infection. We must also include in this group the irritations of neurogenic origin, which occur from reflex gastro-intestinal disturbances, fear and fatigue. In this series there were thirty-seven cases with premature beats and six with paroxysmal tachycardia in which no specific evidence of cardiac disease could be discovered from history or physical findings. Focal infections were considered as possible causes but chronic follicular tonsillitis, sinusitis, dental abscesses, or acute infections, such as influenza, were not strikingly in evidence in this group of cases, and removal of some of these sources of infection was disappointing in its results. Modification of habits with reference to tea, coffee, tobacco, and elimination of intestinal disturbance and fear of serious cardiac disease, were much more productive of improvement. Premature beats were found in a considerable number of the cases belonging in the degenerative groups, but were not the main factors interfering with the well being of the patient, and apparently had little prognostic significance.

THE INFECTIONS

The second group includes those having valvular lesions and associated myocarditis, usually the result of acute endocarditis with extension into the myocardium, and occasionally involving the pericardium. The great majority of these cardiac insults occurred in early life. Eighty-two cases belonged in this group, fifty males and thirty-two females, and 57 per cent of them were less than fifty years of age.

The prevailing infections noted in the history were inflammatory rheumatism, chorea, acute and chronic tonsillitis, and influenza. The percentage of cases having had measles, diphtheria, scarlet fever, pneumonia and typhoid fever was not above the average found in the whole group and these diseases could not be considered of special etiological significance except in an occasional case. The lesions found were: mitral stenosis, 60; mitral regurgitation, 11; aortic regurgitation, 9; and aortic stenosis, 6. In four cases more than one valve was involved, and in three cases of mitral regurgitation there was slight suggestion of mitral stenosis, and many of those with mitral stenosis as the predominating lesion were complicated by regurgitation. Experience convinces me that the percentage of cases with pure mitral regurgitation is very small. In the 800 cases studied, 164 had systolic apical murmurs that were considered functional. The electrocardiographic findings revealed 13 with premature beats, 38 with notched *P*-waves, and 10 with prolonged *P-R* intervals. Eleven had auricular fibrillation, in most cases in conjunction with mitral stenosis, and 11 had low voltage. Poor *T*-waves were as follows: 31₁, 38₂, 34₃, and inverted *T*'s, 12₁, 20₂, 27₃, all suggesting definite myocardial changes probably due to myocarditis. There were 16 cases that had arteriosclerosis in addition to the valve lesions, and we noted 16 with *Q*-waves larger than 25 per cent of the tallest *R*-wave. All of the 82 had abnormal cardiograms but those with the simpler or less extensive valve lesions revealed only minor

changes such as prolonged *P-R* intervals, notched *P*-waves, and *T*-waves of low voltage.

DEGENERATIVE PROCESSES

The third group, comprising degenerative types, includes cardiograms of auricular fibrillation, bundle-branch block, heart block and a variety of abnormal tracings such as inverted *T*-waves, those of low voltage, and large *Q*-waves, in various combinations. We found 101 with bundle-branch block, 7 with heart block, 55 with auricular fibrillation, and 512 with myocardial degeneration with or without arterial disease in various degrees or angina pectoris. There were 511 males and 164 females in this group, and 568, or 84 per cent of these patients, were more than fifty years of age. These figures indicate a marked preponderance of the degenerative diseases in the males and confirm their occurrence in the later decades of life. In considering other etiological factors in this group, acute infections in early life seem to be of little importance. A history of influenza was obtained in 269 cases. This type of infection may aggravate an already established cardiac condition. Similarly chronic focal infections may be factors in hastening the progress of myocardial, if not of vascular, disease. The eradication of such foci seems justified.

In this group of 675 cases, the influence of heredity was shown to be of great importance, since in 72 per cent a family history of some type of cardiovascular disease was found. Among these, 111 had a positive history in both branches of the family and it is interesting to note that in these cases

manifestations of cardiovascular troubles began as a rule earlier in life than where only one branch of the family was involved. These facts strongly suggest that arteriosclerosis with its degenerative processes is constitutional in nature. Obesity must also be considered as a serious factor in hastening degeneration, as it occurred in 64 per cent of these cases. The early control of this condition will be considered later in discussing management of this group.

SYMPTOMS OF CARDIAC INEFFICIENCY

The symptoms that lead to suspicion of cardiac inefficiency are rather few in the early stages of degenerative cardiovascular disease. Dyspnea is practically always the first, but is frequently overlooked by both patient and physician. The patient often considers moderate dyspnea normal or due to advancing years or over-weight. It is of the utmost importance to determine the amount of effort that produces this symptom. If it occurs during minor or ordinary activities, it should be regarded as very suggestive of cardiac inefficiency. Marked shortness of breath is not apt to be noticed by the patient unless he indulges in vigorous exercise at frequent intervals. In this group of cases dyspnea occurred in varying degrees in 558 cases, and in many was the only subjective sign of beginning cardiac inefficiency. The most difficult cases to judge from the point of history and symptoms were those of very sedentary habits, and here a few vigorous hops or climbing a flight of stairs were usually a convincing proof of a limited cardiac efficiency.

Palpitation or heart-consciousness is perhaps the next most frequent symptom experienced in this group. It is essential to obtain a clear idea of what the patient may mean by palpitation, as it may be a simple tachycardia not related to effort. Palpitation was noted 322 times. When these two subjective symptoms, dyspnea and palpitation, appear together with arterial hypertension and obesity, we should not fail to make a thorough study of cardiovascular efficiency.

Chest pain or precordial discomfort is another important symptom; it does not always mean angina pectoris but may mean aortitis or some other form of heart disease. This symptom occurred 296 times but was radiating in type in only 140 cases and not all of the latter justified the diagnosis of angina pectoris.

Our examination included search for such objective findings as basal pulmonary congestion, abnormal heart sounds, blood pressure, cardiac hypertrophy, and cardiographic findings. Basal congestion was noted 166 times and is worthy of careful study from day to day as evidence of the patient's progress in overcoming decompensation. High blood pressure findings are of extreme importance as they give a picture of cardiac labor with the patient at rest and must be recognized as a handicap to the heart muscle. The systolic pressure was found to be above 150 in 415 cases, and below in 260; the diastolic was above 90 in 366, and below in 309 cases, showing a decided preponderance of blood pressures above 150/90 mm. Hg. In this group a larger percentage of those with blood pressure less than 150/90

occurred in the cases having bundle-branch block, auricular fibrillation, and in a group classified as simple chronic myocardial degeneration. Among these are many with arteriosclerosis, diagnosed as such, not by blood pressure, but by the presence of tortuous or palpable arteries and increased density of the aorta or peripheral vessels determined by X-ray. It was found important to make X-ray examinations of the arteries in the lower extremities in diabetes in order to anticipate possible gangrene, and in other cases to verify the probability of intermittent claudication, as these conditions are often found with a blood pressure less than 150/90. As the diastolic pressure progresses above 100, the prognosis for cardiac efficiency and length of life becomes increasingly unfavorable. In the study of blood pressure, whether high or comparatively low, it is very necessary to consider pulse pressure, which is of important significance in cardiac efficiency.

Heart murmurs are of less significance in this group. Only 49 were found which could be considered organic with reasonable certainty, as compared to 180 murmurs which were thought to be functional. All of these latter were systolic in time and nearly all were located at the apex. These functional murmurs are often diagnostic pitfalls and sources of anxiety to physician and patient respectively. To determine the true significance of murmurs is important, but of equal if not greater importance in this group of cases is a careful study of the heart tones, whether muffled, distant, or distinct, or of good quality. The term "heart tones" is not limited to the valve

sounds alone but includes the muscle tone, the result of the ventricular contractions. Tones that were poor in quality, or muffled, occurred in 324 cases in both the reclining and upright positions and aroused suspicion as to the quality of the heart muscle or the possibility of pericardial effusion. Gallop rhythm, which was found in 34 patients, occurred only in the more serious cases, and should always be regarded as an unfavorable prognostic sign.

In this group of cases of degenerative cardiovascular disease the cardiogram is of great value in forming an opinion of the condition of the myocardium. We found extra systoles 69 times, notched *P*-waves 16 times, prolonged *P-R* interval 44 times, all of which are of interest but not of great significance. Other findings deserve a little more detailed consideration.

Auricular fibrillation occurred 67 times and in this group must be considered indicative of myocardial degeneration. It often has a fair prognosis under proper therapeutic management. Bundle-branch block occurred 101 times and whenever found should be considered as positive evidence of extensive myocardial degeneration. In this series, where it was possible to follow up our cases, 55 per cent died within fifteen months after the bundle-branch block was discovered. Among these cases of bundle-branch block a few are found which present no symptoms either subjective or objective except the cardiogram, and these may go on for years without any symptoms of cardiac inefficiency; but in spite of this each case deserves careful management and the patient should be

warned against unusual effort. Muffled heart sounds are very frequently found to be accompanied by dyspnea, precordial discomfort, poor tolerance for exercise, moderately high blood pressure or evidence of a limited cardiac efficiency, and these cases should be managed with extreme care. The cases showing low voltage numbered 134, and in some of them repeated observations are deserving of special interest. A number of such cases has gradually developed impairment of cardiac efficiency and as a group they deserve a careful study with repeated observations to determine the prognostic value of this type of tracing.

THE SIGNIFICANCE OF SOME ABNORMAL CARDIOGRAMS

The inverted *T*-wave deserves mention, being found with considerable frequency in the degenerative cases. It occurred 231 times in T_1 , 172 times in T_2 , and 186 times in T_3 . Inverted T_1 and T_2 alone or in combination are considered of pathological significance, but inverted T_3 alone is not looked upon as evidence of disease. I am not sure that inverted T_3 is without significance, especially if T_2 is of low voltage. I am inclined to believe that a low T_2 with inverted T_3 will often develop into an inverted T_2 and T_3 and thus may be of pathological significance. In 11 cases where cardiograms have been taken at intervals over a period of years, I have found this change to occur, coupled with evidences of progressive cardiac inefficiency.

The *T*-waves of low voltage are of more frequent occurrence than the inverted *T*-waves, but in similar pro-

portions, there being 234 T_1 , 205 T_2 , and 207 T_3 of low voltage. Both the inverted T -waves and those of low voltage occur with greatest frequency in patients with general arteriosclerosis and obesity, and must be looked upon as positive evidence of myocardial degeneration. We find that not a few of the poor T -waves later become inverted. I have noted these changes in 15 cases. These observations are dwelt on in detail to emphasize the importance of low voltage T -waves as evidence of insidious changes taking place in the myocardium. They deserve our careful consideration when interpreting the cardiogram, and attention should be called to T -waves as being suggestive of low voltage before they reach the point of measuring 1 mm. or less.

Large Q -waves in Lead III of more than 25 per cent the height of the R -waves have been brought to our attention by Pardee as evidence of pathological lesions of the left ventricle. In our series, large Q -waves were found 257 times and occurred with greatest frequency in cases of angina and general arteriosclerosis. In 137 cases of angina, a large Q -wave was found 95 times. Here again I suggest the presence of an inverted T_3 and large Q -wave as still more positive evidence of myocardial disease as far as Lead III is concerned. Further study of the poor T and inverted T and large Q -waves should be encouraged and, where possible, the nature of pathological lesions of the myocardium determined.

The coronary or cove wave in coronary thrombosis is another abnormal picture that is of diagnostic value con-

firmatory of the subjective or objective findings of this serious cardiac condition. In my experience, the cove, or abnormal S - T interval, appears within a few days after the insult, and in the cases that survive and finally develop a fair myocardial efficiency, the tracing returns to approximately normal as far as the S - T interval is concerned. The nearer the tracing approaches to normal, the better the prognosis. Cases under observation for from three to seven years have tracings with little or no evidence of the coronary wave. This wave was found 26 times and occurred in cases of coronary thrombosis or angina pectoris only. In one case attacks of paroxysmal tachycardia occurred during a stormy convalescence. Here, absolute rest, small doses of quinidine sulfate and digitalis and proper use of sedatives, proved most effective in eliminating the attacks.

COMMENT

The management of the various types of cases found in this review may be briefly outlined. The premature beats and paroxysmal tachycardia are of minor importance but sometimes are very annoying to the patient. The best program in my experience is to eliminate anxiety or fear and consider focal infections and toxins, such as coffee, tea and tobacco, as possible causes. It is also important to eliminate reflex disturbances of gastrointestinal origin. In addition we should consider the advisability of the use of quinidine sulfate and sometimes of a mild sedative for relief. Auricular fibrillation, another form of arrhythmia, deserves a good prognosis under proper management. Careful judgment

must be used in the exhibition of quinidine sulfate, as permanent relief of arrhythmia results in only a small percentage of cases. It should be avoided in severe cases of mitral stenosis for fear of unpleasant complications. Whenever there is a suggestion of decompensation, digitalis is the remedy of choice. For the cases with arteriosclerosis and hypertension, bundle-branch block, and associated myocardial degeneration, it is very important to recognize myocardial changes as early as possible and take into consideration the effect of arterial hypertension, the condition of the pulse pressure and the presence of obesity.

In developing a program for these cases it is of great value to outline a proper amount of exercise, as experience proves that it is of extreme importance to maintain the best possible muscle tone and endurance in these individuals. Each case must be considered individually when developing a program of exercise. A careful weight reduction for the obese is of great importance. With patients under close observation, a rather vigorous program of weight reduction by diet and physiotherapy (hydrotherapy, heliotherapy, and massage) may be ventured in the more robust types, if definite evidence of myocardial inefficiency is lacking. In such cases a loss of five

to eight pounds a week may be risked, but with cases not under close observation, a loss of one or two pounds a week is usually safer. The control of food intake and exercise is of greatest importance in these cases. It is surprising how little food is necessary to maintain the desired weight when it is once established. In cases of marked hypertension, particularly those with high diastolic pressure and marked renal inefficiency, the protein intake can be safely reduced to 50 or 60 grams a day, or lower, over a considerable period of time. The use of fruits and fruit juices should always be encouraged and should furnish a considerable portion of the carbohydrate.

Experience convinces me that the greatest reduction in blood pressure and improvement in cardiac efficiency is obtained by reduction in weight, exercise, and a careful regulation of the individual's daily program with reference to work and recreation. Nervous tension, anxiety and fear, should be combatted in all of these cases. Institutional management affording careful observation over considerable periods of time, with the various forms of physiotherapy, dietetic regime and personal contact with the patient, usually produces the best results.

The Value of the Posterior-Anterior Chest Lead in Cardiac Diagnosis*†

By ABRAHAM LIEBERSON, M.D., and FRANK LIBERSON, M.D., *New York*

FROM the very nature of the cardiac action current, it is evident that the number of leads which can be used to conduct the current from selected skin zones to the string galvanometer is legion. It was inevitable that in cases where the three conventional leads failed to furnish enough information about the condition of the heart muscle, some other, taken in another plane, would be tried in the hope that it might supply the needed data. Thus Waller¹ (1887) placed his electrodes all over the body, and in all the natural orifices, searching for "significant" leads. Lewis² (1909), studying the action of the auricles in fibrillation, discovered that the workings of this chamber could be best investigated by a special additional lead from the front to the back of the chest. To date this has found very little clinical application. Recently, however, Wolferth and Wood³ (1932) have applied the chest lead (from front to back of chest) in the diagnosis of coronary occlusion. They report one case where the three conventional leads were practically normal, except on the fourth day, whereas for eight days after the original infarction the Anterior-Posterior chest lead showed striking deviation of the *S-T* interval; and another instance where the evidence for coronary occlusion was present in only two leads, the first and A-P chest leads, the *S-T* deviation being much more striking in the A-P chest lead than in the first lead. They examined 33 non-coronary cases as controls and found no deviation of the *S-T* interval in the A-P chest lead in these cases.

Using a slightly different technique (smaller electrodes and a Posterior-Anterior direction, to be detailed later), and taking the chest lead in conjunction with the usual three in a series of 75 cases, 20 of which were normals, 50 cardiac suspects, and 5 "coronaries", we likewise found the additional chest lead very useful in determining the presence and extent of coronary involvement. We report the following case as especially demonstrative of the fact that the chest lead may point to a diagnosis of coronary occlusion where neither the clinical picture nor the E.K.G. taken with the usual leads suggests it. Often the conventional leads begin to show at a later date those changes seen days and weeks before by the chest lead.

*Received for publication March 30, 1932.

CASE REPORT

H.M., white male, age 53, admitted to the U.S.P.H.S. Hospital, Stapleton, S.I., December 1, 1931. The past history was negative, except for moderate occipital headache and nocturia for ten years. On November 27, 1931 the patient's left leg suddenly felt weak,

and by the 30th it was limp and helpless. He entered with this sole complaint of weakness of the left leg.

Physical Examination. A well-developed white male of 53, not acutely ill. Head, heart, lungs, and abdomen negative. The left foot showed flaccid paralysis. The blood and

FIG. 1. (January 25, 1932). Patient showed no cardiac signs (except fall of blood pressure from 170 to 120 mm. Hg in three weeks). Leads I, II, and III are considered as take-off in Lead III. The Posterior-Anterior chest lead shows, however, an S-T elevation of fully 5 millimeters—practically pathognomonic of coronary occlusion.

spinal Wassermann, urine and blood count were all negative. Temperature 37°; pulse 90; respiration 20; blood pressure 170/90 mm. Hg. The headaches and hypertension suggested a cerebral thrombosis or hemorrhage as possible cause of this monoplegia. Aside from the hypertension the case appeared to be of neurological interest only. The patient did well under rest in bed and physiotherapy to the affected leg, complaining only occasionally of pain in the head or "an upset stomach". His blood pressure, however, fell from 170/90 mm. Hg to 120/66 mm. Hg, and it was thought advisable to make an electrocardiographic examination before transferring him to the Neurological Service. The graph obtained, January 25, 1932, using the three conventional leads and the Posterior-Anterior chest lead was surprising to the clinician (figure 1). The three usual leads showed every fourth beat to be ectopic; there was L.A.D. (old nomenclature). Aside from an occasional, questionable high take-off of the *T*-wave there was in these leads no definite indication of myocardial damage. In the P-A chest lead, however, instead of a symmetrical *T*-wave arising from the isoelectric point, there was fully 5 mm. elevation of the *S-T* interval, with total asymmetry of the *T*-wave. In spite of the negative evidence in the three conventional leads, and the absence of clinical symptoms, it was postulated that the patient had definite coronary damage, the type of curve suggesting an acute process.

The patient was transferred one day later (January 26, 1932) to the Neurological Service of the U.S.P.H.S. Hospital, Ellis Island, where his pulse was found to be very irregular and intermittent, varying between 62 and 104 during the next two days. This was thought to be due to the excitement incident to his transfer. A teleoroentgenogram taken at this time showed a contour of the heart suggesting slight enlargement to the left, but on the whole probably within normal limits in size and shape. There was slightly increased density in both bases and faint triangulation of the cardiac shadow suggestive of myocardial weakness. The E.K.G. of this date (January 26, 1932) employing only the three conventional leads

was reported as showing frequent ventricular extrasystoles, L.A.D., but no significant myocardial changes. After two days the patient began to feel better. The use of the left leg slowly returned in part, and he was discharged improved February 1, 1932.

Patient was readmitted to U.S.P.H.S. Hospital, Stapleton, S.I., on February 9, 1932 as an urgent case, complaining of pain in the upper abdomen and chest of four days' duration, beginning after a heavy meal, and accompanied by a mild non-productive cough and difficulty in breathing.

Physical Examination. Patient acutely ill; facies anxious, shallow and rapid breathing, moderately coarse râles at both bases with altered breath and voice sounds, especially on the right. The apex beat was in the fifth interspace, 8 cm. to left of the midline, and in the midclavicular line. Rhythm regular, pulse weak and thready. The temperature was 38° on admission and varied between 36.4° and 37.8° for the next five days. There were 14,400 W.B.C. with 74 per cent polymorphonuclears. Bedside X-ray at this time showed enlargement of the cardiac outline, with pulmonary congestion but no evidence of pneumonia. The patient for the first two days was in such a state of shock that the clinician thought it inadvisable to subject him to even the slight strain of electrocardiographic examination. He was given small doses of digitalis (2 grains a day) and showed improvement. On the fourth day (February 12, 1932) the E.K.G. (figure 2) showed a definite intraventricular block and a faint suggestion of an elevated *S-T* interval in the conventional leads. The P-A chest lead showed complete inversion of the *T*-wave, a very unusual finding in this lead. The complexes in the chest lead had changed so in the short period between January 25 and February 12, that one had to consider them as evidence of an active process taking place in the coronaries. An E.K.G. taken three days later, February 15, 1932 (figure 3) pointed again to coronary involvement, and showed for the first time a definitely elevated *S-T* segment in both Leads II and III; the P-A chest lead showed again marked changes in the low voltage *T*-wave.

With the rapid change in the complexes over the three week period, and finally with

the almost pathognomonic E.K.G. in all leads at the end of this period, the diagnosis of coronary occlusion could be made with definiteness, and was apparently corroborated by the later clinical course. At 2:30 the next afternoon, February 16, 1932, the patient suddenly developed a convulsive attack with stertorous breathing which rapidly changed to a Cheyne-Stokes type. The heart stopped; the breathing ceased soon after. In spite of medication he died within fifteen minutes.

The mode of death appeared very much like that seen in ventricular fibrillation.

COMMENT

From the electrocardiographic point of view the interesting fact in this case is that by use of the P-A chest lead coronary occlusion could be diagnosed with some definiteness at a time when no other evidence for it (except

FIG. 2. (February 12, 1932). One week after an attack of pain in the epigastrium and chest, followed by leukocytosis (14,400) and a temperature of 37° - 38° C. Leads I, II, and III show intraventricular block, but no definite change in the S-T interval, while the Posterior-Anterior chest lead shows marked inversion of the T-wave—an extremely rare occurrence in this lead. The fact that this graph differs so from the former one would indicate that we are dealing with an acute process—coronary occlusion.

perhaps falling blood pressure) was present. The early findings in the conventional leads were quite insufficient to warrant such a diagnosis. When car-

possible to demonstrate in all leads an *S-T* interval abnormal enough to definitely indicate coronary occlusion. When this occlusion took place is hard

FIG. 3. (February 15, 1932). Taken three days after figure 2. There is a definite elevation of the *S-T* segment in Leads II and III. The conventional leads have assumed the typical aspect of recent coronary infarction. The Posterior-Anterior chest lead also shows marked changes from the previous tracing.

diac symptoms appeared, the P-A chest lead showed clearly those manifold rapid changes in the ventricular complexes that are so suggestive of coronary occlusion. It was not until the day before death, however, that it was

to say from either the history or the tracings, but in the first E.K.G. (January 25, 1932) there is already definite evidence (in the P-A chest lead) of coronary occlusion (possibly a slow closure); while the sudden attack of

epigastric pain and beginning decompensation of February 5, with the subsequent electrocardiographic evidence of acute coronary closure in the con-

ter), the "Right Arm" electrode being placed along the medial edge of the spine of the right scapula (about the level of the third dorsal spine), the

FIG. 4. Several examples of normal findings in the Posterior-Anterior chest lead, either in normal individuals, or in cardinals showing normal electrocardiograms. Note that *P* is upright; *Q-R-S* diphasic and relatively large; the *u*-waves are prominent. The *T* take-off is never elevated more than 3 millimeters. Perhaps most important is the symmetry of the *T*-wave.

ventional leads, is especially suggestive of a recent thrombosis.

The technic used in obtaining the chest leads consists of the application of small, wet, gauze-covered copper electrodes (about one inch in diame-

"Left Arm" electrode going to the cardiac apex area. Great care is taken to avoid undue resistance by keeping the saline solutions warm, cleansing the skin thoroughly, and rubbing it lightly with a very fine copper wire

brush before applying the burnished electrodes. The string is carefully standardized before the taking of each lead; and no tracing is considered satisfactory that shows appreciable overshooting.

Thus far the electrocardiograms of 75 individuals have been taken, showing all four leads. Of these, 55 were cardiac suspects (5 of whom were cases of coronary damage) and 20 were normals. By a study of these normals it was found that the Posterior-Anterior chest lead is not less constant than the conventional leads. It shows characteristically a small up-right *P*-wave; a biphasic *Q-R-S* of high amplitude; a relatively large, up-right, symmetrical *T*-wave; and an *S-T* take-off of no more than 3 mm. elevation above the isoelectric line. The *u*-waves are usually prominent. A number of typical tracings of the Posterior-Anterior chest lead are shown in figure 4, and indicate the usual range of variation in this lead. An asymmetrical or inverted *T*-wave is always abnormal. The most constant finding in an acute coronary closure is a high *S-T* take-off with resultant asymmetry of the *T*-wave. This finding in the Posterior-Anterior chest lead may precede similar changes in the

other leads by days or weeks. This would tend to indicate that the axis of this chest lead is so situated as to register more surely the lesions produced by cardiac infarction. We believe, therefore, that the Posterior-Anterior chest lead is of definite clinical value.

CONCLUSIONS

A case is presented where marked *S-T* interval elevation was seen in the Posterior-Anterior chest lead fully three weeks before similar changes in the conventional leads. This permitted the diagnosis of coronary occlusion in the absence of any other definite sign. The further course of the illness and the later electrocardiograms appear to have substantiated this diagnosis.

Twenty normal individuals were studied to determine the normal range of variation in the Posterior-Anterior chest lead. This information helped substantially in the diagnosis of coronary involvement, which was made in five out of fifty-five cardiacs examined.

We wish to express our indebtedness to Medical Director M. H. Foster, in charge of the U.S.P.H.S. Hospital, Stapleton, S.I., for the privilege of using the hospital records, and to Assistant Surgeon S. P. Cooper, in charge of the Medical Service, for his kind cooperation in obtaining the electrocardiograms.

Localized Atrophy of Subcutaneous Fat Following Repeated Injections of Insulin*†

Report of a Case

By FRIEDRICH ENGELBACH, M.D., *Ann Arbor, Michigan*

THE localized atrophy of subcutaneous fat following repeated injections of insulin was first described by Depisch¹ in 1926, and since then has been reported by Barborka,² Davison,³ Mentzer and DuBray,⁴ Carmichal and Graham,⁵ Chapman,⁶ Rabinowitch,^{7,11} Lawrence,⁸ Priesel and Wagner,^{9,17} Avery,¹⁰ Fischer,¹² McCormick and Moorhead,¹³ Stransky,¹⁴ Price,¹⁶ Boller,¹⁸ Eeg-Olofsson,¹⁹ and Williams.²¹ Less than sixty cases are recorded in the literature, and of these, less than half are described even briefly, and only two biopsy reports are given.

The atrophy noted was almost always at sites of frequent insulin injections and began several months to several years after starting the injections of insulin into the areas later affected. It always involved the subcutaneous fat but produced no apparent changes in the skin or in the underlying muscles. The condition was more common in females than in males, and apparently was not related to the age of the patient, the duration of the diabetes nor to its severity, nor

to the make or amount of insulin used, nor to the methods used in sterilizing syringes and needles. Fischer¹² found the condition present in two-thirds of a group of diabetic children taking insulin. Depisch¹⁵ states that about 10 per cent of patients taking insulin have localized atrophy of subcutaneous tissues at the sites of injection. In one case described by Priesel and Wagner,¹⁷ the fatty atrophy was apparent only after the boy began to gain weight, there being no deposits of fat in the areas frequently used for the injection of insulin. Chapman⁶ reported a patient in whom fat returned in the areas of atrophy, these areas appearing normal two and a half years after discontinuance of the use of insulin. Various other authors report partial return of the fat. Boller¹⁸ and Stransky¹⁴ report a case where the atrophy of fat was noted at the areas of repeated insulin injections and also in one cheek where no injections had been made. The fatty atrophy of the cheek was treated by weekly procaine injections into the area, and three and a half months later the cheek appeared almost normal. Some of the patients experienced pain on the injection of insulin, but many did not. Boller be-

†From the Department of Internal Medicine, University of Michigan, Ann Arbor.

lieves that if procaine is injected with the insulin no pain will occur and no fatty atrophy will result from its use.

Various theories have been advanced to explain the disappearance of the subcutaneous fat. Rabinowitch⁷ was unable to demonstrate the presence of lipase in insulin as a possible cause. Priesel and Wagner⁹ believe that the tricresol used in preserving insulin is the cause, but Depisch¹⁵ gave daily injections of tricresol solution for over two months without producing a fatty atrophy. Avery¹⁰ believes the subcutaneous fat atrophy is a nonspecific reaction, the result of repeated small traumata to the panniculus adiposum. Fischer¹² considers the most plausible explanation to be a low grade inflammatory process set up by repeated injections of insulin, the resultant damage causing replacement of the soft areolar tissue by scar tissue. He also considers the possibility that insulin may raise the level of local tissue metabolism, and thus eventually lead to the disappearance of fat by oxidation. Depisch¹⁵ believes that insulin causes injury to the nerve fibers. Williams²¹ thinks that insulin may injure the membrane that covers the fat cells, releasing fat globules, which, acting as foreign bodies, result in the formation of histiocytes which take on lipophagic activity.

Mentzer and DuBray⁴ report that sections from biopsy of the lesion show no lymphocytic foci and no evidence indicative of inflammatory changes. Eeg-Olofsson¹⁰ on microscopic examination found most of the change to be due to an ordinary atrophy of fat tissue, but that occasionally small areas of round cell infiltration

were found around the vessels. He found nothing which threw light on the origin of this atrophy of the fat tissue.

CASE REPORT

Patient M.B., thirty-two year old American woman, was first admitted to the University Hospital March 20, 1929, at which time she complained of weakness and dizziness of two months' duration and a loss of twenty pounds during this period. Physical examination showed evidence of some recent loss of weight, mild neuroretinitis, a slight diffuse enlargement of the thyroid, and a barely palpable liver and spleen. Urine showed 4 plus sugar and 2 plus diacetic acid. A diagnosis of diabetes mellitus was made and she was placed on a diet of 55 gm. protein, 220 gm. fat and 65 gm. carbohydrate with insulin as needed, the dosage varying from eight to seventy units daily. She was advised to continue the diet and insulin after discharge. On April 21, 1932 she was brought into the University Hospital in diabetic coma, having taken more food than her diet allowed and not having controlled with insulin her glycosuria of several months' duration. She was given large doses of insulin, recovered from the coma, and after a stay of about two weeks' duration was discharged on a diet similar to that prescribed before, with fifteen units of insulin twice daily.

In March 1931, about two years after starting to use insulin, she noticed disappearance of the subcutaneous fat in the anterior and lateral aspects of the upper arms, which were the areas where the insulin had been injected. In March 1931 she stopped using the arms as sites of injection and began using the anterior parts of the thighs. About six months later fatty atrophy began to occur in the anterior parts of the thighs and has been progressive since then. During the last year the fatty atrophy of the left arm has tended to diminish slightly. The accompanying photographs illustrate the extent of the fatty atrophy. In the depressed areas muscle could be felt beneath the skin, there being no evidence of fat at these points. Sensation was entirely normal and there was

FIG. 1

no loss of muscle power. No pain had been experienced from the injections of the insulin which had been made repeatedly in the same areas.

Biopsy was done, a piece of skin and subcutaneous tissue being removed from the affected area on the anterior part of the

is an increased number of small blood vessels, some with slight thickening of the walls, and there is a slight perivascular lymphocytic infiltration. Some of the involved fat cells contain a small amount of albuminous material, but there is no evidence of fatty acid crystals or of soap formation "

FIG 2

right thigh. This was examined in the pathology laboratories of the University Hospital, and Dr. Carl V. Weller has been kind enough to furnish the following report. "The pathological changes resulting in the local atrophy in this material are confined to the panniculus. In the involved lobules the adipose tissue cells are very small and collapsed with a marked reduction in the total lipid content. With this change there

SUMMARY

A case of localized atrophy of the subcutaneous fat following repeated injections of insulin has been described.

Although the actual mechanism that causes the disappearance of the subcutaneous fat is not known, the condition seems to be associated with

frequent injections in localized areas, and, to prevent the condition it would be advisable to scatter the doses of insulin over as large an area of the body as possible.

Primary Spondylitis*†

By W. PAUL HOLBROOK, M.D., F.A.C.P., ROBERT M. STECHER, M.D.,
and EDWARD M. HAYDEN, M.D., *Tucson, Arizona*

IN approaching the study of spondylitis, or arthritis of the spine, one may properly ask that its relation to the large group of chronic arthritide be defined.

Any discussion of chronic arthritis is at present most confusing because of the numerous classifications and the many variations in terminology. Classifications now in use are, in general, based upon etiological or pathological suppositions. Etiological classifications can be of little help, as no single factor has definitely been proved to be the specific causative agent. One needs to recall but a few of the present affirmed etiological factors to realize that chronic arthritis is as yet a disease of unknown origin. The neurogenic theory, the theories of vascular deficiency, trauma, endocrine deficiency, presenile changes, disturbed metabolism, infection, and many other hypotheses all have ardent supporters. Pathological groupings are but little better as material is very difficult to secure at progressive stages, and scattered observations during different stages of the same disease are apt to be misleading. The number of pathological examinations that have been correlated with

clinical studies are far too few upon which to base an opinion. One of us (W.P.H.) has asked many pathologists in this country and abroad for such information only to be told that the pathologist's interest lay elsewhere, or that insufficient material could be secured to be of any value.

It has been a hopeless task from our standpoint to fit our arthritis patients into existing ready-made groups. During several recent medical conferences in which arthritis was a special interest, leading authorities have proposed more than a dozen separate classifications and have recommended equally diversified treatment. Because of this existing confusion and the absence of uniform clinical concepts, we decided to study a large group of arthritides completely and uniformly. These studies were made under the most complete control and supervision of the patient and in ideal climatic surroundings. During the past eighteen months three hundred patients with chronic arthritis have been selected from our hospital and outpatient department for this study. We have tried to consider these patients from two standpoints. We have attacked the problem as a research which involved many exhaustive tests and examinations. But we have also attempted the simplest clin-

Primary Spondylitis*†

By W. PAUL HOLBROOK, M.D., F.A.C.P., ROBERT M. STECHER, M.D.,
and EDWARD M. HAYDEN, M.D., *Tucson, Arizona*

IN approaching the study of spondylitis, or arthritis of the spine, one may properly ask that its relation to the large group of chronic arthritide be defined.

Any discussion of chronic arthritis is at present most confusing because of the numerous classifications and the many variations in terminology. Classifications now in use are, in general, based upon etiological or pathological suppositions. Etiological classifications can be of little help, as no single factor has definitely been proved to be the specific causative agent. One needs to recall but a few of the present affirmed etiological factors to realize that chronic arthritis is as yet a disease of unknown origin. The neurogenic theory, the theories of vascular deficiency, trauma, endocrine deficiency, presenile changes, disturbed metabolism, infection, and many other hypotheses all have ardent supporters. Pathological groupings are but little better as material is very difficult to secure at progressive stages, and scattered observations during different stages of the same disease are apt to be misleading. The number of pathological examinations that have been correlated with

clinical studies are far too few upon which to base an opinion. One of us (W.P.H.) has asked many pathologists in this country and abroad for such information only to be told that the pathologist's interest lay elsewhere, or that insufficient material could be secured to be of any value.

It has been a hopeless task from our standpoint to fit our arthritis patients into existing ready-made groups. During several recent medical conferences in which arthritis was a special interest, leading authorities have proposed more than a dozen separate classifications and have recommended equally diversified treatment. Because of this existing confusion and the absence of uniform clinical concepts, we decided to study a large group of arthritics completely and uniformly. These studies were made under the most complete control and supervision of the patient and in ideal climatic surroundings. During the past eighteen months three hundred patients with chronic arthritis have been selected from our hospital and outpatient department for this study. We have tried to consider these patients from two standpoints. We have attacked the problem as a research which involved many exhaustive tests and examinations. But we have also attempted the simplest clin-

*Accepted for publication April 26, 1932.

†The Desert Sanatorium and Institute of Research. Tucson, Arizona.

ical approach, and it is this practical clinical study that is responsible for the grouping shown in table 1.

The average length of time these patients were under observation was slightly over five months. Many of them were in the hospital the entire time, and nearly all of them were hospitalized at intervals. This group of patients has been carefully analyzed as to history, physical examination, laboratory, roentgenologic studies, and response to treatment. We have not assumed any specific etiology but have grouped them solely upon a clinical basis.

The greater portion of our patients come from widely separated points geographically, and so should represent an accurate cross-section of types. It is only fair to say that most of them are "last-resorters", and so should be thought of as representing the very chronic or advanced stage of the disease.

It seemed at the beginning an endless task, but there have emerged to date six well defined groups. No argument is being made at this time for a separate etiology. Indeed it is wholly possible that several groups may have one or many etiological factors in common. We have, however, found such a grouping practical and very helpful in selecting therapeutic measures; table 1 presents a brief analysis of the six groups.

Group I is an afebrile, insidious, progressive, symmetrical, deforming, and crippling disease. Arthritis deformans, rheumatoid arthritis, atrophic arthritis, and proliferative arthritis are other common terms loosely applied to any severe polyarthritis. This group is

separated from Group II, which appears infectious in its manifestations, because of Group I's marked predilection for women beyond the third decade, its symmetry, the lack of fever, the marked and wide-spread demineralization, the early cartilage destruction, the trophic skin and muscle changes, and the complete failure of therapy when directed toward infection or when the problem is attacked solely from the standpoint of foci of infection. It is a disease often dramatically affected by the patient's emotional life, and in most instances is associated with some form of gastrointestinal dysfunction. If infection plays a major rôle in this group of cases, its manifestations are not obvious, and there are surely other necessary factors.

Group II Arthritis is most commonly termed chronic infectious. It is also known as atrophic, or rheumatoid, and is referred to in many other terms. It is in general not separated from Group I. In contrast to Group I, however, there is fever, malaise, and other constitutional symptoms of infection. Everyone is familiar with this picture of infectious polyarthritis with pain, heat, redness, and swelling in the joints at some stage of the disease and usually at the onset. In this most acute phase it is with difficulty that it is differentiated from acute rheumatic fever.

Group III Arthritis is often classified as osteoarthritis, hypertrophic arthritis, degenerative arthritis, and streptococcus viridans arthritis. This is a disease which comes on rather late in life with insidious onset, and usually first noted because of stiffness of the spine or fingers. Heberden's nodes

often occur, and there is usually only pain and swelling of the joints without heat or redness. The weight and health are excellent. The blood pressure is normal or elevated, and the constitutional type tends toward the sthenic. It is relatively a benign disease producing lipping and spurring in various joints.

Group IV is the group of primary spondylitis which we will discuss shortly.

Group V is often referred to as metabolic, traumatic, or menopausal. The important factor in this group is that a weight-bearing joint, usually a hip or a knee, is involved. Ordinarily, not more than one or two joints are affected, and this is one respect in which it differs from Group III osteoarthritis which is a generalized disease. Patients of Group V are usually overweight with no significant findings except in the weight-bearing joints or in joints that have suffered trauma. The riding master with an arthritis of the hips, the watch-maker with involvement of the cervical vertebrae, and the trap-shooter with arthritis of the shoulder are included as well as the overweight, middle-aged woman with painful knees.

Group VI may properly be termed pre-arthritis and in it are included all manifestations of neuritis, myositis, bursitis, and fibrositis.

We have included spondylitis for purposes of simplicity in grouping as one of the groups of chronic arthritis. Primary chronic arthritis of the spine represented by Group IV may be separated into two general groups: Type A (without bony ankylosis), and Type B (with bony ankylosis). The lipping

and spurring of the spine seen commonly with generalized osteoarthritis is not included in this grouping but it is included under the generalized disease of Group III. It should be clearly understood that this discussion is limited to what may be properly called primary spondylitis as manifested by a painful rigid spine. In reviewing the last three hundred patients seen with chronic arthritis, twenty-two cases of primary arthritis of the spine were found. Thus over 7 per cent of the total three hundred suffered from primary spondylitis. Of the twenty-two, ten were Type A (without bony ankylosis), and twelve were Type B (with bony ankylosis). These cases of spondylitis are briefly tabulated in tables 2 and 3.

Type A spondylitis, (table 2), is an unusual disease, or more probably an unrecognized syndrome, for we have found no description of this condition in the literature. Most remarkable is the observation that only males have been seen with this disease. The age of onset is in early adult life from seventeen to thirty. The duration of the disease has varied from one to sixteen years and has averaged six and nine-tenths years. All patients of this group are still alive and under periodical observation. The onset is insidious and gradually progresses to a poker spine. There is much pain and muscle spasm in the back. The patient walks with a peculiar waddle characteristic of a fixed spine and pelvis, exaggerated no doubt by adductor muscle spasm in the thighs. Dyspnea on exertion is the rule because of fixation of the rib cage. Chest expansion is often scarcely perceptible. The head is us-

*These two patients later developed acute polyarthritis without any change in the spine condition and with all manifestations of Group II Arthritis.

usually carried slightly forward and tends to produce a dorsal kyphosis with a loss of lumbar curvature. The constitutional type involved is the asthenic individual. The general health is poor and the patient shows evidence of a severe constitutional disease. Loss of weight is often marked, and in our series varies from fifteen to seventy pounds. The spine alone is usually involved, although muscle spasm in the back in most cases produces limitation of motion as well as pain in the shoulders and hips. In spite of evidences of severe constitutional disease with marked fatigue, loss of weight, and pain and stiffness in the spine, there is no fever, no anemia, no leukocytosis, and no obvious infectious foci in the majority of these patients. Most astonishing, however, is the absence of demonstrable roentgenologic changes in these completely stiff spines. One of this group has had the disease for nearly sixteen years, having much pain with rigidity of the spine, and as yet the spine shows no demonstrable bony ankylosis. All of the patients show an unusual roentgenologic appearance of the sacroiliac joints. There is loss of cartilage and presumably fusion. Very complete studies have been done on these patients but only a brief summary can be given here. These patients are alike as peas in a pod. No one can fail to recognize the picture when familiar with it. Patients who suffer from this disease are so identical in their many manifestations and so different from other types of arthritis that we have felt justified in considering Type A spondylitis as a separate disease syndrome.

Type B spondylitis (table 3) is

characterized by stiffness of the spine associated with bony bridging between the vertebrae. The bridging may be local or generalized to include the entire spine. It may be associated with involvement of the hips and shoulders, and there is often ossification of the ligamentous attachments of muscles about the pelvis. The condition described by Knaggs as *Spondylitis Ligamentosa Ossificans* may be identical and the term is undoubtedly a good descriptive one for this group of cases. This striking picture must not be confused with the benign lipping and spurring so frequently seen in the spines of Group III Osteoarthritis. Type B spondylitis differs from Type A in several interesting respects, although the patients do not appear widely different on casual examination. Again, these patients are limited to the male sex. The average age and the age of onset are quite similar to the Type A cases. The character of the onset, however, is often acute, with a febrile illness, while the insidious onset is distinctive of Type A. The constitutional type, the general health, and the weight loss are not particularly different from Type A. Several of these Type B patients gave a history of one or more peripheral joints having been involved. Foci of infection are frequent in this group of patients and exceedingly rare in Type A. Attention must be called to the frequency with which tuberculosis occurs in the Type B group. Seven patients out of a total of twelve had presumptive tuberculosis. Fever is the rule in this group, while but one patient in the Type A group had fever and that only with occurrence of an acute infection.

Anemia and leukocytosis occur more frequently in Type B than in Type A. However, the most startling difference between the two groups is in the roentgenologic findings. Type B shows massive bridging of the spine with calcification of ligaments, and many times this extends to the muscle attachments about the pelvis. The Type A patients reveal absolutely nothing to account for the rigidity of the spine.

To find twenty-two men with stiff, rigid, and painful spines among the three hundred routine chronic arthritics studied was something of a surprise. We have since gone over all the additional patients possible in search of a female with this disease, but up to the present time have not found one. This seems more significant, because of the three hundred arthritics studied more than half were women. The men of both groups were all afflicted in the prime of life, and nearly all of them had lived sheltered and protected from physical strain. Physicians, dentists, lawyers, and accountants were frequently victims. This spondylitis should not be confused with the condition ordinarily known as "laborer's spine". The pain and discomfort suffered by patients with Type A spondylitis is not unlike a severe and permanent lumbago, if one can imagine such an unhappy afflic-

tion. Coughing or sneezing may produce the most agonizing pain as well as marked intercostal muscle spasm. The Type B patients get much relief from pain when the ankylosis becomes complete and many of them reach an entirely painless stage in which their major discomfort is limitation of motion. Complete case reports, together with a discussion of etiology, treatment, and prognosis will appear shortly in a more detailed paper.

SUMMARY

1. Two specific types of primary chronic spondylitis occurring only in males are reported,—one with bony bridging, and one without bony bridging. The twenty-two cases reported represent 7 per cent of the three hundred patients with chronic arthritis studied.

2. The Type A spondylitis without bony bridging is emphasized as being a clinical entity not usually recognized and about which little has been known. The surprising frequency of this condition warrants its consideration in the diagnosis of every young man with back pain.

3. A clinical grouping of chronic arthritis based upon similarity of clinical findings is given to present the relationship of spondylitis to this grouping.

The Teaching of Inheritance of Disease to Medical Students*

A Proposed Course in Medical Genetics

By MADGE THURLOW MACKLIN, A.B., M.D., *London, Canada*

GENETICS has made greater strides in the last twenty-five years than any other of the biological sciences. So exact has this study become that the position of the ultimate determiner of hereditary characters is plotted on a chromosome map with the same exactitude with which the explorer denotes the geographical position of any given place on the earth's surface. With such an increase in knowledge, it is inevitable that an application of genetics to man should be made. Because it is much easier to trace the hereditary wanderings of some *peculiar* character through a human pedigree than it is to follow the trail of normal characters that are so common that they are universal, the study of human heredity has largely centered about pathological conditions.

This interest in pathological heredity has been enhanced to a certain extent by the fact that the brilliant work done in preventive medicine by the immunologists and sanitation experts has served to decrease very materially the death rate from infectious diseases. Persons spared from death by infection are kept alive to succumb to their constitutional disorders, so that we

find the death rate from many of the degenerative disorders of the circulatory system, from cancer and from diabetes, rising. As many of these constitutional ills have an hereditary background, the triumphs of modern preventive medicine have served to throw into stronger relief the problems of human inheritance.

The medical profession as a whole has a very limited conception of how many diseases are inherited. It is true that many of them are rare, fortunately so, and that they do not bulk as large in numerical importance as do the infectious diseases, but being inherited they increase alarmingly as the years go by. From the standpoint of financial burden to the public, the whole public health program probably does not cost the people as much as do the hereditary diseases of the nervous system alone, with their schools for the feeble-minded, institutions for the insane, special schools for the blind and deaf, etc.

Premedical Training. The biologist who trains the medical student in his premedical days does much to stimulate interest and to instruct the student in the fundamentals of genetics. Unfortunately, however, most students

*Received for publication July 5, 1932.

are not able to see the value of this work, because the illustrations given them of necessity deal so largely with plant and animal life, usually animal life of a relatively low order. The information gained is thus apt to seem almost wholly dissociated from the realm of human disease, which is to be the practitioner's life work.

Even if the biologist were to give examples from pathological inheritance in man, the student is not yet sufficiently advanced to understand either the terminology or the significance of the illustrations used. One cannot make inheritance in Friedreich's ataxia mean anything to a student, when he has no idea of what Friedreich's ataxia is, what a knee jerk is, what claw foot is, etc. The student can absorb only so much at a time. The biology course should not include clinical subjects; it should give the student training in the fundamentals of genetics, so that when he comes to his clinical work the terms used in the discussion of inherited diseases may be intelligible to him.

Necessity for Medical Training in Genetics. The formal teaching of genetics should, however, not stop with the course in biology. Much knowledge concerning the inheritance of disease has been accumulating which is of very practical importance to the practitioner; practical because it will increase his diagnostic acumen, his therapeutic skill, his prognostic ability, and will at the same time enlarge his opportunities for preventive work. This knowledge, it is true, has not been taught to the medical student in the past, except as it came in as an aside in the clinical lectures of some clinician particularly interested in heredity.

This lack of formal instruction in the past explains why many of our clinical teachers of today are not trained to bring the significance of heredity into their lectures. The students of today are receiving little information on the subject and as they become the clinical teachers of tomorrow, the lack of teaching in this branch will continue. For this reason we should have a definite course designed primarily to teach the student what is known of heredity in disease. It is true that not a great deal is known of some aspects of human inheritance, and that what we teach must be taught with many reservations. The same is true of many of the so-called facts of our medical knowledge of today. That does not deter us, however, from teaching what is known.

One of the greatest values accruing from the inclusion of such a course would be not so much the knowledge it gave to the particular students, as the knowledge they would ultimately give to us to correct our faulty notions and our incomplete observations. The student who is alive to the importance of heredity will observe and report accurately its manifestations in his patients. The student who never knew that diabetes and pernicious anemia were inherited will pass by the hereditary aspects of these diseases, because he will feel that it was by mere chance that several brothers and sisters were affected in one family. At a recent talk before physicians, I was astonished to find the numerous striking instances of inheritance of pathological conditions which even a group of only twenty-five men could recall from their practices. In some cases the knowledge

of the condition in other members of the family was of help in diagnosis. Thus they recalled a parent and two children with heart block; a man and his son operated upon for renal calculi; three generations of displaced lens; marked mental deficiency in mother and children; pernicious anemia running through several generations, etc. But none of these had ever crept into the clinical literature, because they had not seemed of sufficient importance. Yet we have those who are skeptical of the influence of heredity in disease, because there are so few published records of it.

I have said that a knowledge of inherited diseases would be of value from the diagnostic angle. It naturally follows that when the diagnosis is better, the therapeutic procedures that follow will be better and the results for the patient improved. Let me cite briefly two examples. So many relatively rare diseases come under the category of inherited diseases that, if they are not mentioned for their heredity value, the student may never hear of them. It is the rare disease that often gives the practitioner his chance to establish a reputation. For example, one roentgenologist advised removal of a child's arm for sarcoma of the humerus. The plate showed a growth, and sarcoma was the diagnosis. The family objected, and the child was sent elsewhere. The second physician showed not only a growth on the arm, but beginning growths elsewhere, and also similar bony excrescences in the father. A diagnosis of hereditary deforming chondrodysplasia was made and the child still has its arm.

A second child with very dry skin,

sparse hair, and only one tooth was treated as a hypothyroid case and given thyroid extract. The patient was not benefited, and finally was taken to another physician, who recognized that the mother had very few teeth and diagnosed the cases of both mother and child as hereditary ectodermal dysplasia. The child showed more extensive involvement than the mother. He recognized the futility, even the cruelty, of thyroid treatment. Here was a child with no sweat glands, who was already handicapped in the endeavor to keep his body cool, being given medication which whipped up his metabolism and thus increased his discomfort.

One has only to think of pernicious anemia, and the opportunities there for preventive therapy with members of the family who have not yet shown the anemia but who are in the achylic and achlorhydric stage, to realize that a knowledge of the inheritance of disease is important from the point of view of preventive medicine.

It seems evident, that information concerning heredity in disease should not be given to students until they have had some lectures dealing with the diseases under discussion, and until they have become familiar with the signs and symptoms of disease. The proposed course which would give to the student a knowledge of heredity in pathological conditions will be of most value to him only if it is given in the final year, when he is acquainted with the subjects of medicine and surgery and all their branches. This does not mean, however, that inheritance is to be ignored in other courses and given to the student only at the

end of his career. The more widely trained our teachers become, the more they will correlate their courses with the course in medical genetics. The student will receive his biological background in his premedical days. When he enters upon his course in embryology, which deals with human development utilizing chick and pig material only for the early stages, he constantly meets with the influence of inheritance. Thus maturation of the ovum and sperm can be made a matter of great fascination by illustrating it with records of inherited human diseases, showing how through maturation comes the opportunity for segregation of characters which we see so strikingly illustrated in human pedigrees. Discussion of the mode of formation of the uriniferous tubule can be made a theme of thrilling interest, by the discussion of polycystic kidney and its inheritance. A dozen malformations of the developing fetus, which serve to emphasize the manner of normal development, can be made real to the student, not only by cooperation with the staff of the children's hospitals, whereby cases can be brought into class, but also by discussion of the inherited factors behind these conditions. I have found my students more than interested in embryology, through which runs a constant thread of heredity not only of the normal but of the abnormal characters.

In gross anatomy, an anomaly found in the dissecting room can form the basis of a short talk on what is known of the inheritance of that particular condition. In physiology the discussion of the mechanism of urine secretion and of the threshold of excre-

tion for salts, sugar, etc., offers an opportunity for pointing out the hereditary factor in ortho-glycemic glycosuria. Pharmacology brings up hereditary peculiarities and idiosyncrasies to drugs. Biochemistry in teaching metabolism can point out the hereditary anomalies which allow certain persons to excrete alkapton, pentose, urobilin, or sugar.

In clinical fields, of course, opportunities are unbounded, and the value of a knowledge of inheritance to the physician who can thus get "diagnostic tips" is very real. The obstetrician who is having a hard time to deliver a woman whose pelvis is deformed through osteogenesis imperfecta and who has to resort to forceps in order to effect delivery may be able to save himself a suit for malpractice, if he brings into the world a baby with three or four fractures. Or if he has delivered a woman of one hydrocephalic child, he may be able to make the same diagnosis much more readily when the second shows the same defect, thus shortening the labor and modifying the technic employed to bring about birth.

The surgeon who is dealing with inguinal hernia, or with varicose veins, has opportunities for discussing the inheritance of these conditions. The pediatrician who has in clinic a baby with fatal jaundice can not only discourse upon the embryology of the formation of bile ducts, but upon the inheritance of that factor which inhibits the normal development of that minute part of the embryo, and so causes many babies in the same family to have the same disease. The neurologist has unlimited opportunities for

bringing out the inheritance factor in disease, and also for emphasizing the fact that knowledge of the presence of an inheritable disease in the family of the patient may be an aid to early diagnosis. Thus the mere diminution of a knee jerk, which might not be noticed ordinarily, becomes most significant when one knows that another member of the family had Friedreich's ataxia; or the enlarged limbs of a still healthy lad may assume a sinister meaning when we know that his older brother had pseudo-hypertrophic muscular dystrophy.

Thus all the way through the medical course the student would be learning of inheritance and of its importance in disease. Such instruction, however, would not remove the need of a course in medical genetics in the senior year. Such a course would round out the student's conceptions of the subject and would enable him to classify systematically the various manifestations of heredity as seen in clinical medicine. The senior student's clinical training would enable him to appreciate this course and to put the knowledge gained to use in his daily work. Even in such things as infectious diseases, he would learn that there are inherited immunities or partial immunities, so that the dark skinned races are less susceptible to skin infections and more susceptible to respiratory infections than are the light skinned races. He would learn that the children of one family respond to even the slightest irritant with a high fever, while in another family, the reaction is much less. He would see that some children have convulsions with a very low fever, while other children do not have convulsions even

with a very high temperature. All such facts he will correlate with the great hereditary complex that goes to make up an individual.

With such a background our students may return to that conception from which modern methods have somewhat deflected us; namely, to the conception of the patient as an individual, not merely a case for the surgeon, the gastro-enterologist, or the gynecologist, but an entity whose physical, mental, and metabolic background contributes to his disorder. More than that, the physician with training in medical genetics will begin to take a long term view of medicine and its preventive and public health aspects. He will not neglect the patient, but he will visualize him as an entity in society. He will not only cure his present ill, if possible, but he will be able to forecast some that may occur to him because of his makeup, and to forestall them.

By Whom Should the Subject Be Taught? The subject should not, however, be left entirely to those who are teaching in the various branches of surgery or medicine, for not infrequently they are not familiar with or interested in the topic. We do not leave the subject of roentgenology to be taught as an aside by the surgeon, even though the latter constantly uses and refers to X-ray pictures as an aid to diagnosis. Similarly, medical genetics should be taught by a medically trained person who is thoroughly conversant not only with the subject of medicine but with the field of genetics, who knows it as intimately as the gastro-enterologist or the roentgenologist knows his special field of diagnosis and therapy.

Medical genetics is a specialty, only

in the same sense that pediatrics, internal medicine, or gynecology are specialties. It touches the work of the practitioner in many intimate ways; as he becomes familiar with it his usefulness to the patient and to the community is increased. Knowledge of medical genetics is far more essential to the practice of medicine than is the carrying out of many of the elaborate experiments in the preclinical years, which are designed for the research worker in that particular branch of science rather than for the medical student. It might be thought that since medical genetics is an essential part of general medical knowledge the teaching of it could be confined to the clinicians who give instruction in the symptomatology, the physical signs, the diagnosis and therapy of disease. The fact cannot be ignored, however, that clinicians do not usually take advantage of their opportunity to give instruction in the inheritance of disease and largely this is because of lack of familiarity with the subject. The data are scattered and often buried in inaccessible clinical reports and so are not available for the preparation of a clinic. The clinicians teach what they know, and leave untaught what is not familiar to them. Of course there are brilliant exceptions. I cannot forbear to mention Dr. Lewellys F. Barker who never misses an opportunity of discussing the heredity of the disease shown in his clinic if there be an inherited background. For the most part, however, it will be necessary that a person with medical training and with particular experience and training in the study of inheritance in disease should be the one selected to

give the students instruction in this field.

It is true that the medical curriculum is over-crowded, but it was pointed out at a recent congress held at Edinburgh University, that the teaching of today is too largely permeated by the curative ideas of the medicine of yesterday rather than by the preventive ideas of medicine of today. It is in the field of prevention that medical genetics promises to be most useful. The meeting went on record as stating that the interest of the student was too largely directed to the end products of disease from the clinical angle, and to an unnecessary wealth of detail which had little or no bearing on his work as a practitioner on the preclinical side. The greatest need was for more applied biology (and what is more evidently applied biology than medical genetics) and also for more emphasis on prevention rather than on cure.

Opportune Time to Introduce Course in Medical Genetics. The time is ripe for the introduction of such a course into medical schools. The popularization of science by biology teachers and writers, the education of the public to some extent by physicians who are "heredity conscious", as well as by lectures, radio broadcasts and literature distributed by eugenic and genetic societies, are stimulating inquiries by the public which the physician must answer. If the medical schools do not recognize their opportunity and their obligation in this matter, the profession will be less well informed than is the laity. Medical courses should prepare the student for future needs; they should give him a background of

fundamentals on which he can erect a sound structure in later years. This is not being done with respect to inheritance in diseases. Although much is being published on this subject by those interested, it is not universally read, because the practitioner has not the necessary basic knowledge to enable him to grasp even the significance of many of the terms which are used.

It is true that at present there does not seem to be a great financial return from this particular study, and that therefore there will be need for the creation of endowed chairs in medical genetics, whereby research workers in this important field can not only teach medical students but can continue their investigations. As the profession and the public become alive to the possibilities, and as the latter learn to seek medical aid before the disease has started rather than after its onset, the physician will get his returns in the field of prevention rather than cure. Physicians are interested, and are becoming progressively more so, as they are learning more of the subject. One enlightened medical health officer, who is on a national Board of Examiners for medical licensure, regularly questions the candidates upon heredity in disease. He is keenly alive as to its public health aspects. The more general inclusion of such questions in State Board examinations would stimulate an interest in the subject. The matter of including in the Royal Society of Medicine in England a section which shall be devoted solely to reports of hereditary diseases is being advocated. The medical atmosphere is working toward the saturation point; there now must soon come a precipitation into an

organized course of medical genetics designed to teach the student what is known of inheritance in disease.

PROPOSED CONTENTS OF COURSE

The following is a brief outline of a proposed course in Medical Genetics to be offered to students in their final year of medicine. The course would consist of thirty-six hours of lectures as a minimum and, depending upon the available clinical material in the hospital at the time, a certain amount of practical work. There would be much leeway here in the line the practical work would follow, just as there is variation in the choice of material for medical or surgical clinics.

The time table would be as follows:

- 2 hours. The fundamental concepts of inheritance, with special reference to the problems as met with in man.
- 2 hours. Heredity in endocrine diseases.
- 3 hours. Blood and blood vascular diseases in relation to heredity.
- 1 hour. Vasomotor and trophic disturbances.
- 1 hour. Genito-urinary disease.
- 2 hours. Digestive diseases and hereditary diseases of the spleen.
- 2 hours. Anomalies of metabolism.
- 3 hours. Eye diseases.
- 2 hours. Skin diseases.
- 2 hours. Skeletal diseases and malformations.
- 5 hours. Diseases of the nervous and neuro-muscular systems.
- 4 hours. Mental diseases.
- 3 hours. Tumors, benign and malignant.
- 1 hour. Miscellaneous conditions.

- 1 hour. Monstrosities and multiple births.
- 1 hour. Correct method of compiling family histories.
- 1 hour. Preventive and public health aspects of the problem.

Below are listed some of the conditions which would be discussed under each of the above headings.

1. Fundamental concepts of inheritance. Direct, indirect, sex-linked inheritance. Variations in mode of inheritance of disease in different families. Age factors in inherited disease.
2. Endocrine disturbances. Goiter, simple, exophthalmic; myxedema. Diabetes insipidus. Obesity. Adiposa dolorosa, Laurence-Biedl syndrome. Addison's disease. Diabetes mellitus. Miscellaneous endocrinopathies.
3. Blood and blood vascular system. Inheritance in blood groups, from medico-legal standpoint. Hemorrhagic diatheses including hemophilia, purpura hemorrhagica, and the great unclassified groups belonging to neither of the above. Telangiectasia, hemoptysis, hematuria, hematemesis. Pernicious anemia. Achylia gastrica. Sickle cell anemia. Polycythemia. Leukemia. Congenital defects of the heart. Hypertension, apoplexy, hypotension, angina pectoris. Varicose veins.
4. Vasomotor and trophic disorders. Urticaria, epidermolysis bullosa, angio-neurotic edema, chronic edema, Raynaud's disease.
5. Genito-urinary diseases. Albuminuria of idiopathic origin. Polycystic kidneys. Bladder atony. Polymastia. Hermaphroditism. Hypospadias. Phimosis. Varicocele. Cryptorchidism, imperforate hymen, etc.
6. Digestive system. Liver and spleen. Gastric ulcer. Absent or malformed parts of digestive tract, such as salivary glands, atresia of esophagus, hypertrophic pyloric stenosis, imperforate anus, situs inversus, etc. Icterus neo-

natorum, acholuric jaundice, Gaucher's disease, cirrhosis of the liver, etc.

7. Anomalies of metabolism. Ortho-glycemic glycosuria, gout, alkaptonuria, cystinuria, pentosuria, steatorrhea, porphyrinuria, urobilinuria.
8. Eye diseases. Ptosis, ophthalmoplegia externa and interna, lagophthalmus, cryptophthalmus, blue sclerae, pterygium, megalocornea, microcornea, keratocornea, cornea plana, embryotoxon, corneal opacities not due to syphilis or tuberculosis, microphthalmus, anophthalmus, hydrophthalmus, glaucoma, defective or absent iris, cataract, ectopia lentis, color blindness, day blindness, night blindness, retinitis pigmentosa, amaurotic family idiocy, juvenile and adult forms of heredo-degeneration of the macula, glioma retinae, optic atrophy, hypermetropia, myopia, nystagmus, astigmatism, strabismus.
9. Skin diseases. Anomalies of hair color, distribution, and absence of hair, teeth, sweat glands, etc. Dystrophies of the nails, of the teeth, of the skin. Tumors of the skin. Albinism, etc.
10. Skeletal malformations. The deformities of hand and foot, as polydactyly, brachydactyly, syndactyly, monodactyly, ankylosis, club foot and hand, contracture of fingers, fragilitas ossium, multiple cartilaginous exostoses, cranio-cleidodysostosis, oxycephaly, acrocephaly, achondroplasia, dwarfism, absent radii, cervical ribs, congenital dislocation of the hip, and numerous dystrophies of the bones and joints, cleft palate, hare lip.
11. Diseases of the nervous and neuromuscular systems. Progressive central muscular atrophy, Wernig-Hoffmann atrophy of infants, amyotrophic lateral sclerosis, hereditary spastic paraplegia, peroneal atrophy, Friedreich's ataxia, Marie's cerebellar ataxia, multiple sclerosis, extra-cortical axial aplasia, cerebral diplegia, Schilder's encephalitis, word blindness.

aphasia, paralysis agitans, hepato-lenticular degeneration, athetosis, facial paralysis, syringomyelia, myoclonus, periodic paralysis, tremor, neurofibromatosis, miscellaneous nervous disorders. Muscular diseases: muscular dystrophies, amyotonia congenita, myotonia atrophica, myotonia congenita.

12. Mental diseases.

Migraine, epilepsy, Huntington's chorea, microcephaly, mongoloid imbecility, macular degeneration, dementia praecox, manic depressive states, feeble-mindedness, etc.

13. Tumors.

All types of tumors of all organs, with evidence from the statistical standpoint as to the frequency of any given tumor in the population at large, and its significance in more than one member of the family.

14. Miscellaneous conditions.

Deaf mutism. Status lymphaticus. Allergic diseases. Hernia. Left handedness.

15. Multiple births. Monstrosities.

Twinning, anencephaly, spina bifida, hydrocephalus, hydropic kidney, etc.

16. Correct method of compiling family history with practical work.

In conclusion, let me again emphasize that, as we eliminate through our admirable public health organizations those diseases which are transmissible from person to person by means of infectious organisms and by filterable viruses, we are raising the percentage of the population who will fall victim to hereditary diseases. Some of these diseases may be of great importance only to the persons immediately concerned, and by the institution of preventive methods, these persons may have their lives still further prolonged for usefulness in the community. Many of the diseases, however, have a very direct public health aspect, since they are transmissible by germ plasm if not by organisms; they are of great economic importance to the public, since their victims require public aid in the maintenance of institutions, doctors and nurses to look after them. The only way to meet both problems is to have a medical profession trained and alert in the matter of human inheritance.

Editorial

THE USE OF LABORATORY PROCEDURES IN THE PRACTICE OF MEDICINE

Medicine has for centuries been so closely interwoven with the social relations of mankind that it is, and always must remain, a social function or profession; therefore, whatever affects people economically will also affect medicine. That such a statement is true, is amply borne out by the present depression of medical activities, and at the same time by the numerous studies and publications which are being constantly brought forward, all dealing more or less with the subject of the excessive cost of medical care, and all seeking a solution of a much unsettled and debatable problem.

Contemporary medicine has not yet been tempered with a proper degree of humility, and professional credulity—a benign form of unintentional dishonesty—has become a disease of very serious public menace. Specialists expound views, describe methods and allege cures, based far too much on impressions rather than facts. Specialism has made almost preposterous growth, and short-cuts to diagnosis, and extravagant methods of therapy are widely exploited. Credulity, as thus utilized in both diagnosis and treatment, has in part been responsible for some of the distrust in the medical profession among the rank and file of laymen, for admitted dissatis-

faction within the ranks of the profession itself, and it has at least a bearing upon this problem of the so-called cost of medical care—a current subject of such heated discussion.

Excessive or improper reliance upon laboratory procedures has been conspicuous, particularly within recent years, and is believed by many to be one potent factor in the production of some of the practitioner's contemporary difficulties. Such a condition, if admitted, need not continue to exist.

There are perhaps four main types of laboratory methods or techniques

(a) Those of pure research

(b) Those of presumed but unproved value. These have a legitimate field; their number will always be large and their diligent study is to be encouraged. From all of them a few will survive, as a result of accredited merit. Probably their clinical application should be studiously restricted to hospitals and teaching institutions, until their relative value, intrinsic sources of error or utter uselessness have been decisively demonstrated.

The alert practitioner and consulting internist should be informed about these two groups, though not actively concerned in their clinical application until their final status has been established.

(c) Those of established value, but of a complexity which puts their application beyond the range of the average individual, by reason of ex-

pensive equipment, the technic required or the time involved, or the infrequency of their need. In such a group one might mention basal metabolic rates, the Wassermann reaction, intricate clinical bacteriological studies, blood chemistry determinations, roentgen-rays and electrocardiographic tracings. Fortunately, the utilization of tests in this group is necessary in but a relatively limited number of cases. To use them intelligently, but three things are needed: An understanding of the physiological or pathological basis for the test; an unwillingness to interpret the results except in correlation with all the clinical data, critically judged by sound common sense; and first-hand information as to the methods used and care exercised in the laboratory in which the tests are made.

(d) Finally, those tests of long-tried and proved worth, simple, requiring a minimum amount of laboratory apparatus and a small expenditure of time, each capable of yielding diagnostic information which every physician should be able to interpret correctly. In this group might be included the simpler studies of the blood, urine, feces, gastric contents, spinal fluid and sputum. Years of teaching and observation corroborate Peabody's remarks that "in spite of the great contributions which the laboratory has made to clinical medicine, there has been surprisingly little change in the character or number of the technical methods that are essential to good practice. In spite of the extraordinary influence the laboratory has had on the development of medical science, as well as of medical education, there is

as yet no cause for the physician to feel that he cannot keep up with the requirements of the best modern methods." The physician who cannot or does not judiciously utilize laboratory procedures is deficient in his clinical practice, and adds needlessly to the economic problems of the profession.

It would be utterly futile to argue against either the value or the usefulness of many laboratory methods which have been evolved in recent years. Yet in the excessive reliance upon, or in the unsound, non-discriminating use of, or the incompetent interpretation of laboratory tests, one can find a tremendous menace to modern medical efficiency; and so long as dogmatic reliance upon laboratory methods keeps reflective thinking and systematic observation subservient, poor clinical practice will continue.

The particular level to which an individual rises in terms of intellectual development depends upon the degree and consistency with which he exercises his many "mental muscles". The power of observation, the process of reasoning, the instincts of curiosity and wonder, keenness in special sense perception, are but so many intellectual muscles. They develop and expand by use; they wither and atrophy through disuse. Mental muscular development can be attained only through industry. This does not begin and end with the conscientious performance of the daily task. For those in the medical profession it means relentless study, inspired by a perennial, insistent demand for the solution of perplexities. Sustained mental development of this sort can be secured only by the exercise of hon-

esty, not merely in our dealings but in our thinking. Too few of us take the pains to study the origin of our cherished convictions. We are incredibly heedless in the formation of beliefs, and become filled with an illicit passion for them when any one proposes to rob us of their companionship. The

world today needs sadly more of the intellectual freedom of the Greeks, the self-detachment and self-abnegating vigor of criticism so strikingly illustrated in the honest "know-nothingism" of Socrates.

SYDNEY R. MILLER.

Reviews

The Practitioner's Library of Medicine and Surgery. Supervising Editor, GEORGE BLUMER, M.A. (Yale), M.D., F.A.C.P.; David P. Smith, Clinical Professor of Medicine, Yale University School of Medicine, Consulting Physician to the New Haven Hospital. *Volume III: Practice of Medicine.* Associate Editor: HAROLD M. MARVIN, B.A., M.D., Assistant Clinical Professor of Medicine, Yale University School of Medicine. lii + 1400 pages, 44 illustrations. 1933. D. Appleton and Company, New York and London. Price, \$10.00.

In the June, 1932, issue of the *ANNALS*, Volumes I and II of *The Practitioner's Library of Medicine and Surgery* were reviewed. These dealt, respectively, with Anatomy and Physiology as Applied to Practical Medicine and with The Technic of Physical and Laboratory Examination in Clinical Medicine. The entire set will consist of twelve volumes of which the last will be a composite index. Each volume is indexed separately as well. The present volume (III, *Practice of Medicine*) presents the material ordinarily covered in the standard textbook on internal medicine, with the exception of diseases of the nervous system. As compared to the texts of but a few years ago the changing emphasis on various diseases is apparent. Thus we find chapters devoted to Tularemia, Undulant Fever, Rat-Bite Fever, Psittacosis, Benzol Poisoning, and Agranulocytosis. Also there is added emphasis upon occupational hazards and industrial medicine in general.

To this volume there are 30 contributors. To list them all, with the subjects upon which they have written, would exceed the limits of this review. J. Burns Amberson provided the section on Tuberculosis; Alvin L. Barach, on Diseases of the Nose, Larynx, Bronchi, Lungs and Pleura; Arthur L. Bloomfield, on Streptococcal Infections; H. L. Bockus, on Diseases of the Liver, Gall-Bladder, Bile Ducts and Pancreas; Oswald E. Denney, on Leprosy; W. W. Duke, on Allergic Diseases; Raphael Isaacs, on The Anemias, Polycythemia, Leukemia, Lymphoblastoma, Agranulocytosis and Hemorrhagic Diseases; H. M. Marvin, on Diseases of the Heart and Diseases of the Blood Vascular System, and John H. Musser, on Typhoid Fever, Colon-Paratyphoid Infection, Tularemia, Influenza, Whooping Cough, Diphtheria, Tetanus, Anthrax and Glanders; to mention but a few of the authors.

As is inevitable with so many different authors, there is a marked difference in scale in the presentation of various topics. Throughout there is an evident desire to present the essentials. Some authors have done more; a few have, perhaps, fallen short of that goal. Generally speaking, those conditions which may be considered of minor importance have received even less attention than their position would seem to indicate. The short chapter of but one and one-half pages on Trichinosis may be taken as an example. As a matter of book-making it is to be questioned whether the many very short chapters should

been grouped; Chapter XXI, Micrococcus Catarrhalis Infections, has but 12 lines of text.

With but very few exceptions, the sections of this book are well written discussions of disease states. No one book can give exhaustive treatment to the constantly expanding field of internal medicine. The expert in a particular disease may find that in this book the extremely detailed information which has come to seem essential to him is lacking. Yet to the student and practitioner this volume can be fully recommended as presenting in a clear and attractive manner the necessary material for an understanding of the basic principles of the Practice of Medicine.

C. V. W.

Children's Tonsils In or Out. By ALBERT D. KAISER, M.D., xvii, plus 307 pages. J. B. Lippincott Company, Philadelphia, 1932. Price, \$5.00.

This book, written as such a work should be by a pediatrician, is an interesting study and discussion of the relationship between pathologic processes in the tonsils and adenoids and general and local disease. It discusses the effects of tonsillectomy and adenoidectomy in prevention and treatment of about twenty different pathological states, not only those known to be associated with diseased tonsils, as rheumatic fever, glomerulonephritis, sore throat, etc., but also such indefinite and elusive conditions as malnutrition, anorexia, and mental retardation.

Most of the statistics are based on a ten-year study of 4,400 school children in Rochester, New York, the removal of whose tonsils was recommended. Half of the children of this group were operated upon; the other half, for various reasons, were not. The children were followed for ten years after tonsillectomy had been done or recommended, and the incidence of disease in both groups studied. For example, of the tonsillectomized group, 36 per cent had repeated attacks of sore throat before operation, and only 10 per cent had such attacks in the ten year period after operation. In the non-tonsillectomized group the figures showed a 41 per cent incidence of repeated sore throats before operation was recom-

mended and a 35 per cent incidence in the following ten year period. The figures for the incidence of rheumatic fever are interesting; 2.3 per cent in the tonsillectomized group and 3.5 per cent in the controls, during the ten year period after operation was either recommended or done.

The lack of comparison of the observed statistics to those reported by other authors is noticeable. One also notes the absence of observation of the efficacy of tonsillectomy in preventing subacute bacterial endocarditis.

The section on anatomy, physiology and bacteriology of the tonsils is written by K. E. Birkhaug; that on the tonsils in communicable disease by W. L. Bradford; that on asthma and hay fever by S. S. Bullen. The indications for tonsillectomy in diabetes mellitus are discussed by G. B. F. Gibbs. A chapter on the surgical consideration of incomplete tonsillectomy and the significance of lymphoid hyperplasia is written by E. S. Ingersoll.

Children's Tonsils In or Out is interesting, easy to read, and the graphic charts can be analyzed at a glance. It is certain to be useful in spreading clearer understanding of the positive and the doubtful indications for tonsillectomy, and will certainly prevent many needless operations.

T. N. C.

Papers Relating to the Pituitary Body, Hypothalamus and Parasympathetic Nervous System. By HARVEY CUSHING, 234 pages with 99 illustrations. Charles C. Thomas, Springfield, Ill., 1932. Price, \$5.00.

The papers included in this volume had been delivered as lectures before prominent medical societies and published in current scientific periodicals. They "have been brought together for the convenience of those whom the general theme may interest". They include:

I. Neurohypophyseal Mechanisms from a Clinical Standpoint, the basis of the Lister Memorial Lecture, delivered at the Royal College of Surgeons of England, July 9, 1930.

II. Posterior-Pituitary Hormone and Parasympathetic Apparatus, basis of the William Henry Welch Lecture at Mount Sinai Hospital, New York, April 30, 1931.

III. The Basophil Adenomas of the Pituitary Body and their Clinical Manifestations (Pituitary Basophilism), basis of the Alpha Omega Alpha Lecture given at Yale University, February 24, 1932.

IV. Peptic Ulcer and the Interbrain, basis of the Balfour Lecture, given on Lister Day at the University of Toronto, April 8, 1931.

In these papers the author deals in a charming way with a fascinating field that is of fundamental importance to the general physician as well as to the neurologist, the endocrinologist, and the neurologic surgeon. The author has devoted much of his professional life and talents to the elucidation of the subjects herein discussed, and if there is a fault to be found in the discussion, perhaps it lies in the possibility that the smoothness of his attractive style may make this difficult, intricate, and controversial field seem too easy and too readily comprehensible. Some of his interpretations have been questioned by equally prominent workers in the same field and the author himself says in the preface, "Dealing as they do with somewhat novel topics—or at least with old topics from a renovated standpoint—it is quite probable that many of the interpretations are based on false premises and that even those which appear to be more securely grounded will not stand the test of time. This will make little difference, provided the papers help to draw attention to the long neglected interpeduncular region of the brain, unquestionably of fundamental importance to each of us, whatever may be his special field of medical work." Such situations are, of course, unavoidable in a rapidly changing scientific field.

Certainly there is no one better fitted by his own work and interests to present this subject to the profession, and the reader's

pleasure will be enhanced by the literary excellence of the presentation and by the evidences of the author's scholarship.

T. P. S.

Asthma, Hay Fever and Related Disorders. A Guide for Patients. By SAMUEL M. FEINBERG, M.D., F.A.C.P., 124 pages, illustrated. Lea and Febiger, Philadelphia, 1933. Price, \$1.50.

The conventional approach, used by the authors of most textbooks upon this subject, is used here. Starting with a historical review of the subject and working through such topics as complications, etiological agents, method of history taking, skin testing procedures, treatment, general care and advice, the book closes with a brief discussion of conditions which are less surely members of the specific sensitivity group of phenomena, although generally conceded as belonging in it, in some instances at least.

The author has limited his appeal strictly to the needs of the lay patient, avoiding the pitfalls inherent in any attempt to reach both patient and physician. Because of this, a dogmatic approach which materially aids in simplifying the subject for the uninitiated is permissible and is used with reasonable restraint.

The subject matter is handled in a clear and satisfactory manner, with the exception of an occasional tortuosity of expression that is not vital.

Certain phases of modern medicine are dependent upon concepts and considerations differing widely from those applying to medicine as a whole; it would seem that this was peculiarly true of manifestations of specific sensitivity. For that reason, a book of this sort should be of definite value as an aid in the clinical management of these cases.

H. M. P.

College News Notes

The executive office of the American College of Physicians will greatly appreciate information concerning any Fellows of the College who will be in Switzerland in August of the coming summer, at the time of the meeting of the International Goiter Conference in Berne.

Acknowledgement is made of the following gifts to the College Library of publications by members:

- Dr. H. Sheridan Baketel (Fellow), Jersey City, N. J.—1 reprint;
- Dr. W. R. Brooksher (Fellow), Fort Smith, Ark.—1 reprint;
- Dr. Ralph O. Clock (Fellow), New York, N. Y.—2 reprints;
- Dr. Ronald L. Hamilton (Fellow), Sayre, Pa.—1 reprint;
- Dr. Maurice Kovnat (Associate), New Brighton, N. Y.—3 reprints;
- Dr. Howard E. Marchbanks (Fellow), Pittsburg, Kansas—2 reprints;
- Dr. Sydney Nussbaum (Associate), Brooklyn, N. Y.—8 reprints.

Dr. Harold F. Machlan (Fellow), was recently officially transferred from the Veterans Administration Hospital at Indianapolis to the hospital associated with the Veterans Administration Home, Dayton, Ohio.

Dr. S. A. Slater (Fellow), Worthington, Minn., was recently reappointed a member of the Minnesota Medical Executive Board. Dr. Slater is Superintendent of the Southwestern Minnesota Sanatorium, a member of the Board of Directors of the Minnesota Public Health Association and, during January of this year, was elected President of the Sioux Valley Medical Society.

Dr. David Riesman (Fellow), Philadelphia, Pa., has been elected Professor of

the History of Medicine in the University of Pennsylvania to fill a newly established chair in this subject.

Dr. P. W. Rowland (Fellow), Professor of Pharmacology, University of Mississippi, was elected President-Elect for 1934-35 of the Mid-South Post Graduate Medical Assembly, at its recent meeting (49th) at Memphis, Tenn.

Dr. John A. Kolmer (Fellow), and Dr. Henry L. Bockus (Fellow), both of Philadelphia, Pa., under the auspices of the Medical Society of New Jersey, in coöperation with Rutgers University, recently delivered lectures on "Pneumonia Therapy" and "Diseases of the Liver", respectively, in connection with a series of graduate lectures for members of the Union County (N.J.) Medical Society.

Dr. John V. Smith (Fellow), Perth Amboy, N. J., has been appointed a member of the State Board of Institutions and Agencies.

Dr. Adolph Sachs (Fellow), Omaha, Nebr., has been elected Vice President of the newly organized Omaha Mid-West Clinical Society, the membership of which is limited to one hundred physicians.

Dr. Harlow Brooks (Fellow), New York City, has been named as an Adviser of the recently organized New York Institute of Clinical Oral Pathology. The initial membership is made up of one hundred physicians and dentists. It is announced that the activities of the organization will be extended over the country.

Dr. Karl E. Kassowitz (Fellow), Milwaukee, Wis., was recently elected President of the Milwaukee Pediatric Society.

Dr. Walter L. Bierring (Fellow), Des Moines, Iowa, was reelected Secretary of the Federation of State Medical Boards of the United States at the Chicago meeting, February 13-14, 1933.

Dr. William D. Cutter (Fellow), Chicago, Ill., who is Secretary of the Council on Medical Education and Hospitals of the American Medical Association, was appointed Managing Editor of the *Federation Bulletin*.

Dr. Henry A. Rafsky (Fellow), has been appointed Consulting Gastro-Enterologist to

the Rockaway Beach Hospital, New York City.

Dr. Charles H. McEnerney (Associate), Washington, D. C., was recently reelected Secretary-Treasurer of the American Society for the Study of Arthritis; also Dr. McEnerney has been appointed as Consultant in Arthritis to the Providence Hospital, Washington, D.C.

Dr. David W. Kramer (Associate), Philadelphia, Pa., was recently promoted to Assistant Professor of Medicine at the Jefferson Medical College of Philadelphia.

ABSTRACT OF THE MINUTES OF THE MEETINGS OF THE BOARD OF REGENTS

Montreal, Canada
February 6-10, 1933

First Meeting, February 5

The Board of Regents of the American College of Physicians was presided over by Dr. F. M. Pottenger, President, Monrovia, Calif. The following members were present: Drs. Francis M. Pottenger, Maurice C. Pincoffs, George Morris Piersol, William D. Stroud, William Gerry Morgan, Walter L. Bierring, John H. Musser, O. H. Perry Pepper, James H. Means, James Alex. Miller, David P. Barr, Arthur R. Elliott, James B. Herrick, Clement R. Jones, Noble Wiley Jones, and W. Blair Stewart.

Dr. Carl V. Weller, retiring Editor of the *ANNALS OF INTERNAL MEDICINE*, was present on invitation. The Executive Secretary, E. R. Loveland, acted as Secretary of the meeting.

Abstracted Minutes of the previous meeting of the Board of Regents held at the College Headquarters, Philadelphia, November 13, 1932, were read and approved.

As incompletd business from the preceding meeting of the Board, the following resolutions were presented by Dr. William Gerry Morgan, Secretary-General.

DR. ELMER HENDRICKS FUNK

In an organization such as the American College of Physicians, with a restricted membership, the withdrawal of

a single member by resignation or death is always an occasion for regret. In the death of Dr. Elmer Hendricks Funk the College sustains a loss greater than the mere withdrawal of one of its most influential members.

He was born in the City of Philadelphia and there he grew up and was educated, having received his medical education at Jefferson Medical College, from which he graduated with honor in 1908. He served there as resident physician, chief resident physician, medical director, and medical director and physician in charge in the department for diseases of the chest. He also served as resident physician in the Philadelphia Hospital for Contagious Disease and the Whitehaven Sanitarium for Tuberculosis. In all of these important posts he left behind him an enviable record for the highest type of medical efficiency as well as for his unflinling gentle courtesy and fair dealing.

Dr. Funk was blessed with the rare gift of winning the confidence, respect, and affection of those great leaders in medicine with whom he was fortunate enough to be thrown during the formative years of his professional career. These happy contacts contributed no little to the rapid strides which he early made in scientific medicine.

He had a prodigious capacity for work so that his days were filled with intensive study "investigation, research, teaching, writing, lecturing, work for organized medicine and civic philan-

thropy," all of the most dependable type and of the highest scientific value.

He contributed to many standard works and published in 1930 his volume entitled "The Diseases of the Respiratory Tract." He was recognized as an authority on the subject of tuberculosis.

On April 1, 1923, Dr. Funk was elected a Fellow of the American College of Physicians. At the San Francisco meeting in April 1932, he was unanimously elected Treasurer. His death occurred on May 13, 1932, before he had been able to undertake the arduous duties attached to that office. His death at the age of 46 prematurely cut short a career of great promise and has robbed the medical profession and the public of one of the most gifted men of his generation.

WHEREAS, Divine Providence has seen fit to remove from our midst through sudden and untimely death Dr. Elmer Hendricks Funk, who although among the younger Fellows was yet an earnest and energetic member and a physician of great promise; therefore be it

RESOLVED, That in his death the profession and the American College of Physicians has sustained an irreparable loss; and be it further

RESOLVED, That we extend to his bereaved family our deepest sympathy and send them a copy of these resolutions, and be it further

RESOLVED, That these resolutions be entered upon our records.

DR. JOHN ALDEN LICHTY

The name of John Alden Lichty is indelibly linked with the history of the development and progress of the American College of Physicians. Perhaps no single member has contributed more toward raising the College to its present enviable place among the outstanding medical organizations of the world. His untiring zeal and devotion to the best interests of the College is one of the bright pages in that history.

Dr. Lichty was born in Meyersdale, Pennsylvania, February 26, 1866. He graduated from Mount Union College, from which he received several degrees, and from the University of Pennsylvania School of Medicine in 1893, and from the University of Berlin in 1896. He occupied many important posts, among which may be mentioned Associate Professor of Medicine, University of Pittsburgh School of Medicine; visiting physician, Mercy Hospital, Pittsburgh; visiting physician, Columbia Hospital, Pittsburgh; consulting physician, Presbyterian Hospital, Pitts-

burgh; Superintendent of Clifton Springs Sanitarium, which position he occupied at the time of his death. He was a member of many of the leading medical organizations of this country, and was past president of the American Gastro-Enterological Association. Dr. Lichty was a prolific writer, having published many splendid articles upon a variety of medical subjects. He contributed to several standard textbooks.

Dr. Lichty was elected a Fellow of the American College of Physicians on December 29, 1916. For many years he was a member of the Board of Regents, and for two years was third Vice-President. Of his many signal contributions to the College, perhaps the most notable was his organization of the Credentials Committee, of which he was the first Chairman, and on which he served with distinction.

In the death of Dr. Lichty on May 2, 1932, the College sustained an irreparable loss. Perhaps no single activity in Dr. Lichty's life was nearer to his heart and thoughts than were the affairs of the College.

WHEREAS, Almighty God in his wisdom has taken from among us Dr. John Alden Lichty, one of our oldest and most devoted members, who for more than forty years was a distinguished clinician; therefore be it

RESOLVED, That we enter upon our records this minute of our lasting regret at his passing, and our sincere appreciation of his long life of devotion to the best interests of his profession and of this College; and be it further

RESOLVED, That a copy of this report, preamble, and resolutions be sent to his bereaved family.

DR. CHARLES G. LUCAS

With the passing of Dr. Charles G. Lucas to his eternal rest July 7, 1932, the American College of Physicians has been deprived not only of one of its loyal members, but also of one of its strong, dependable guiding influences throughout nearly all of the years since it came into being.

Born in Cincinnati in 1868, Dr. Lucas received his education both premedical and medical in the institutions of Louisville, Kentucky. It was there that he carried on the practice of his profession. And during all those years was a member of the faculty of the Medical Department of the University of Louisville, in which in 1915 he was made Chief of the Department of Gastro-Enterology, a position he held until his death.

Dr. Lucas was a member of many of the leading medical organizations of the United States, among which was the American Gastro-Enterological Association, of which he was President in 1926; and the American College of Physicians, and served on the Board of Regents 1922-1923 and 1925-1928.

Few men in our profession enjoyed as wide a circle of devoted friends as did this outstanding physician. He will be keenly missed throughout the land wherever medical men foregather.

WHEREAS, By the inscrutable decree of Divine Providence the American College of Physicians has lost in the death of Dr. Charles G. Lucas one of its most esteemed members, who for many years took a leading and active part in the conduct of its affairs, as well as being an outstanding member of his profession; therefore be it

RESOLVED, That we enter upon our records this minute of our lasting regret at his passing and our sincere appreciation of his long life of devotion to the best interests of his profession and of this College; and be it further

RESOLVED, That a copy of this report, preamble, and resolutions be sent to his bereaved family.

Dr. Morgan further reported upon deaths of members during the past year, amounting to twenty-five Fellows and seven Associates; sixteen of these had been previously reported to the Board of Regents, the following being the additional list:

Fellows:

F. T. Billings, Pittsburgh, Pa., January 5, 1933.

Edward Bates Block, Atlanta, Ga., October 25, 1932.

Henry Daspit, New Orleans, La., December 19, 1932.

Gayfree Ellison, Norman, Okla., December 22, 1932.

William Engelbach, Springfield, Ill., November 22, 1932.

Edward Louis Heintz, Chicago, Ill., December 7, 1932.

Frank H. Pratten, London, Ont., December 10, 1932.

William Sydney Thayer, Baltimore, Md., December 10, 1932.

Carl Victor Vischer, Philadelphia, Pa., November 15, 1932.

Associates:

Alfred Henry, Indianapolis, Ind., December 12, 1932.

Fenton Benedict Turck, New York, N. Y., November 16, 1932.

Upon motion regularly moved, seconded and carried, it was

RESOLVED, that the report of the Secretary-General be accepted.

Dr. William D. Stroud, Treasurer, reported, in connection with incompleting business from the previous meeting, that in accordance with resolutions adopted by the Board of Regents, new bank accounts had been opened in the Royal Bank of Canada, Montreal, and the Provident Trust Company, Philadelphia; and that the securities belonging to the College had been transferred from Pittsburgh to the Girard Trust Company, Philadelphia.

The report of the Treasurer was received and placed on file.

In the absence of Dr. Sydney R. Miller, Chairman of the Committee on Constitution and By-Laws, the Executive Secretary presented his report. In accordance with instructions of the Board of Regents, the Committee on Constitution and By-Laws had published the recommended amendments to the By-Laws in the January Issue of the ANNALS OF INTERNAL MEDICINE. The amendments provide for:

(1) A consolidation of the Committee on Credentials, so that in the future there will be but one Committee for both Fellowship and Associateship. This Committee to be comprised of three members from the Board of Regents and three members from the Board of Governors;

(2) To provide that the Editor of the ANNALS OF INTERNAL MEDICINE shall be an ex-officio member of the Board of Regents.

The amendments were to be submitted at the General Business Meeting at Montreal on February 9. Upon motion regularly adopted, it was

RESOLVED, that the amendments, as presented by the Committee on Constitution and By-Laws, be approved.

Dr. George Morris Piersol, Chairman of the Committee on Credentials, presented the

following candidates, whose election to Fellowship was recommended:

Charles William Crankshaw, Consultant and Medical Advisor, Staff of the Medical Department-General, Prudential Life Insurance Company, Newark, N. J.;

Luis Manuel De Bayle, Nicaraguan Minister to the United States, Washington, D. C.;

Charles Austin Doan, Professor of Medicine, Ohio State University College of Medicine, Columbus, Ohio;

John B. Doyle, former Assistant Professor of Neurology, Graduate School of Medicine, University of Minnesota, and Neurologist to St. Vincent's Hospital, Hospital of the Good Samaritan and Queen of Angels Hospital, Los Angeles, Calif.;

Everett Colgate Jessup, Assistant Clinical Professor of Medicine, Columbia University College of Physicians and Surgeons, Roslyn, N. Y.;

Josephine Carrier Lawney, Dean and Professor of Medicine, Woman's Christian Medical College, Shanghai, China;

Malcolm Thomas MacEachern, Director of Hospital Activities, American College of Surgeons, Chicago, Ill.;

Thomas Turlay Mackie, F.R.C.P. & S., D.N.B., Instructor in Medicine, Columbia University College of Physicians and Surgeons, New York, N. Y.;

Harry A. Pattison, Director, Potts Memorial Hospital, Livingston, N. Y.;

George Alfred Skinner, Colonel, M.C., U. S. Army, Omaha, Nebr.;

Willard Burr Soper, Associate Professor of Medicine, Yale University School of Medicine; Medical Director, William Wirt Winchester Hospital, New Haven, Conn.;

Nathan Bristol Van Etten, Member, Committee on the Costs of Medical Care; Medical Director, Morrisania Hospital, New York, N. Y.

For Advancement from Associateship to Fellowship:

Arnold S. Anderson, St. Paul, Minn.

Ralph Lee Fisher, Detroit, Mich.

Michael Robert Haley, Dayton, Ohio.

Arthur Fisher Heyl, New Rochelle, N. Y.

John Francis Kenny, Pawtucket, R. I.

Erwin Curtis Miller, Worcester, Mass.

Frank B. Morrissey, St. Paul, Minn.

Rudolph Virchow Powell, St. Louis, Mo.

Benjamin Bruce Souster, St. Paul, Minn.

Edwin Chester Swift, Jacksonville, Fla.

Henry Hubert Turner, Oklahoma City, Okla.

J. Russell Twiss, New York, N. Y.

Upon motion by Dr. O. H. Perry Pepper, seconded by Dr. Arthur R. Elliott, and regularly carried, it was

RESOLVED, that the above list of physicians be and herewith is elected to Fellowship in the American College of Physicians.

Dr. Carl V. Weller, retiring Editor of the ANNALS OF INTERNAL MEDICINE, presented a report, reviewing his experience as Editor of the ANNALS and making suggestions and recommendations concerning the journal in the future. Among his comments, he mentioned the fact that 393 separate papers passed through the editorial office in the last nineteen months, indicating that there is an increased volume of material from which to select articles for publication in the journal, and, therefore, an added opportunity to improve the quality of the material selected for publication. In the past, it had been Dr. Weller's practice to devote approximately fifty per cent of the available space in the ANNALS to the papers delivered at the Clinical Sessions and fifty per cent to the papers selected from those submitted from at large for publication. In addition, it has been his aim to have the final article in each number represent the history of medicine, or ethical, or cultural aspects of medicine. He suggested the desirability of occasionally giving a comprehensive survey or review of some subject such as has not been done in the past. In regard to the size of the ANNALS, he recommended the present size of approximately one hundred and fifty pages per issue as desirable, but with effort expended upon the improvement of the quality of the journal; and he further recommended that the personality and individuality which the journal has achieved be maintained, and that changes in format and composition of material should be gradually

changed, if such changes are thought desirable. Dr. Weller has considered the *ANNALS OF INTERNAL MEDICINE* chiefly as a medium for postgraduate education in internal medicine. Its purpose was not to broadcast the more complicated pieces of work in experimental medicine, but to serve as the medium for postgraduate education to the more than three thousand subscribers scattered over the country.

On motion by Dr. Means, seconded and regularly carried, it was

RESOLVED, that the Board of Regents of the American College of Physicians extend to Dr. Carl V. Weller a vote of thanks for his very able conduct of the *ANNALS OF INTERNAL MEDICINE* since the death of Dr. Warthin.

The following resignations, after being individually considered, were by resolution accepted:

Fellows:

William P. Buffum, Providence, R. I.
A. H. W. Caulfeild, Toronto, Ont.
Clyde L. Cummer, Cleveland, Ohio.
Linton Gerdine, Athens, Ga.
H. Brooker Mills, Philadelphia, Pa.
A. W. Moody, Winnipeg, Man.
Walter B. Mount, Montclair, N. J.
Warren T. Vaughan, Richmond, Va.

Associates:

Edwin H. McIlvain, Philadelphia, Pa.
Henry J. Walton, Baltimore, Md.

Action on the resignation of the following was by resolution deferred:

Fellows:

I. Hope Alexander, Pittsburgh, Pa.
Thomas B. Fitcher, Baltimore, Md.
Edward Livingston Hunt, New York, N. Y.

Associates:

R. W. Baer, Frederick, Md.
James W. Bruce, Louisville, Ky.
J. W. Earl Ellenberger, Wilkinsburg, Pa.
James J. Gable, Norman, Okla.
Charles A. Howland, Schenectady, N. Y.
Thaddeus Walker, Grosse Pointe, Mich.
Everett E. Watson, Salem, Va.

President Pottenger suggested that there were two matters that should receive some

thought and be referred to the proper Committees. The first one concerns the question of the admission of new members to Associateship. The By-Laws provide that a candidate may be presented for Associateship after he has been graduated but three years, but this does not give the candidate sufficient time, in many cases, to be known by our Fellows in his locality, nor does it assure the College of the fact that he will remain in the field of internal medicine.

Dr. Pottenger, after some discussion by the members of the Board, suggested that possibly the Regent or the Governor in a given district might have a Committee of five or six Fellows appointed before whom candidates would come for a personal interview before their credentials would be referred to the Committee on Credentials.

The other matter President Pottenger wished to present was the suggestion of a change in our method for electing Life Members. He wished to refer to the Finance Committee for their consideration some plan by which members, so to speak, might underwrite their dues for the balance of their lives, and thus become Life Members. For instance, the maximum Life Membership Fee might be, as at present, \$400.00, in addition to a Fellow's initiation fee. However, from the period of forty-five years of age to sixty-five years of age (when a member's dues may be waived), the member would need to pay only an amount equal to his dues for the intervening years. For instance, if a man is fifty years of age, he would pay his dues for fifteen years and become a Life Member, which would entitle him to active membership not only until sixty-five years of age, but for his entire lifetime. Many Fellows should be attracted to this plan of Life Membership who have not been attracted to the previous plan, requiring a total payment of \$500.00. Dr. Pottenger further referred to findings established by skilled actuaries which show conclusively that life membership could be carried successfully and to the benefit of the organization initiating this plan.

Adjournment.

Second Meeting, February 7

The following members of the Board of Regents were present: Drs. F. M. Pottenger, George Morris Piersol, Maurice C. Pincoffs, Noble Wiley Jones, William D. Stroud, William Gerry Morgan, Walter L. Bierring, George E. Brown, John H. Musser, O. H. Perry Pepper, James S. McLester, Jonathan C. Meakins, James H. Means, James Alex. Miller, David P. Barr, Arthur R. Elliott, James B. Herrick, Clement R. Jones and Mr. E. R. Loveland, Executive Secretary.

Minutes of the previous meeting were abstracted and approved as read.

Dr. William Gerry Morgan, Secretary-General, presented several cases concerning fees and dues of individual members. Individual action is recorded in the official Minutes of the College. The following principles, however, were maintained: (1) the regular rules concerning annual dues as printed in the folder of the College should be maintained. This refers to the matter of \$10.00 being the minimum to which the dues of full-time medical teachers and full-time employees of the State may be reduced; (2) former members who were dropped because of delinquency may be reinstated by the Board of Regents subject to the payment of all their delinquent dues; (3) the Board of Regents may waive partially, or fully, the dues of members who are physically incapacitated, but the waiver of said dues shall be made from year to year, subject to the recovery of the member and his again entering practice; (4) members shall not be required to pay dues after they have reached the age of sixty-five years, but the responsibility for notifying the Executive Offices shall be that of the member.

Upon motion regularly moved, seconded and carried, it was

RESOLVED, that the College donate to the John Crerar Library of Chicago the *ANNALS OF INTERNAL MEDICINE*, Volume VI, Nos. 1 to 6, inclusive.

Upon motion by Dr. McLester, seconded and regularly carried, it was

RESOLVED, that the Board of Regents approve of the action taken and the letters submitted by Drs. Pottenger and Morgan in connection with adding the influence of

the American College of Physicians to the Medical Library Association for a reduction in the prices of German medical journals to subscribers in this country.

On behalf of the Chairman of the Board of Governors, Dr. W. Blair Stewart, who was absent, the Executive Secretary presented the following list of 112 candidates whom the Board of Governors had recommended to the Board of Regents for election to Associateship:

Edward Lee Alexander, Newport News, Va.

Francis William Baldwin, New York, N. Y.

Paul M. Bassel, Temple, Texas.

George C. Beach, Jr., Fort Sam Houston, Texas.

Orpheus J. Bizzozero, Waterbury, Conn.

LeRoy Walton Black, Rutherford, N. J.

James Lewis Blanton, Fairmont, W. Va.

Frank Runcorn Borden, Randolph Field, Texas.

James Albert Bradley, New Orleans, La.

Raymond W. Bradshaw, Oberlin, Ohio.

Timothy F. Brewer, Hartford, Conn.

Paul Brindley, Galveston, Texas.

Boyd Franklin Brown, Huntington, W. Va.

Harold F. Brown, Buffalo, N. Y.

Clyde Windom Brunson, Brooklyn, N. Y.

D. Grant Campbell, Montreal, Que.

Guy Walter Carlson, Appleton, Wis.

Douglas Gordon Chapman, Richmond, Va.

Charles Walter Clarke, New York, N. Y.

Thomas J. Coogan, Chicago, Ill.

Henry Charles Crossfield, East Orange, N. J.

Grover Cleveland Dale, Goldsboro, N. C.

Ward Darley, Jr., Denver, Colo.

Frank Lowell Dunn, Omaha, Nebr.

Edgar Durbin, Denver, Colo.

Philips J. Edson, Pasadena, Calif.

Ray Elledge, Hammond, Ind.

William White Falkener, Newport News, Va.

Ralph Manos Fellows, Galveston, Texas.

Clement Coleman Fenton, Morgantown, W. Va.

Carl Herman Gellenthien, Valmora, N. M.

Mark Gerstle, Jr., San Francisco, Calif.

George Albert Gray, Abilene, Texas.

Percival Allen Gray, Jr., Santa Barbara, Calif.
 Edward Alfred Greco, Portland, Maine.
 David S. Greenspun, Bridgeport, Conn.
 Joseph Hajek, New York, N. Y.
 Ronda Horton Hardin, Banners Elk, N.C.
 Robert Ammiel Hare, Santa Barbara, Calif.
 Benedict Richard Harris, Hamden, Conn.
 Edward Hagerman Hashinger, Kansas City, Mo.
 Michael Gerard Healy, Randolph Field, Texas.
 Joseph Emmet Hirsh, Birmingham, Ala.
 Roy Herbert Holmes, Muskegon, Mich.
 D. Waldo Holt, Greensboro, N. C.
 Arthur Hartt Jackson, Washington, Conn.
 Guy Carleton Jarratt, Vicksburg, Miss.
 Clarence Emory Johnson, Long Beach, Calif.
 George Stephen Johnson, Denver, Colo.
 Harry Gardner Johnson, Buffalo, N. Y.
 Ernest L. Kiesel, Scranton, Pa.
 John Glenwood Knauer, Washington, D.C.
 Vincent W. Koch, Janesville, Wis.
 Rudolph A. Kocher, Carmel, Calif.
 Elmer Elgin Kottke, Des Moines, Iowa.
 Manfred Kraemer, Newark, N. J.
 Roderick Alexander Macaulay, Springfield, Mass.
 Frank Rowe Maddison, Tacoma, Wash.
 Bernard Abraham Manace, Corvallis, Ore.
 Frank Raymond Mazzola, Jamaica, N. Y.
 David William McKechnie, Montreal, Que.
 Bernardine Thomas McMahon, Loomis, N. Y.
 Joseph Marion Messick, Rochester, Minn.
 Albert John Michels, East Liverpool, Ohio
 Ida J. Mintzer, Jamaica, N. Y.
 Edward Winfield Miskall, East Liverpool, Ohio.
 Morris Eli Missal, Rochester, N. Y.
 Daniel Murrall Molloy, Guatemala City, Guatemala
 Allen Hoyt Moore, Doylestown, Pa.
 Anita Mary Mühl, San Diego, Calif.
 Frederick William Mulsow, Cedar Rapids, Iowa.
 Jerome A. Murphy, Buffalo, N. Y.
 Frederick W. Niehaus, Omaha, Nebr.
 Edward Sterling Nichol, Miami, Fla.

Joseph Frederick Painton, Buffalo, N. Y.
 George Washington Parson, Texarkana, Texas.
 John Ryer Poppen, Washington, D. C.
 Ernest Boring Porter, Coronado, Calif.
 Harold Walter Potter, Newport News, Va.
 Harry Hansell Preston, Hot Springs, Ark.
 Robert McNair Purdie, Houston, Texas.
 Warren Wilson Quillian, Coral Gables, Miami, Fla.
 Jesse Dean Riley, State Sanitorium, Ark.
 James O. Ritchey, Indianapolis, Ind.
 Samuel Frederick Rosen, Savannah, Ga.
 Max Harold Ruby, Waterbury, Conn.
 Edwin Philip Russell, Rome, N. Y.
 Robert Burns Sanderson, Crown Point, Ind.
 Victor Ewald Schulze, Rochester, Minn.
 Francis J. Scully, Hot Springs, Ark.
 Harold Nathan Segall, Montreal, Que.
 Laurence Fox Segar, Detroit, Mich.
 Henry Kirven Speed, Sayre, Okla.
 George Black Stericker, Springfield, Ill.
 Landon Elwood Stubbs, Newport News, Va.
 George Courtney Stucky, Lansing, Mich.
 George B. Topmoeller, Cincinnati, Ohio.
 Clarence Johnson Tidmarsh, Montreal, Que.
 Neville Thompson Ussher, Santa Barbara, Calif.
 Samuel A. Vogel, Buffalo, N. Y.
 James C. Walsh, Watertown, N. Y.
 Harold M. Walton, Loma Linda, Calif.
 James Harold Watkins, Montgomery, Ala.
 Francis Charles Weber, Newark, N. J.
 Emil Weiss, Chicago, Ill.
 William Graham Weston, Vicksburg, Miss.
 James H. Wheeler, Henderson, N. C.
 Joseph Wiener, Asbury Park, N. J.
 Dwight Locke Wilbur, Rochester, Minn.
 John Woodworth Wilce, Columbus, Ohio.
 Ruth Walker Wilson, Beaver, Pa.
 Burton L. Zohman, Brooklyn, N. Y.
 The entire list was examined individually by members of the Board of Regents, after which the following resolution was adopted:
 RESOLVED, that the above list of candidates shall be and are herewith elected to Associateship in the American College of Physicians.

The Executive Secretary presented mimeographed copies of the financial report of the College for 1932. The accounts of the College had been audited by an accountant and his detailed report was attached. Estimated income and expenditures for 1933 and suggested budgets were also presented. The reports were not discussed, but put in the hands of the Regents for examination and later analysis.

The Executive Secretary presented a list of forty-four names of members who were two or more years delinquent in their dues, and who, according to the By-Laws, are subject to being dropped from membership. The list had been presented to the Board of Governors and some of them expressed a desire to have a few weeks to go over it in a final effort to influence desirable members to retain their memberships and to make provision for the payment of their dues. It was pointed out that out of a total membership of more than twenty-eight hundred, this was a comparatively small list of delinquent members. On motion by Dr. Pepper, seconded and regularly carried, it was

RESOLVED, that the list of members delinquent for two or more years be referred to the individual Governors for the districts in which such delinquents reside, and if after a period of a month thereafter such delinquent members do not make arrangements for the payment of their dues, they may be dropped automatically from the rolls of the College.

Dr. James Alex. Miller, in the absence of Dr. Charles G. Jennings, Chairman, presented the report of the Committee on Public Relations as follows:

REPORT OF COMMITTEE ON PUBLIC RELATIONS

The final report of the Committee on the Costs of Medical Care is entitled: "Medical Care for the American People."

It is the twenty-eighth publication of a series representing an extensive and intensive effort to collect the factual data concerning numerous problems involved. These studies were made over a period of five years, after the expenditure of an extraordinary amount of thought, effort, and money.

The facts presented are of immense

importance to the country as a whole and the medical profession in particular. They deserve the most careful study and consideration.

The detailed information is contained in the twenty-seven interim reports previously published, and only a brief summary is included in the final report. The main emphasis of the final report is placed upon certain definite recommendations proposed by the Committee as the basis for a plan of reorganization of medical practice, so as to meet the social and economic defects of the existing system brought out by the factual data.

These recommendations are in the form of separate majority and minority reports with a few members of the Committee declining to assent to either report.

The widespread discussion which has followed the publication of the final report is centered upon the recommendations suggested. This is most unfortunate as it has overshadowed the great value and significance of the studies upon which these recommendations are presumably based.

It is the opinion of your Committee that the publication of definite recommendations was premature and unjustified by the facts presented. A careful analysis of the text of the reports shows that the recommendations are really only tentative suggestions for future consideration and careful experimentation, and in our opinion should have been offered as such.

It is also our belief that the actual factual data contained in the various reports are of such value that they deserve most careful study on the part of the medical profession. These facts reveal a situation which calls for consideration and action leading to modification of existing medical practice, and in any such modification the medical profession should take a leading part.

It would be very unfortunate if prejudice caused by differences of opinion concerning the recommendations should belittle the value of the facts themselves. It would be still more unfortunate if either prejudice or inaction should deprive the medical profession of its rightful position of leadership in any program for remedying existing inequalities or injustices in the operation of the practice of preventive and curative medicine.

Our Committee, therefore, recommends that the individual Fellows of the American College of Physicians be urged to study the facts presented in the report of the Committee on the

Costs of Medical Care, uninfluenced by the acrimonious discussion which has been raised by the publication of the various recommendations, and we also recommend that the organized representatives of the medical profession in each community be urged to consider these problems in the light of their varying local needs and conditions, for it is our belief that by this method the enlightened leadership of the medical profession can point the way to improvements of great value, both to the public and to the medical profession itself.

In commenting upon the report, Dr. Miller said that the Regents might desire to have this report read at the General Business Meeting of the College and to have it published in the *ANNALS OF INTERNAL MEDICINE*. On motion recorded and regularly carried, it was

RESOLVED, that the Board of Regents of the American College of Physicians hereby approves the report of the Committee on Public Relations and directs that said report be printed in the *ANNALS OF INTERNAL MEDICINE*.

Dr. James B. Herrick re-presented the cordial invitation of the City of Chicago, as extended at the November meeting of the Board of Regents, for the College to meet in Chicago during 1934.

Adjournment.

Third Meeting, February 10

With Dr. George Morris Piersol presiding, as the new President, the meeting was attended by the following Regents: Drs. George Morris Piersol, Francis M. Pottenger, Maurice C. Pincoffs, William D. Stroud, William Gerry Morgan, Walter L. Bierring, John H. Musser, O. H. Perry Pepper, James S. McLester, Jonathan C. Meakins, James H. Means, James Alex. Miller, David P. Barr, Clement R. Jones, W. Blair Stewart, Luther F. Warren and Mr. E. R. Loveland, Executive Secretary.

Dr. Piersol introduced Dr. Luther F. Warren, of Brooklyn, newly elected member of the Board. The Executive Secretary acted as Secretary of the meeting.

By resolution, the Minutes of the previous meeting of the Board of Regents were dispensed with. The President called upon

the Executive Secretary to present his report on the finances of the College, which follows. Mr. Loveland analyzed for the Board the comparative cost of conducting the last four Clinical Sessions and other details of the financial statements. He said in part: "When I submitted estimates of Income and Expenditures for 1932, one year ago, I estimated that the surplus for the year would be \$9,970.00. The year's operation discloses a surplus of \$9,623.08, or a difference of only \$356.92. The total cash income for 1932 was \$75,785.31, which is mentioned merely to apprise the Board of the volume of College business transacted. During the year 1932, \$9,623.08 was added to the General Fund, making a total of \$64,810.97; \$975.00 was added to the Endowment Fund, making a total of \$53,375.00. The combined funds now amount to \$118,185.97.

" Increased expenditures for 1932 were occasioned by a far more expensive meeting, due to its being held in San Francisco and due to the awarding of the John Phillips Memorial Prize for the first time. While the *ANNALS OF INTERNAL MEDICINE* showed a deficit of \$1,266.13 on Volume V, the journal showed a surplus for the calendar year of 1932 of \$196.27. This improvement in the financial publication of the journal is due chiefly to the following: (a) a reduction in printing costs; (b) an increase, even under the present financial conditions, in the advertising income; (c) efficient and helpful coöperation of the Editor. A comparison of the advertising income in the past four years follows:

1929—\$2,263.46

1930— 3,543.49

1931— 3,929.26

1932— 4,536.84

"Your Executive Secretary's office has been conducted as conservatively as possible, consistent with the business interests of the College. A reduction was secured in the rental of the College Headquarters, the extra budget for the Treasurer's office has been eliminated since the Treasury was transferred to Philadelphia, and one of the more highly paid secretarial assistants in the Executive Secretary's office was dispensed with on June 1, 1932. In the last

instance we may have erred, because the burden of work thrown upon the other assistants and the Executive Secretary has been so great in the preparation for this Session that all have frequently had to work late at night, Saturday afternoons and Sundays.

"During the year 1932, \$4,077.82 has been invested, or reinvested, additionally in securities, bringing the total holdings up to \$65,574.55. The cash balance on December 31, 1932, amounted to \$48,285.55, of which \$18,311.79 was on deposit in closed banks. During 1932, \$8,892.54 was repaid by closed banks. The balance is carried on the books at its face value, due to the fact that the ex-Treasurer, Dr. Clement R. Jones, has assured the Board of Regents in the past that these balances will be paid in full.

"The budgets submitted for 1933 have been prepared as conservatively as possible by me. In view of the reduced income from Fellowship initiation fees occasioned by changed admission requirements, the reduction of Fellowship dues from \$20.00 to \$15.00 and of Associateship dues from \$15.00 to \$12.00, the reduction of Clinical Session guest fees from \$15.00 to \$12.00, the estimated surplus for 1933 is \$5,142.50. The budgets provide for such economies as: a continued reduction in the office staff of the Executive Secretary, a reduction of 10 per cent in the Executive Secretary's salary, a reduction of 10 per cent in the Editor's salary, a reduction of \$20.00 per month in the rental of the College headquarters, and all other savings that can reasonably be made."

Dr. Clement R. Jones, Chairman of the Finance Committee for 1932-1933, presented his report, recommending the following: (1) that remaining College accounts in closed banks in Pittsburgh be assigned by him as the former Treasurer to the "American College of Physicians"; (2) that the Board of Regents authorize the purchase of \$5,000 in U. S. Bonds in addition to the \$1,000 authorized at the meeting on November 13, for permanent investment; (3) the Committee recommends to the Board of Regents the reduction in the cost of Life Membership to \$300.00, plus the initiation

fee, up to the age of forty-five years. After forty-five years of age, the Life Membership fee shall be equivalent to the initiation fee plus the amount of dues from that age to sixty-five years of age. All Fellows now paying for Life Membership on the installment plan may come under this reduced amount; (4) the Committee recommends to the Board of Regents that the Editor's compensation shall be restored to \$2,500 a year; (5) the Committee recommends to the Board of Regents the approval of the auditor's report and the financial accounts for the year 1932.

Dr. Pottenger commented upon the recommendation of the Committee in regard to Life Membership. He said that up to forty-five years of age, a member will pay his regular \$300.00, plus the initiation fee; at forty-six, he would deduct from the \$300.00 one year's dues; at forty-seven, two years' dues, and so on. He stated that the plan gives the member an opportunity of paying his Life Membership while he is productive, and expressed the hope that a great many members would desire to pay their memberships in full during the time their income is greatest, thus avoiding the burden the dues might be in later life. On the other hand, fees so paid will go into the permanent fund of the College.

Upon motion, seconded and regularly carried, the report of the Committee on Finance was accepted and the recommendations adopted.

Dr. W. Blair Stewart, a member of the Committee on Insignia, requested the Executive Secretary, Mr. Loveland, to read the report of the Chairman, Major Edgar Erskine Hume, who could not be present. The report was discussed freely and its recommendations were adopted in the following form:

"(a) A cross of the shape of that of the Key of the College, approximately three inches in height, of green velvet or cloth to be worn at the option of the member on the right side of the academic gown to indicate Fellowship in the College;

"(b) A similar cross of gold braid or cloth of gold would indicate Mastership in the College.

"The use of cloth insignia of this type is in accordance with historical

precedent, and some of the gowns worn by continental University officials and others have such badges to indicate rank or special marks of merit. This plan has the advantage of being quite inexpensive, and as it is optional there should be no complaint by members of having to purchase insignia. On the other hand, if used by Fellows and others on commencement and other occasions, it will be a dignified means of indicating membership in this College. Moreover, if it is decided at some future time to adopt some special gown or hood, there would be practically no expense to making the change."

Upon motion made, seconded and regularly carried, it was

RESOLVED, that the Editor of the ANNALS OF INTERNAL MEDICINE and the Executive Secretary of the College, in conference with the Committee on Publications, be given the authority to change the printer of the ANNALS if they feel it desirable between now and the next meeting of the Board of Regents.

Dr. Stewart, Chairman of the Board of Governors, reported briefly on the work of the Board of Governors during the year, and of their meetings in Montreal. His report indicated that there has been a great deal of activity among the Governors in their individual communities and all are thoroughly interested in the work of the College. He reported to the Board of Regents that he, as Chairman of the Board of Governors, and by authority delegated to him by the Board, had appointed as members of the Committee on Credentials Dr. Egerton L. Crispin, Los Angeles, Calif., for a period of three years; Dr. Chas. H. Cocke, Asheville, N. C., for a period of two years; and Dr. Ernest B. Bradley, Lexington, Ky., for a period of one year.

The first matter under new business was the election of the Secretary-General and the Treasurer for the ensuing year. Dr. Clement R. Jones nominated the present incumbents, namely, William Gerry Morgan for Secretary-General and William D. Stroud for Treasurer, which nominations were regularly seconded. Dr. Musser moved the nominations be closed, said motion being seconded and carried. The Secretary, Mr.

Loveland, was instructed to cast the ballot, and declared Dr. Morgan and Dr. Stroud regularly elected as Secretary-General and Treasurer, respectively, for the ensuing year.

In accordance with the provisions of the Constitution and By-Laws, the following Executive Committee for 1933-1934 was elected:

George Morris Piersol, Philadelphia, Pa.,
Chairman

Jonathan C. Meakins, Montreal, Que.

William Gerry Morgan, Washington, D.C.

William D. Stroud, Philadelphia, Pa.

Walter L. Bierring, Des Moines, Iowa

James H. Means, Boston, Mass.

James Alex. Miller, New York, N. Y.

Maurice C. Pincoffs, Baltimore, Md.

Francis M. Pottenger, Monrovia, Calif.

Upon motion by Dr. Pincoffs, seconded and regularly carried, it was

RESOLVED, that the American College of Physicians accept the invitation of the City of Chicago to hold its 1934 Clinical Session there.

Upon motion by Dr. Pincoffs, seconded and regularly carried, it was

RESOLVED, that Dr. James B. Herrick be appointed General Chairman of the 1934 Clinical Session, and that the exact date of the meeting and the headquarters be left to the General Chairman and the Executive Secretary.

President Piersol, in accordance with authority included in a resolution adopted by the Board of Regents on November 13, 1932, appointed the following standing Committee on Finance:

Charles F. Martin, Montreal, Que.,
Chairman. (3 years)

James Alex. Miller, New York, N. Y.
(2 years)

James S. McLester, Birmingham, Ala. (1
year)

President Piersol reported that there were certain other Committee appointments to be made, but with the approval of the Board, he would prefer deferring the appointments for some of these vacancies, until he had had an opportunity to consider the requirements more fully.

Adjournment.

ABSTRACT OF MINUTES OF THE MEETINGS OF THE
BOARD OF GOVERNORS

Montreal, Canada

February 6-10, 1933

First Meeting, February 6

A regular meeting of the Board of Governors was held on the above date, and presided over by Dr. W. Blair Stewart, Chairman, with the following additional members present: Drs. Oliver C. Melson, Edward L. Tuohy, A. Comingo Griffith, Charles Hartwell Coeke, Clarence H. Beecher, J. Morrison Hutecheson, D. Sclater Lewis, Lewis B. Flinn, Edwin W. Gehring, Luther F. Warren, A. B. Brower, Charles T. Stone, Egerton L. Crispin, Henry F. Stoll, Samuel E. Munson, Thomas Tallman Holt, Adolph Sachs, Allen A. Jones, Leander A. Riely, Edward J. G. Beardsley, John O. Manier, Jabez Elliott, Charles Edward Riggs and Mr. E. R. Loveland, Executive Secretary.

The Executive Secretary, E. R. Loveland, acted as Secretary of the meeting, and read abstracted Minutes of the last meeting of the Board, which were approved as read.

He commented upon the application of the new rules for the admission of members, and asked Governors to investigate candidates fully and to write accordingly to the College Headquarters concerning each candidate. Dr. Stewart then reviewed the time requirements for Associates, namely, that a physician to be presented for Associateship must be a graduate of three years' standing, must not be younger than twenty-six years of age, and that after he has been elected an Associate, he becomes eligible for proposal for advancement to Fellowship at the end of three years, and must qualify for Fellowship within five years. At the end of that time, except by specific action of the Board of Regents, he will be automatically dropped from the rolls of the College. There followed some discussion as to whether or not twenty-six years of age is not too young, and whether three years after graduation is not too short a time for a man to be considered for Associateship. It was directly inferred that members of the Board of Governors should have this in mind when recommending younger men for election to Associateship,

and that possibly only exceptional candidates should be considered at this early age.

Dr. Stewart also pointed out the effect of the new amendment to the By-Laws, which would consolidate the Committee on Credentials for Fellowship and the Committee on Credentials for Associateship; the new Committee to be composed of three members from each Board.

The Chairman further commented upon the list of elections to Fellowship by the Board of Regents, explaining that those elected directly to Fellowship were men of great prominence in various parts of the country, and outstanding men in the medical profession. They are physicians of mature years in professional work. All of their cases have been thoroughly investigated, and every one of them unanimously approved for election to Fellowship. The College is not interested in number of members, but in men of outstanding ability.

Chairman Stewart commented upon the clinical program prepared for the Montreal meeting, and expressed the opinion that the College owed the General Chairman, Dr. Meakins, a debt of gratitude for his work and that of his Committees. The President, Dr. Pottenger, also had prepared an outstanding program for the general sessions, and his work deserved the highest commendation. Dr. Stewart then expressed his appreciation and thanks to the Executive Secretary, Mr. Loveland, for his work. He said the Executive Secretary should not be considered an employee of the College, but as a man who has had the interests of the College at heart from the very moment he took his position, and whose work deserves outstanding recognition by all.

Chairman Stewart introduced President-Elect George Morris Piersol, who spoke briefly of the work of the Committee on Credentials, of which he had been Chairman for many years, and of the new Consolidated Committee which is planned to further facilitate and improve the work of selecting members in the future. He commended

the work of the various Governors and pointed out that they could be of even greater assistance by being firm in applying the requirements of the College to new candidates and by not forwarding to the College Headquarters any proposals but those which in their opinion merit election. He pointed out that the cost of investigating candidates varies from five to twelve dollars, depending upon the size of the community from which the proposal comes. This cost is made up chiefly from clerical service and postage, because letters or inquiry cards are addressed to every Fellow of the College in the community, or city, from which the proposal arises. Dr. Piersol further stated that present economic conditions have caused an increasing number of members to present their resignations, although the number coming into the College is much smaller than the average of other organizations. It is an appropriate function of the Governors to investigate such resignations, and not only to report upon them to the Executive Secretary, but to make an effort to retain desirable men in the College. Dr. Piersol then took occasion to say that the members were deeply indebted to the Executive Secretary for his work and for his coöperation in cutting down the expenses of the College.

At the request of Chairman Stewart, the Executive Secretary read a letter, expressing his regret at being unable to attend the meeting and conveying his regards to the Board, from Dr. Edward O. Otis, Governor for the State of New Hampshire, and dean of the Governors, being the oldest member.

Chairman Stewart introduced President Pottenger, who had just entered the meeting room. Dr. Pottenger spoke briefly of the importance of the Board of Governors in connection with their work in building the membership of the College and the selection of candidates. The Board of Governors should be an increasingly active body; it stands between the Board of Regents and the College membership; it fulfills the essential requirement of having a thoroughly active member representing every State and every Province. Dr. Pottenger re-emphasized the remarks made by President-Elect

Piersol in regard to the application of the standards of admission.

Dr. Allen A. Jones, Chairman of the Committee on Credentials for Associateship, presented a list of sixty-four candidates whose credentials had been carefully reviewed by the College and deemed adequate for election to Associateship at a meeting of the Committee on November 13, 1932, at the College Headquarters, and another list of forty-eight candidates whose credentials had been reviewed on February 5 at Montreal.

Upon motion by Dr. Crispin, seconded by Dr. Griffith and regularly carried, it was

RESOLVED, that the complete list of 112 candidates be approved by the Board of Governors and recommended to the Board of Regents for election to Associateship. (The complete list appears in the Minutes of the Board of Regents as published on another page.)

The Executive Secretary presented a list of forty-four delinquent members of two or more years standing who were subject to being dropped from the rolls of the College. He asked individual members of the Board of Governors to look over the list for their particular districts and to be prepared to make recommendations in the course of the next month. In the meantime, the Board of Regents would be asked to delay action on the list, pending recommendations of the Board of Governors.

The Executive Secretary reported the death of twenty-five Fellows and seven Associates since the San Francisco Clinical Session.

The Executive Secretary reported upon action of the Board of Regents in connection with accepting and deferring various resignations. He distributed mimeographed copies of the financial reports of the College for 1932, and analyzed important features thereof.

On motion by Dr. Cocke, seconded and regularly carried, it was

RESOLVED, that it be the sense of the Board of Governors to express their appreciation to the Executive Secretary for his splendid work in this time of stress and for his efforts in maintaining such an excellent financial status as shown by the reports.

The Chairman opened the meeting for an open forum for discussion or comment by members of the Board.

Dr. Edward L. Tuohy, Governor for Minnesota, made the following inquiries: to what degree are the Associates in Minnesota qualifying for Fellowship under the three-year rule; does the College encourage membership among physicians engaged in border-line specialties, such as Pediatrics, Neurology and Roentgenology; should not the College concentrate more upon Internal Medicine; has the Board of Regents given any more attention to the matter of regional conferences with fewer annual meetings of the wider scope.

The Executive Secretary was asked to answer the first question. He pointed out that Associates who had been elected previous to 1929 were under no obligation to qualify for Fellowship, but those elected during 1929 and thereafter are required to qualify for Fellowship within five years. At the end of three years after election, an Associate is notified by the Executive Secretary that he is now eligible to be considered for Fellowship, and that he is expected to present the qualifications for Fellowship within two more years. In Minnesota, the majority of the Associates elected in 1929 have qualified for Fellowship. For the Committee on Credentials, Dr. Allen A. Jones expressed the opinion that Dr. Tuohy's second point was well taken, and that it should have further consideration. The Committee on Credentials have considered men engaged in the border-line specialties of Pediatrics, Neurology and Roentgenology eligible, provided they present proper credentials. It was pointed out that the General Chairman of each Clinical Session attempts to provide something in the Program for the men interested in the affiliated specialties, as well as Internal Medicine.

It was stated that there was a consensus of opinion that the present type of Annual Clinical Sessions would have greater value than regional conferences, but that the leading city would be alternated from one section of the country to another, in order that members in each region would have opportunities to attend the meetings periodically,

if they could not travel longer distances every year.

Dr. Crispin opened a discussion concerning the minimum age for Associates, and expressed the opinion that most men at this age are not qualified for Associateship, and that they must be selected with considerable care. Dr. Crispin expressed the opinion that it is incumbent upon the Governors to handle these cases as best they can, but to have in mind the possibility of recommending a higher minimum age than at present provided.

Dr. Samuel E. Munson, Governor for Southern Illinois, made inquiry concerning how Governors shall report unfavorable action by the Committee to the candidates. Dr. Stewart suggested that this must be left to the individual judgment of the Governors. Dr. Cocke, of the Committee on Credentials, stated that approximately fifty per cent of the candidates proposed for Associateship are not immediately elected, but are put on a deferred list for additional data, seasoning, etc.

Adjournment.

Second Meeting, February 9, 12:30 p.m.

The second meeting of the Board of Governors was attended by the following, with Dr. W. Blair Stewart presiding: Drs. Oliver C. Melson, Edward L. Tuohy, A. Comingo Griffith, Charles Hartwell Cocke, J. Morrison Hutcheson, Edwin W. Gehring, Charles T. Stone, Egerton L. Crispin, Henry F. Stoll, Thomas Tallman Holt, Roger I. Lee, Adolph Sachs, Allen A. Jones, Leander A. Riely, Edward J. G. Beardsley, John O. Manier, Jabez Elliott, Charles Edward Riggs and the Executive Secretary, Mr. E. R. Loveland.

The Executive Secretary read an abstract of the Minutes of the previous meeting, which were approved as read.

The Executive Secretary reported that the complete list of candidates recommended by the Board of Governors had been regularly elected to Associateship by the Board of Regents; that the Board of Regents adopted a resolution providing that after the list of delinquent members presented at the previous meeting has been thoroughly

reviewed by members of the Board of Governors, which may be a period of a month or six weeks, such delinquents may be dropped, in accordance with provisions of the By-Laws, unless arrangements are satisfactorily made by which their delinquencies will be remedied.

At the direction of Chairman Stewart, the Executive Secretary read the report of the Committee on Public Relations, as approved by the Board of Regents.

Chairman Stewart declared an open forum for the discussion of any subject any member wished to present. He commented himself upon the matter of regional meetings. And this matter was discussed also by Dr. Tuohy, Dr. Cocke, Dr. Griffith, Dr. Roger Lee, Dr. Jabez Elliott and Dr. Crispin. Chairman Stewart summed up the remarks by stating that the matter of regional gatherings rests wholly with individual Governors, that the sentiments favor very largely the social type rather than the academic type of gathering.

Adjournment.

Third Meeting, February 9, 5:50 p.m.

The third meeting of the Board of Governors was held immediately after the General Business Meeting for the purpose of organization of the Board for the new year. The following members were present: Drs. Oliver C. Melson, Edward L. Tuohy, A. Comingo Griffith, W. Blair Stewart, Charles Hartwell Cocke, Clarence H. Beecher, J. Morrison Hutcheson, Edwin W. Gehring, Luther F. Warren, Charles T. Stone, Egerton L. Crispin, Henry F. Stoll, Samuel E. Munson, Thomas Tallman Holt, Roger I. Lee, Adolph Sachs, Allen A. Jones, Leander A. Riely, Edward J. G. Beardsley, Joseph Edward Knighton, Wallace Mason Yater, and Mr. E. R. Loveland, Executive Secretary.

The Executive Secretary, Mr. Loveland, acted as Secretary of the meeting, and Dr. W. Blair Stewart presided.

The terms of the Chairman and Vice-Chairman had expired with the Montreal Session, and following the election of new members of the Board of Governors, it be-

came the duty of the Board to review the standards of admission.

Dr. Allen A. Jones, Chairman of the Committee on Credentials for Associateship, presented a list of sixty-four candidates whose credentials had been carefully reviewed by the College and deemed adequate for admission to Associateship at a meeting of the Committee on November 13, 1932, at the University of Chicago.

The latter motion was seconded by Dr. Tuohy, and another list of candidates whose credentials had been reviewed by the College and deemed adequate for admission to Associateship at a meeting of the Committee on November 13, 1932, at the University of Chicago. The latter motion was seconded by Dr. Tuohy, and another list of candidates whose credentials had been reviewed by the College and deemed adequate for admission to Associateship at a meeting of the Committee on November 13, 1932, at the University of Chicago. The latter motion was seconded by Dr. Tuohy, and another list of candidates whose credentials had been reviewed by the College and deemed adequate for admission to Associateship at a meeting of the Committee on November 13, 1932, at the University of Chicago.

The Executive Secretary presented a list of 112 candidates for the unanimous reelection of the Board of Governors for the ensuing year. Members of the Board applauded.

Dr. Stewart expressed his appreciation of the confidence the Board had reposed in him, and expressed the assurance that he would try to fulfill his duties to the best of his ability.

Nominations for the Vice-Chairman were opened, whereupon Dr. Adolph Sachs placed in nomination the name of Dr. Ernest B. Bradley for reelection.

The nomination was regularly seconded, and upon motion nominations were closed and the Executive Secretary instructed to cast one ballot for the unanimous election of Dr. Bradley.

Upon motion by Dr. Samuel E. Munson seconded and regularly carried, the Chairman of the Board of Governors was instructed to appoint three members to serve on the Committee on Credentials. Chairman Stewart stated he would announce his appointments in the near future.

Adjournment.

NOTE: At the end of the Clinical Session, Chairman Stewart announced the appointment of the following members to serve on the Committee on Credentials:

- Egerton L. Crispin, Los Angeles, Calif. (3 years)
- Charles Hartwell Cocke, Asheville, N. C. (2 years)
- Ernest B. Bradley, Lexington, Ky. (1 year)

ABSTRACTED MINUTES—GENERAL BUSINESS MEETING
of the
AMERICAN COLLEGE OF PHYSICIANS

Montreal, Canada

February 9, 1933

The Annual General Business Meeting of the College convened at five o'clock in Windsor Hall, Montreal, with President Francis M. Pottenger presiding.

The Executive Secretary, E. R. Loveland, read an abstract of the Minutes of the previous meeting held in San Francisco, April 7, 1932, which was approved as read.

Dr. William Gerry Morgan, Secretary-General, was called upon and read the report of the Committee on Public Relations, approved by the Board of Regents.

William D. Stroud, Treasurer, presented the following report for the year 1932:

"Upon assuming the office of Treasurer on July 1, 1932, the Treasurer's Office was transferred to the Central Office at 133-135 S. 36th Street, Philadelphia, and the major portion of the secretarial work has been carried on in that office, thus eliminating the extra budget for the Treasurer's Office, entailing a saving to the College of some \$500 during the last half of 1932, and approximately \$1000 a year in the future.

"The total cash income for the year 1932 was \$75,785.31, with operating expenditures, including the unusually heavy expenses of the San Francisco Session, \$66,162.23, leaving a surplus of \$9,623.08, which has been added to the General Fund.

"On December 31, 1932, the Assets of the College were as follows:

General Fund	\$64,810.97
Endowment Fund	53,375.00
Total	\$118,185.97

Of this total, \$65,574.55 is in securities on deposit in the Girard Trust Company of Philadelphia.

"\$18,311.79 is still owing from the three banks in Pittsburgh which went into the hands of receivers in 1930 and 1931. \$8,892.54 has been repaid by these banks during the year 1932. The cash balance on deposit in the Girard Trust Company of Philadelphia, the Provident Trust Company of Philadelphia, the First National Bank of Pittsburgh, and the Royal Bank of Canada was \$48,285.55.

"There have been no defaults in interest by any of our securities during the year 1932, and such interest has totaled \$2,906.43—considerably more than the Phillips Memorial Prize.

"At the November 13, 1932 meeting of the Board of Regents in Philadelphia, the Fellowship yearly dues were reduced from \$20 to \$15, and Associate dues from \$15 to \$12. Considering the times financially, the year 1932 has been definitely successful for the American College of Physicians. For this, much credit is due to the efficiency of the Executive Office and the Executive Secretary.

"Respectfully submitted,
William D. Stroud, M.D.,
Treasurer."

Upon motion seconded and regularly carried, the report of the Treasurer was accepted and placed on file.

The Executive Secretary, E. R. Loveland, presented his annual report. This covered some analysis of the financial report for the year, a report upon the financial side of the publication of the ANNALS OF INTERNAL MEDICINE, the cost of conducting the Annual Clinical Sessions, membership statistics, registration at the Montreal Session and the conduct of the Executive Offices.

Upon motion seconded and regularly carried, the report of the Executive Secretary was accepted and placed on file.

Dr. William Gerry Morgan, Secretary-General, was asked to present the report of the Committee on Constitution and By-Laws. He read the proposed amendments, Article by Article and Section by Section, as published in the January issue of the ANNALS OF INTERNAL MEDICINE.

On motion by Dr. O. H. Perry Pepper, seconded and regularly carried, the amendments were unanimously adopted.

President Pottenger expressed his pleasure at having been the President of the College for the past year and thanked the members of the organization for their coöperation and aid. He especially complimented the efficient organization of the Executive Office.

ces of the College and the organization by Drs. Meakins and Martin of the Montreal Session. He then asked Dr. O. H. Perry Pepper and Dr. W. Blair Stewart to escort the new President, Dr. George Morris Piersol, to the platform.

In introducing Dr. Piersol, Dr. Pottenger said, "It is a happy occasion in one's life when his colleagues elect him to an office such as the Presidency of the American College of Physicians. It is an especially happy occasion at this time because our new President is a man who merits this position, not only because of his professional attainments, but also because of his devoted service to this organization. Dr. Piersol has been one of our hardest-working members. He has been ever thinking of this organization and looking after its interests. I present to you my successor, Dr. Piersol."

Members arose and applauded, after which Dr. Piersol assumed the chair. In his remarks, Dr. Piersol said in part, "Less than a year ago when you honored me by electing me to the head of this organization, I tried to express to you my appreciation and gratitude for that honor. I repeat it now. I am truly grateful to you for having conferred this distinction upon me and for the confidence and trust that you have indicated in me. I am not going to presume on your time now to try to make any sort of a formal address. My opportunity for that, I take it, will come next year. I do want to say, however, that in assuming this office, I do so with full realization of the responsibilities that go with it. I know that it will be a difficult task to live up to the record that has been established by our retiring President and his predecessors. I am hoping that the incoming administration, by reason of its interest and enthusiasm, will be able to accomplish the work in a meritorious way. In order that, during these rather difficult and uncertain times, we can continue to widen the sphere of influence of this organization and maintain its prestige, I earnestly bespeak the coöperation of all of you. Without that, no administration can succeed, but with that help and with the wise advice and counsel of the Board of Regents and the unfailing interest of the Board of Governors, it may be possible dur-

ing this year to have an administration that will terminate its office one year hence in a successful manner. I want to thank you again and tell you how I am counting on all of you for help during the coming year."

Dr. E. J. G. Beardsley, in the absence of the Chairman of the Committee on Nominations, presented the following report:

"A meeting of the Nominating Committee was held at the office of the College in Philadelphia on the evening of November 12, 1932.

"The following nominations were made:

For President-Elect—Dr. J. C. Meakins, Montreal

For First Vice-President—Dr. C. G. Jennings, Detroit

For Second Vice-President—Dr. N. W. Jones, Portland

For Third Vice-President—Dr. J. H. Means, Boston

For Regents:

(Terms expiring 1936)

Dr. W. L. Bierring, Des Moines

Dr. J. H. Musser, New Orleans

Dr. O. H. P. Pepper, Philadelphia

Dr. F. M. Pottenger, Monrovia

Dr. L. F. Warren, Brooklyn

Terms expiring 1934 (to fill vacancy)

Dr. William J. Kerr, San Francisco

The following nominations were made for the Board of Governors:

For the term expiring in 1936:

Dr. Oliver C. Melson, Arkansas

Dr. Hans Lissner, Northern California

Dr. Tom Bentley Throckmorton, Iowa

Dr. Joseph Edward Knighton, Louisiana

Dr. James D. Bruce, Michigan

Dr. Edward L. Tuohy, Minnesota

Dr. A. Comingo Griffith, Missouri

Dr. Edward O. Otis, New Hampshire

Dr. D. Sclater Lewis, Quebec

Dr. W. Blair Stewart, New Jersey

Dr. Charles Hartwell Cocke, North Carolina

Dr. Julius G. Arnson, North Dakota

Dr. Alexander M. Burgess, Rhode Island

Dr. Robert Wilson, Jr., South Carolina

Dr. Clarence H. Beecher, Vermont

Dr. J. Morrison Hutcheson, Virginia

Dr. Frederick Epplen, Washington
 Dr. John N. Simpson, West Virginia

For the term expiring in 1934:

to take Dr. Luther F. Warren's place—
 Dr. Robert Anderson Cooke, New York

For the term expiring in 1935:

(to take the place of Dr. William Gerry
 Morgan, who has become Secretary-
 General—

Dr. Wallace Mason Yater, Washington,
 D. C.

On motion regularly made, seconded and unanimously carried, the report of the Nominating Committee was accepted and the Secretary-General instructed to cast one ballot for the election of all the candidates nominated. The Secretary-General, Dr. Morgan, announced the ballot had been cast, and the nominees elected.

Dr. O. H. Perry Pepper: "Mr. President, it is proper that we should at this meeting pass a vote of thanks to all the various agencies which have contributed to this very remarkably successful meeting. We should include in this vote of thanks the various institutions of Montreal, the various hospitals of the city, the Convention and Tourist Bureau, the press, and other local agencies. We should include especially the General Chairman, Dr. Meakins. Under Dr. Meakins' supervision there have been five or six Committees at work—the Committee on Arrangements, the Committee on Entertainment of Visiting Women (Chairman, Mrs. Meakins), the Committee on Transportation (Chairman, Dr. Kaufman), the Committee on Publicity (Drs. Sutherland and Benoit, joint Chairmen), the Committee on Convocation (Drs. Martin and Harwood, joint Chairmen). To all of these agencies and individuals Mr. President, I move you a rising vote of thanks by the College." The members arose and applauded.

President Piersol asked the President-Elect, Dr. J. C. Meakins, to come to the platform and make a few remarks.

Dr. Meakins: "Mr. President, Masters, Fellows of the American College of Physicians: I wish to express my few words in logical sequence to what has happened this afternoon. I must confess that I read pages

of the ANNALS OF INTERNAL MEDICINE from a scientific point of view more than I do from the news point of view. I have been taught a very sharp lesson. It was just a week ago last night when our Executive Secretary, Mr. Loveland, was dining with me at my home that he informed me I had been nominated for President-Elect, and it had been published in the January issue of the ANNALS. I was, you may quite realize, tremendously surprised that you should have deemed me worthy of such an honor. I am probably one of the younger members of the College. I feel this confidence which you have placed in me imposes the serious obligation to fulfill your expectations. I have a long line of predecessors who have done noble work, and it is difficult to follow such a royal succession. But you may be assured, I will do everything in my power to maintain the dignity, to maintain the scientific and the professional standard of the College, which means so much to the medical profession of North America. I can only thank you sincerely for this honor which you have done me. I accept it with due humility.

"The organization here in Montreal, although there are only a few of us, are all loyal Fellows of the College. It was our desire to make this meeting as great a success as we could. My part in the matter was one as 'general', I suppose, and no general has yet ever won a campaign without brilliant staff officers. The success of this meeting depended upon the staff officers. For them I accept the vote of thanks, and I thank them as well myself. If it had not been for them, the whole organization would have been a miserable failure.

"I cannot let this opportunity pass without expressing my sincere thanks on behalf of myself and the local Committees to Dr. Pottenger for his unfailing kindness, consideration and courtesy to us. Furthermore, I want to make another expression, and that to Mr. Loveland. We were rather ignorant, true, as far as running this campaign was concerned, but his wise guidance, his almost uncanny penetration of our difficulties and what we should do, his clear letters, his unfailing and prompt consideration of us, made this possible.

"I think the American College of Physicians should be particularly thankful that they have such a capable Executive Secretary. It is only those who work with him who can fully appreciate that. I never appreciated it. I thought it was just an ordinary job. It is not; when one gets into the ramifications of it and sees the multitude

of details which he puts before the local Committee, clearly and succinctly, one cannot help but offer him, on my behalf and on behalf of my committee, a very sincere vote of thanks."

All business scheduled to come before the Fellows and Masters of the College having been completed, adjournment followed.

NUMBER 11

The Clinical Significance of the Systolic Murmur*†

A Study of 1000 Consecutive "Non-Cardiac" Cases

By A. R. FREEMAN, M.D., and SAMUEL A. LEVINE, M.D., F.A.C.P.,
Boston, Massachusetts

INTRODUCTION .

THE significance of the systolic heart murmur has long been a matter of considerable discussion. Not so very long ago, if a heart murmur was heard in a patient, the physician would quickly make a diagnosis of some organic heart condition. If it were systolic in time, and especially if apical in origin, a diagnosis of mitral insufficiency would be made. About fifteen years ago, particularly as a result of the extensive experience with neurocirculatory asthenia, or the so-called soldier's heart during the great war, the pendulum began to swing to the diametrically opposite position. It was found that systolic murmurs were very common in the absence of organic heart disease and gradually the point of view developed that systolic murmurs had no significance whatever. Sir James Mackenzie was frequently

heard to say that it would be better "to throw the stethoscope away". He meant by this that more could be gained by eliciting the symptoms and obtaining an intelligent history of the case, and that auscultation was comparatively valueless. Cabot¹ stated that, "systolic murmurs without other signs of cardiac disease are of no importance as evidence of valve lesions", and that, "a diagnosis of mitral regurgitation without stenosis is never justified". We believe that the truth lies somewhere between these two extreme positions and that, although systolic murmurs are fairly common and often have no importance, frequently they have a definite significance, and a significance that clinically can be ascertained and properly explained. This is in accord with the view recently expressed by Herrick.² On the other hand P. D. White³ stated that "a functional systolic murmur in the pulmonary area is heard in at least 50 per cent of all individuals in the recumbent position". Thayer⁴ found 74 apical

*Received for publication August 29, 1932.

†From the Medical Clinic of the Peter Bent Brigham Hospital, Boston, and the Harvard Medical School.

functional systolic murmurs among 218 normal young individuals in the recumbent left lateral position. Lee⁵ found that 70 per cent of normal individuals showed a systolic murmur in the pulmonic or apical regions, in the recumbent position after strong expiration. Yet McCrudden⁶ found a definite decrease in life expectancy in individuals with no other signs of heart disease except an apical systolic murmur.

A study therefore was undertaken to determine how frequently systolic murmurs are present in routine examinations. An attempt was also made to analyze conditions under which systolic murmurs were found. For this purpose 1000 patients were carefully examined with the deliberate aim of detecting heart murmurs. In about half the instances, the patients were examined by both authors. It was quickly found that the observations by one corresponded quite well with those of the other. In order to avoid the large group of heart patients that are present in any general medical clinic, cases in the medical wards were included in the study to only a small extent. As many routine admissions to the surgical service of the Peter Bent Brigham Hospital as we could study were included. Seventy patients in the neighboring infants' and children's hospital were also examined, so that the study might not be confined to adults. Forty-seven students and house officers in the hospital and 120 nurses were included as representative of healthy young adults. In addition, 100 consecutive patients in a tuberculosis sanitarium were added so that we might determine the frequency of

murmurs in a disease which, although wasting, rarely if ever causes changes in the valves of the heart. This is an entirely different approach from that customarily undertaken, when the significance of a systolic murmur in patients coming for cardio-vascular examination is studied. White⁷ in such a study found that 76 per cent of 1050 unselected patients with an apical systolic murmur had organic heart disease.

It is not the purpose of this study to analyze the frequency of systolic murmurs in heart disease or even to try to explain the physical mechanism of these murmurs. It is common knowledge that systolic murmurs are present with valvular and myocardial disease. It is also quite well known that murmurs may be heard although the heart is normal when anemia or changes in metabolism such as occur in hyperthyroidism are present. The confusion in interpretation has not been diminished a great deal by the addition of the terms "organic" and "functional" murmurs. Many a patient has organic heart disease and still has a relative or "functional" mitral systolic murmur. We also believe that many systolic murmurs which are regarded as functional because the patient has no other evidence of heart disease, are, in fact, organic, in the sense that there is a structural change in the valves causing the murmur.

In trying to analyze the significance of systolic murmurs it became evident that the intensity of the murmur was of considerable importance. The situation is in no way different from that found in studying other clinical data. The amount of albumin in the urine is now fairly well standardized by the

terms, S.P.T. (slightest possible trace) ; S.T. (slight trace) ; L.T. (large trace), etc. Likewise the Wassermann reaction is often indicated by the terms of 1 to 4 plus. The same may be said of globulin in the spinal fluid, and of other tests. It is not a difficult matter to train one's ear so that the loudness and duration of the murmur can be indicated by the figures 1 to 6. On this scale, the systolic murmur of grade "1" intensity is the faintest bruit that can be definitely heard. Although quite faint, this sound must have an appreciable duration. It must continue after the first heart sound and well into systole and must not be confused with a prolonged first heart sound that often is present in hyperactive hearts or in thin-chested individuals, merely as a result of the impact of the heart against the chest wall. We wish to emphasize the importance of this definition of the heart murmur: that it must have appreciable duration after the first heart sound. With this understanding a good deal of confusion can be avoided.

A murmur of intensity "2" may be called a slight murmur. Inasmuch as the examiners in this study were well trained and exercised considerable care in auscultation, it is fair to say that murmurs of the first intensity (grade "1") are probably overlooked or not heard for the most part in routine general practice. It follows, therefore, that what has been called a murmur of grade "2", probably corresponds to what the general physician might term a faint systolic murmur. A murmur of grade "3" would have moderate intensity. One of grade "4" would be loud, while "5" and "6" would be very

loud and the loudest possible murmurs, respectively. There naturally are comparatively few cases with murmurs of the intensity of "5" or "6".

After a little experience and by thinking in the above terms, observers learn very quickly to gauge the intensity of murmurs with such accuracy that they do not differ in their estimates by more than one gradation, and frequently even agree completely. The same observer would in fact find very satisfactory accord in his designation given to a heart murmur in a patient examined from week to week. This matter of terminology has been gone into in some detail because we feel that the use of uniform terms is absolutely essential to success in any attempt to bring some order out of chaos in this complicated question of the significance of the systolic murmur.

The customary interpretation of the apical systolic murmur of moderate intensity is that it is due to regurgitation of blood through the mitral valve. If there is found additional evidence of valvular disease such as signs of mitral stenosis, or if the patient is known to be rheumatic, this regurgitation is regarded as organic and due to a structural change of the mitral valve. On the other hand, if the patient is not rheumatic and shows evidence of the degenerative form of cardiovascular disease such as hypertension, coronary artery symptomatology, and the like, the systolic murmur is looked upon as the result of a relative dilatation of the mitral ring, resulting from a dilatation of the left ventricle so that normal leaflets fail adequately to close the mitral orifice. It also has been thought that, either as a result of

changes in the character of the blood or because of dilatation of the myocardium, a similar systolic murmur might be present with anemia. Although the explanations are varied and obscure, it likewise has been believed that systolic murmurs can develop as a result of fever, emotion, hyperthyroidism, hypertension, and increased heart rate.

It has occurred to us that one of the factors in the production of a systolic murmur which has been very much neglected in our teaching of clinical medicine is the speed of blood flow. Systolic murmurs are frequently found in the same conditions in which, as Blumgart⁸ has shown, the rate of blood flow (not the heart rate) is also increased. In hyperthyroidism, after effort, and in pernicious anemia, systolic murmurs are common and the rate of blood flow is increased. Here the murmur cannot be due to dilatation of the heart, for X-ray studies have shown that the heart after effort and during hyperthyroidism is not dilated and may even be smaller. In some of the other conditions, such as fever, emotion, neurocirculatory asthenia, etc., may not a systolic murmur which is occasionally present be due to a similar mechanism, even if the increased speed of the ejection of blood is limited to the short distance from the heart to the large branches of the aorta? In other words, may not the snapping method by which the blood is expelled from the heart in these hyperactive states in some way cause a systolic murmur, apart from the factor of dilatation?

Furthermore, in the interpretation of systolic murmurs it is of import-

ance whether the murmur is present in the apical region or at the base of the heart, and whether it is heard with the patient recumbent or upright. Recently it has become the custom on the part of many physicians to listen to the heart after effort or during the held expiration. We have attempted to analyze all these factors in the production of the systolic murmur.

In a study of this sort, in which the objective finding that is being analyzed is one detected by auscultation, it is of some interest to compare our observations with those obtained by other physicians. For this purpose a comparison was made between the detection of murmurs by the house officers of the Peter Bent Brigham Hospital and our own observations on the same patients. As has been mentioned above, a systolic murmur, as we define it, must have an appreciable duration after the first heart sound; and what some observers might call a murmur we merely regard as a prolonged first sound, because there is no true bruit lasting into systole. We expected to find no murmurs at all where others had found systolic murmurs because it has become the habit of some house officers and students to say that a systolic murmur is heard, knowing that no great importance will be attached to that finding and fearing that some one else will hear a murmur which they have not noted. The findings in 427 cases were compared for this particular analysis. In 331, or 77 per cent, there was agreement between our observations and those of the house officers. In 28 cases, or 7 per cent, we found a systolic murmur when none was previously noted, and in 68 cases, or 16 per

cent, we failed to find a murmur when it was previously thought to be present. In four of these latter cases what was thought to be a systolic murmur was designated by us as a prolonged first sound. Although in a few instances it is reasonable to assume that a murmur may have been present at one time and not at another, the above discrepancy probably depends upon more careful auscultation and close adherence to the definition of a systolic murmur.

PROLONGED FIRST HEART SOUND

Reference has been made concerning the use of the term prolonged first heart sound. Frequently patients are thought to have a systolic murmur when on careful auscultation one really can hear no bruit extending into systole, during the interval between the first and second sounds. We have found in these cases that the phenomenon consists of a prolongation of the first sound but that systole itself is clear. This seems to be more common in thin-chested individuals and where the heart action is hyperactive, but not necessarily fast. There were 47 instances in these 1000 patients in which a prolonged first sound was heard. Twenty-five were males, and 22 were females. Although in different individuals the prolonged first sound was heard sometimes at the apex and sometimes at the base, and with the patient sometimes recumbent and sometimes upright, it was most usually found at the apex and with the patient lying down. Of these 47 cases, six had hypertension, four had definite fever, eleven had a pulse over 100, three had a hemoglobin less than

60 per cent, six were over 60 years of age and eight were under twenty. It would not seem, therefore, that the prolonged first sound had any clinical significance.

INCIDENCE OF MURMURS IN RELATION TO AGE, SEX AND LOCATION

In this series of 1000 cases there were 471 males and 529 females. The ages varied from infancy to old age. The distribution through the various decades is indicated in table 1. Throughout the decades there was no significant variation in the sexes except in the last two decades where the males predominated. The average age of the males was 39.4 and that of the females 34.6 years.

There were 196 of these 1000 patients who showed a systolic murmur of grade 1 or 2. Those having louder murmurs make up a special group which will be discussed below, where it will be evident that all cases with murmurs louder than grade 2 have organic cardio-vascular disease. Murmurs of fainter intensity, which one might call "functional" murmurs, therefore were present in 19.6 per cent of our series. This figure, however, will be very much reduced when the cases are more carefully analyzed, ruling out further instances of organic disease. Of these 196 patients there were 132 females and 64 males. This indicates that systolic murmurs of this type are about twice as frequent in females as in males. The distribution of these patients with murmurs throughout the various decades is indicated in table 2. It can be readily seen that the predominance of females with murmurs in

this group obtains in most of the decades up to the age of 60. This is especially true between the ages of 20 and 29, merely because there were so many normal nurses included in this study. The average age for the males is 43.0 years and for the females 36.2 years. Both of these figures are somewhat higher than the average of the

about 20 per cent will have a systolic murmur of low intensity and that this will be distributed somewhat unevenly throughout the various ages, with a definite preponderance in the female sex, and with the lowest incidence in males between the ages of 20 and 49 years.

The location of the murmur now

entire 1000 cases (39.4 years and 34.6 years, male and female ages, respectively).

The percentage of murmurs in the different decades varied somewhat but ranged approximately between 15 per cent and 25 per cent. There was a definite diminution in this percentage between the ages of 20 and 50, with a greater incidence during the first two and the last few decades (table 2). The lowest incidence, 7.0 per cent (table 3), was found in the group of males between the ages of 20 and 49. It therefore can be seen that, of a large group of routine, unselected patients,

needs to be considered. The two areas studied were the apex and the base of the heart. No differentiation was made as to whether the murmurs were audible in the pulmonic or aortic areas. For the most part it was in the pulmonic area that these basal murmurs when present were prominent, except in the older group where basal murmurs were generally aortic. Of the 196 patients who showed a systolic murmur, in 122 it was present at the apex and in 145 at the base of the heart. In many it was present in both areas. The distribution of these murmurs according to location throughout

the various decades and in the two sexes is indicated in table 3. It is evident from this table that the systolic murmurs at the apex were about one and one-half times as common as at the base in males over 19 years of age. Of 401 males over 19 years old, there were 38 apical and 25 basal systolic murmurs, i.e., 9.5 per cent and 6.2 per cent respectively. The reversed re-

lation held for 401 females, where systolic murmurs predominated at the base, the figures being 20.4 per cent and 13.5 per cent respectively. In the first two decades (table 3) the above relation did not hold, for in males of the younger group, basal systolic murmurs were almost twice as frequent as apical. These relations are graphically illustrated in table 4.

TABLE IV
A GRAPHIC ILLUSTRATION OF FIGURES
SHOWN IN TABLE 3

INTENSITY OF MURMURS IN RELATION TO AGE, SEX, AND LOCATION

As has been stated above, in these 196 cases were included only those that showed a systolic murmur of grade 1 or 2, whether it was heard at the apex or base of the heart. It seemed to be of some interest to determine whether the intensity of the murmur was greater in one region than in the other and whether there were any variations in the intensity either with sex or with age. A figure was obtained indicating the intensity of the murmur at the apex or base of the heart for any group of cases in the following manner. There were, for instance, 23 females under the age of 20 who had apical systolic murmurs. There were 11 of these with murmurs of grade 2 and 12 with murmurs of grade 1. That made a total count of 34 ($11 \times 2 + 12 = 34$). The intensity index therefore was 1.48 (34 divided by 23). In a similar manner, figures were

obtained for males and females in the three age groups of 0-19, 20-49 and over 49 years. These results are shown in table 3. This table indicates that in females apical murmurs are louder than basal in the first two age groups but become less loud in the older group. The apical murmurs in males, on the other hand, increase in intensity with advancing years. Furthermore, the intensity of apical murmurs is less in males than in females during the first two decades. The intensity indices for the apical murmur in females are 1.48, 1.42, 1.14 for the three age groups respectively, those for males being 1.21, 1.38, 1.44. These results are graphically shown in table 5.

TABLE V
A GRAPHIC ILLUSTRATION OF FIGURES
SHOWN IN TABLE 3

It must be of some significance that apical murmurs of the type analyzed in this study diminish in intensity with increasing years in females, although the actual incidence is not materially different throughout the decades (table 4). One might infer from this that an apical systolic murmur of grade 2 would not only be less com-

mon in elderly females but would have more importance when present.

EFFECT OF POSITION ON SYSTOLIC MURMURS

Throughout this study wherever possible (about 900 cases) notations were made whether murmurs were present at the apex and base of the heart with the patient recumbent as well as upright. The purpose of this was to compare the intensity of systolic murmurs under various circumstances. The relative frequency of apical and basal murmurs has already been discussed. Of the 196 patients with grade 1 or 2 murmurs, 167 were examined while recumbent and upright. The remaining 29 were examined only while recumbent. Of the patients examined in the two positions, 71.2 per cent showed a basal systolic murmur with the patient recumbent, and in 61.3 per cent it was present in this location in the upright position. At the apex, 62.3 per cent showed a murmur in the recumbent position, and only 54.8 per cent had the murmur in the upright position. Thus it is seen that for murmurs of grades 1 and 2, the most common location is at the base with the patient recumbent, and the least common is at the apex with the patient upright. The intensity of the murmurs followed fairly closely the percentages just given for the incidence, the loudest being at the base recumbent and the faintest at the apex upright. It must not be inferred that the same relations hold for murmurs customarily heard with organic heart disease, for these "organic" murmurs are more common at the apex than at the base of the heart.

EFFECT OF HELD EXPIRATION ON PULMONARY SYSTOLIC MURMURS

The findings in the pulmonic area during held expiration we believed needed investigation. Many physicians auscult the heart carefully for murmurs while the patient holds the breath in expiration. This is done to avoid the confusion of respiratory sounds and to have the heart nearer the chest wall by displacing the overlying lung. To study this point more carefully, 22 normal individuals were examined during normal quiet breathing and during held expiration. In none of these were murmurs heard during normal breathing. In one a systolic murmur of grade 1 and in another a murmur of grade 2 were present in the pulmonic area during the held expiration. This same finding has been frequently noted in the larger group of cases included in this study. Furthermore, systolic murmurs were also frequently found to be accentuated by this method. We therefore feel justified in concluding that although a held expiration may uncover a diastolic murmur not otherwise heard at the base of the heart, the appearance of a systolic murmur in this location during this maneuver is of no importance.

SYSTOLIC MURMURS AFTER EFFORT

It has become the custom in recent years for physicians to examine the heart before and after effort for the purpose of detecting murmurs. Various exercises have been used as functional tests of the heart. As a result of this, notations have been made of a systolic murmur or an irregularity disappearing or developing after these exercises. It is not the purpose of this

discussion to take up functional tests in general, but to comment on the appearance of a systolic murmur after effort. Many examiners for life insurance companies have occasionally found systolic murmurs after prescribed exercise tests and on the basis of this have either refused the applicant insurance or have increased his rating. We therefore studied ten normal physicians ranging in age from 24 to 41 before and after a brisk effort. The exercise consisted of running rapidly for about 100 yards. In none of these was a systolic murmur present before the exercise. Within one minute after the exercise and with the pulse ranging from 122 to 176, nine of these ten individuals showed a systolic murmur of grade 1 or 2 at the apex or base of the heart. Generally the murmur was present in both areas and for the most part it was louder in the pulmonic area. At the end of two or three minutes the murmurs all diminished in intensity or disappeared. Although the effort here was much more violent than that required in the usual tests in physicians' offices we feel quite definitely that a systolic murmur that appears after effort, when it was not present before the test, has absolutely no significance and may be found in most normal people.

ANALYSIS OF MURMURS OF GRADES 3 AND 4 INTENSITY

The group of patients with a systolic murmur of greater than grade 2 requires detailed analysis. There were 14 instances in which the murmur had a grade 3 intensity and five instances of grade 4. For the most part these patients were found in the medical

wards. In order to have a fairer distribution of our cases and not to exclude a legitimate proportion of patients with heart disease, 100 patients on the medical service were included, among whom one would naturally expect to find a fair number with organic heart disease. These are the cases that furnish most of the data concerning murmurs of greater than grade 2 intensity. In practically all of these cases the systolic murmur was as loud or louder at the apex than at the base of the heart. In one patient with congenital heart disease, the intensity of the murmur was greatest in the pulmonic area, and in one of the hypertensive cases the murmur was louder over the aortic area than at the apex.

Among the patients with grade 3 murmurs there were seven who had distinct hypertension, one of which had an additional luetic aortic insufficiency. Three additional cases had organic rheumatic valvular disease and one had myocardial failure following coronary thrombosis. Of the remaining three, one had suffered a violent hemorrhage from a gastric ulcer reducing the red blood count to 2,200,000 and shortly later was found to have well marked hypertensive heart failure. One had chronic nephritis with a red blood count of 2,000,000; and the third was a luetic patient who had thyrotoxicosis and cardiac hypertrophy. Of the five patients with a systolic murmur of grade 4, four had well marked rheumatic valvular disease, and one had congenital patent ductus arteriosus. It is evident from the above analysis that the louder systolic murmurs for the most part are

due to organic valvular, hypertensive, or myocardial heart disease that can be definitely recognized, and that systolic murmurs of this intensity only occasionally result from a severe anemia or its accompanying cause.

ANALYSIS OF MURMURS OF GRADES 1 AND 2 INTENSITY

One of the important parts of this study is the consideration of some of the clinical factors that may either be responsible for, or in some way be related to, the systolic murmurs of grades 1 and 2 which were present in 196 cases. The factors particularly studied were hypertension, anemia, hyperthyroidism, a past history of rheumatic fever, chorea or scarlet fever, definite evidence of organic heart disease, and age. In a small number miscellaneous conditions like syphilis, the presence of fever, etc., were considered. There were 40 instances of hypertension, of which 17 were under 50 years of age. It is quite well known that patients with hypertension may or may not have a systolic murmur. It is generally accepted that as a group, people with hypertension will show a systolic murmur more often than normal individuals. Indirect evidence for this view was found in this study. The average readings of 179 consecutive patients in this study not showing murmurs were 129 mm. of mercury systolic and 79 mm. diastolic. The average readings for 115 consecutive patients with murmurs of grade 1 or 2 were 144 mm. of mercury systolic and 84 mm. diastolic. This difference is real and indicates that hypertension is a factor in the production of the systolic murmur.

Thirteen of the 196 cases had anemia (red blood count under 3.5 million), of which six had no other factor of importance to account for the murmur. Nine had hyperthyroidism and one of these had rheumatic fever in addition. It is very significant that twelve had a definite history of rheumatic fever or chorea and sixteen others had evidence warranting suspicion of a previous rheumatic state in that they had early growing pains, vague rheumatics, frequent spontaneous epistaxis, and repeated sore throats. We know that many rheumatic patients have no more definite past history than is indicated by the above symptoms. There is no doubt in our minds that many of these cases were rheumatic patients and that the systolic murmur had more than an accidental significance. In twelve cases there was a past history of scarlet fever, in eight of which other factors were present which may have had some bearing. We feel that scarlet fever is occasionally responsible in some individuals for the presence of a systolic murmur, but that in such cases one can generally also find evidence suggestive of rheumatism.

Definite organic heart disease was found in 18 of these patients, ten of whom had valvular and eight non-valvular heart disease. This group needs no further explanation for it is common knowledge that heart disease in one form or another may be accompanied by murmurs of this intensity.

In studying the question of age as a factor in the production of systolic murmurs we found 19 cases who were over 50 years of age and in whom none of the other factors mentioned

above could be held responsible for the murmurs. Some of these no doubt had cardio-vascular disease of which we were not aware, for cardiac enlargement and coronary artery disease could easily have escaped our attention in this routine study.

There remained 74 patients with a systolic murmur not explained by the above factors. Of these there were 29 in which there were suggestive influences that might have a bearing on the production of a murmur, such as tertiary syphilis, leukemia, displaced heart, etc. In fact there were 16 with a definite fever, and we believe that in some instances the hyperactivity of the heart accompanying fever may be responsible for a murmur that disappears with the return of the temperature to normal. There remained, however, 45 patients with a systolic murmur in whom not even the additional factors just mentioned were present. In some of these cases the data such as blood counts, blood pressure reading, and past history of rheumatic disease were not available. It is interesting that only 11, or 24 per cent, of these 45 patients with an unexplained murmur had a murmur of grade 2, whereas in the entire group of 196 patients with murmurs 77, or 39 per cent, had grade 2 murmurs. This means that for the most part murmurs that have no definite or suggestive explanation for their presence are apt to be of the faintest intensity.

Of these 45 patients with unexplained systolic murmur 13 were males and 32 were females. The systolic murmur was confined to the apex in 12 cases, to the base in 25 and was present at both areas in 8. This bears

out the impression obtained from studying the entire group that faint, unexplained and what might be considered insignificant systolic murmurs are most common at the base of the heart in the female sex. In fact the comparative frequency of systolic murmurs in nurses (28 per cent) increased the total incidence appreciably, for systolic murmurs of grade 1 or 2 were only present in 19 per cent of the patients in the surgical wards of the hospital.

From the above analysis it follows that only 4.5 per cent of 1000 patients had a systolic murmur that could not be explained by some fairly definite clinical cause and that only 1.1 per cent had such an unexplained murmur which was louder than the very faintest that can be heard. If more were known of these cases their numbers would probably be still less. These murmurs can rightly be called "functional" or benign, although many of the other systolic murmurs that had a definite clinical cause (such as those with hyperthyroidism, anemia, etc.) might also be called functional in the sense that the valves were not diseased.

While we agree with McCrudden⁶ that the average life expectancy of patients with systolic murmurs is definitely diminished, we believe that if from a series of such cases one rules out those showing the presence of such causative factors as heart disease, hypertension, hyperthyroidism, etc., there will remain a group in which this prognostic rule will not hold true. In other words, while the life expectancy for our group of 196 patients with grade 1 or 2 systolic murmurs probably is lower than for a similar group without

murmurs, we do not believe an appreciable difference will occur in the final 45 cases of the 196, in whom no explanation could be found for the murmur. This is especially true for the 34 of these 45 cases in whom only the faintest murmur could be heard.

It must not be inferred from this detailed study of the systolic murmur and from the emphasis that has been placed on attempts to correlate such murmurs with definite clinical conditions that murmurs need indicate serious disease, nor that they even indicate heart disease. Patients with heart disease and loud murmurs may be in better health and live longer than other patients with heart disease without murmurs or with faint murmurs. It must be borne in mind that there are many patients with murmurs who have no heart disease at all. The main purpose of this study is to show that systolic murmurs often have a clinical explanation. Furthermore we believe that a systolic murmur of greater than grade 1 intensity should be regarded with suspicion and that a proper interpretation of systolic murmurs will lead to more intelligent diagnosis, prognosis, and treatment of disease.

SUMMARY AND CONCLUSIONS

An analysis was made of the incidence and significance of systolic murmurs in 1000 consecutive individuals distributed as follows: 663 patients in the surgical wards of the Peter Bent Brigham Hospital, 100 patients in a tuberculosis sanitarium, 47 healthy house officers and medical students, 120 nurses, and 70 infants and children in the wards of the Children's Hospital. It quickly became evident

that no progress in such a study could be made unless the systolic murmur were accurately defined and the intensity of the murmur were estimated. By a systolic murmur we mean a distinct bruit that is heard definitely following the first heart sound and extending appreciably into systole. This excludes sounds that are often called systolic murmurs but which are merely impurities or prolongations of the first heart sound. As to intensity, we have divided murmurs into six gradations. Grade 1 is the faintest definite murmur of the type that although distinct will not be heard unless auscultation is most carefully done. Grade 6, although extremely rare, is the type in which the murmur can be heard without a stethoscope and away from the patient's chest. Grade 2 is probably of that slight intensity which in ordinary auscultation not expertly practised, would be called a faint or slight murmur. Grades 3, 4, and 5 might correspond to the terms moderate, loud, and very loud. This method of gradation is practical. Different observers will agree very closely in their estimation of murmurs.

There were 47 instances in these 1000 patients in which a prolonged first heart sound was heard. Although present at times at both the apex and base of the heart with the patient recumbent or upright it was most common at the apex with the patient lying down. This sound was not found to have any clinical significance.

There were 196 cases, or 19.6 per cent, that showed a systolic murmur of grade 1 or 2. The murmur was present about twice as frequently in females as in males. The average age

of those with murmurs was 43.0 years for the males and 36.2 years for the females. The incidence of the murmur in the different decades varied somewhat. The lowest incidence was found to be in males from 20 to 49 years.

A study was made as to the relative frequency of murmurs at the apex and base of the heart. Apical murmurs were one and one-half times as frequent as basal in males and the reverse relationship obtained for females.

A method was devised to obtain an index of the intensity of the murmurs heard at the apex and base of the heart in the two sexes and at different ages. It was found that apical murmurs of grades 1 and 2 diminish in intensity with increasing years in the females, but that in males apical murmurs increase in intensity with increasing years.

Wherever possible patients were examined in both the recumbent and the upright positions. In this group of 196 patients it was found that murmurs of grades 1 and 2 were most common with the patient recumbent and least common at the apex with the patient upright.

In 22 consecutive individuals who had no murmurs on ordinary examination, there were 2 who had a systolic murmur in the pulmonic area during a held expiration. We believe that this procedure, although it may uncover a significant diastolic murmur, has no clinical importance in relation to a systolic murmur.

Ten normal physicians without murmurs were examined before and after a brisk effort. In nine a murmur of grade 1 or 2 was present either at the apex or base of the heart one or two

minutes after the effort. We believe that a murmur not previously present, brought out by this method, is a normal phenomenon.

In these 1000 cases, there were 14 with murmurs of grade 3 intensity and five of grade 4. In every instance, organic disease was found, adequate to explain the murmurs. Of the 14 with grade 3, seven had well marked hypertension, three had rheumatic valvular disease, one had a coronary thrombosis, one had marked anemia with a red cell count of about 2,000,000, one had marked anemia and myocardial failure and one had syphilis, thyrotoxicosis, and marked cardiac hypertrophy. Four of the five patients with grade 4 murmurs had rheumatic valvular disease and the other had congenital patent ductus arteriosus. We therefore feel that the louder systolic murmurs can never be dismissed as insignificant.

In an attempt to discover how many patients have a systolic murmur not associated with any important disease, past or present, it was found that of 196 who had murmurs of grade 1 or 2, 40 had hypertension, 13 had anemia, 9 had hyperthyroidism, 12 had a definite past history of rheumatic fever or chorea and 16 had a suspicious history of a previous rheumatic state. There were 12 cases with a past history of scarlet fever. We believe that all the above factors may have some relation to the murmurs present. There were 18 cases with definite organic heart disease, 10 valvular and eight non-valvular. There were 19 cases over 50 years of age in which none of the above factors except age were present. In some of these no doubt, cardio-vascular disease existed which we did not

detect. There were 29 cases in which suggestive influences which might have a bearing on the production of the murmur were present such as tertiary syphilis, leukemia, displaced heart, etc. In fact 16 of these had a definite fever. Finally there remained 45 patients (4.5 per cent) in whom none of the definite or possible influences in the production of the murmur could be elicited. Only 11 (1.1 per cent) of these had murmurs of grade 2.

In conclusion we wish to speak against the prevailing opinion that systolic murmurs have little or no significance and to emphasize the fact that although they are frequently present in the absence of heart disease, a proper interpretation of the intensity of the murmur and of the possible causative factors considered above will aid greatly towards more accurate diagnosis, prognosis, and treatment of disease.

Apoplexy*†

A Study of 801 Cases Admitted to the Kings County Hospital During the Five Years from 1923 to 1928

By ORMAN C. PERKINS, M.A., M.D., F.A.C.P., *Brooklyn, New York*

A STUDY has been made of all the cases of apoplexy admitted to the Kings County Hospital during the five years, 1923-1928. Several important factors must be borne in mind in considering this material. The Kings County Hospital is a city hospital and the largest in the Borough of Brooklyn. Its ambulance service covers the largest area served by any hospital in the borough and in addition many patients are brought to Kings County Hospital by the ambulances of other hospitals. These conditions result in the admission of a large number of cases of apoplexy. The patients fall into one of two groups. In the first, the patient has been stricken at his work, or on the street, or perhaps in the home and is admitted shortly after the onset. In the second group we find those patients who have been cared for in the home for from a few days up to a week or more and are admitted to the hospital because they have not shown satisfactory improvement.

In this study only those cases were included in which a definite diagnosis

of vascular accident was made. Not all of the patients presented symptoms or signs of motor involvement. In the five year period selected, 801 cases were found to fall into this group.

It has been noted by previous investigators in this field that the importance formerly attributed to certain etiologic factors was much exaggerated. For example, it is now recognized that it is exceptional for any of the cerebral vascular accidents, even hemorrhage, to occur during great exertion. Natural acts involving effort, such as defecation and coitus, and even mental excitement are considered of very little importance as precipitating factors. There are other factors which are matters of discussion and dispute. Foremost among these debatable points are: the influence of the season of the year on the frequency of vascular accidents; the predominance of such lesions in the male or the female; the question as to which cerebral hemisphere is most often affected; the relation of the height of the blood pressure to such lesions; the connection between syphilis and apoplexy; and the age period in which the highest incidence of apoplexy is found. In the study presented in this paper data bearing on these disputed points are

* Received for publication September 29, 1932.

† From the Department of Neurology, Kings County Hospital, Brooklyn, N. Y.

presented. To reach definite conclusions a much larger group of cases must be subjected to analysis, but I believe that it is important to add our series of cases to the literature for future reference.

AGE

No period of life is exempt from cerebral hemorrhage, but inasmuch as arterial degeneration is most common in the later periods, it is after middle life that we find the chief liability to apoplexy. On this point, however, there seems to be some want of agreement in the published statistics.

The following tabulation is from the postmortem records of St. Bartholomew's Hospital, and is based on 124 cases of intracranial hemorrhages in which the age was ascertained.

AGE	MALE	FEMALE	TOTAL	PCT.
8-20	6	2	8	6.4
21-30	4	3	7	5.6
31-40	11	6	17	13.7
41-50	32	11	43	34.6
51-60	18	6	24	19.3
61-70	14	6	20	16.1
71-80	5	0	5	4.0
Total	90	34	124	

From this table the liability to apoplexy seems to be greatest in the period between forty and fifty and to decline appreciably with each succeeding decade.

We must not overlook the fact that cerebral hemorrhage may occur in very early life. Potts² states that the fact that apoplexy is not infrequent in early life does not seem to be generally recognized. In the statistics collected by Thomas from the records of the Johns Hopkins Hospital, 135 out of 740 cases occurred during the

first ten years of life, a number greater than during any subsequent decade until the fifth.

Gintrac's³ figures have been freely quoted by succeeding authors. According to Gintrac's tables the percentage of cases increases with each decade from the age of thirty to attain its maximum between sixty-one to seventy. It is also noticeable that as many as 17 per cent fall between seventy to eighty.

In our series of cases (table 1) birth hemorrhages have not been included. The first cases to be noted occurred between the ages of twenty to twenty-four. Only one case fell in the age period between ninety-six to one hundred and none was over one hundred years of age.

TABLE I

AGE OF PATIENT AT TIME OF VASCULAR ACCIDENT						
Age	1923	1924	1925	1926	1927	Total
20	0	1	0	0	2	3
24	3	2	0	0	2	7
28	2	2	2	2	3	11

56	21	21	27	17	11	97
60	17	35	17	17	34	120
64	17	18	26	20	19	100
68	16	20	15	15	15	81
72	6	9	14	9	14	52
76	6	4	3	8	2	23
80	6	1	4	7	7	25
84	1	1	0	1	1	4
88	0	0	0	5	0	5
92	1	0	0	1	2	4
96	0	0	0	0	1	1
100	0	0	0	0	0	0
Total	149	179	159	152	162	801

Study of this table shows that there is a gradual increase in the number of cases from the age of thirty-six up to sixty-four and a decline thereafter. If we examine each year separately we notice that this same finding is consistent. Two hundred and twenty cases, or 29.9 per cent, occurred between the ages of sixty to sixty-eight. We find only 49 cases between the ages of twenty and forty.

BLOOD PRESSURE

In the total of 801 cases, the blood pressure was taken in 647 cases. There seems to be the impression among many physicians that apoplexy is usually associated with very high blood pressure. Table II shows the number of cases for each ten points rise of systolic pressure, separately for each year in order to show how consistent these figures seem to be.

We find the number of cases increasing with the increase of blood pressure from 100 up to 140 millimeters of mercury. The total number of cases with systolic blood pressures of 140 millimeters of mercury or less was 105, which is 16.2 per cent of the total group. In the group with systolic blood pressures between 140 and 170 millimeters of mercury there were 205 cases, or 31.6 per cent. These figures indicate that the belief that very high blood pressure is essential for apoplexy is inaccurate.

SYPHILIS

Of the 801 cases, 617 had a Wassermann test done during their stay in the Hospital. In table 3 is shown, arranged by year, the number of patients who had positive and negative

Wassermann tests. The average age of those who had positive Wassermann tests, whether they died or improved during their stay in the Hospital, and their average systolic pressure, are also indicated in this table.

The fact that a positive blood Wassermann test was obtained in only 8.58 per cent of 617 cases of apoplexy investigated is evidence against the belief of some that syphilis plays a considerable rôle in the causation of this condition. The high mortality in this group may perhaps be explained as follows. The most common vascular lesion of the brain due to syphilis is an endarteritis and thrombosis resulting in

softening. Thrombosis, as Jones⁶ has shown in a series of 143 autopsied cases, is twice as apt to occur during sleep as is hemorrhage. It may be presumed that many of these cases therefore occurred in the patients' homes and it would be in accord with our experience that they would not be transferred to this Hospital from the

their stay in the Hospital for each month during the five years.

Even from as large a series as this, it is difficult to draw clean cut conclusions. However, it is evident that the admissions were fewest in number in July, August and September and that the largest number admitted was in January. From January to July the

home until their condition had become critical.

INFLUENCE OF SEASON

It seems to be accepted almost as an axiom that cold weather predisposes to cerebral hemorrhage if the blood vessels are diseased and the blood pressure is high. Tooth's¹ figures, however, show very little seasonal difference. Gintrac's figures sustain the impression that the accident is more likely to happen in the cold months. The theory that has been suggested is that the cold weather produces a contraction of the peripheral vessels and that consequently there occurs a rise of the blood pressure in the vessels of the internal organs. In table 4 there is recorded the number of cases admitted and the information as to whether these patients died or recovered during

number ran consistently high. As to the percentage of deaths, we find a variation. The mortality ran high from September to January 1st, but we also find a high death rate in March, May and July. If we are to consider the cold weather theory seriously we should expect a high mortality in January when the largest number of admissions occurred, since an increase of blood pressure would predispose to the more fatal accident of hemorrhage rather than to the less fatal one of thrombosis. Instead, we have in January the third lowest death rate.

INFLUENCE OF SEX

As to the predominance of sex, we find it quite agreed that men outnumber women. Jelliffe and White⁷ state that: "Men are more often affected

(seven to five) than women." Tooth says: "As to sex there can be no doubt that women are much less liable to cerebral hemorrhage than men." Reference to the table of Tooth shows 90 males (72.5 per cent) and 34 females (27.4 per cent). Here, perhaps, the statistics of the postmortem room of a

years are 56.1 per cent males to 43.9 per cent females. It is noteworthy that these are practically the same as Gintrac's figures.

SITE OF LESION

There is still a difference of opinion as to which side of the brain is most

general hospital may lead to an erroneous conclusion. Many of the men are brought in from the street or from their work where they have fallen; women who are more likely to be seized at home are also more apt to remain at home. Perhaps Gintrac's conclusions are nearer the truth, namely, that the relation between male and female cases is about 57 per cent to 43 per cent.

The sex distribution of our cases is presented in table 5. The number of male patients runs consistently higher each year than that of the females. The average percentages for the five

TABLE V
SEX DISTRIBUTION OF CASES

Year	Male	Female	Pct. of Males
1923	86	63	57.7
1924	100	79	55.8
1925	87	72	54.7
1926	83	69	54.6
1927	94	68	58.0

commonly affected. From Morgagni's early dictum concerning the greater prevalence of right-sided hemorrhages general opinion has swung at the present time to the belief that the right and the left sides are about equally

involved. Jones⁶ collection of 1733 cases showed an incidence of 53 per cent of lesions of the left hemisphere.

In the study of the cases in our series we find that 53.2 per cent of the patients who had involvement resulting in paralysis had a lesion in the left hemisphere resulting in a right hemi-

of the data brings out the following points of interest.

1. The largest number of cases, or 29.9 per cent, occurred between the ages of sixty to sixty-eight.

2. Of the 647 patients whose blood pressure was taken, 205, or 31.6 per cent, had systolic blood pressures of

TABLE VI
COMPARISON OF MOTOR INVOLVEMENT AND MORTALITY RATE

Year	Right Hemiplegia	Left Hemiplegia	No Paralysis	% of Right Hemiplegia	% of Deaths
1923	82	57	10	58.9	69.7
1924	89	76	14	53.3	77.6
1925	70	63	26	57.6	77.9
1926	51	50	51	50.4	92.1
1927	77	78	7	49.6	76.5

plegia. This figure is practically the same as that of Jones.

MORTALITY

The mortality in this series was 78.6 per cent, a figure not far from that reported for the large number of cases collected by Jones. This mortality rate seems high, but it is no doubt to some extent affected by the circumstances, already described, under which our patients with apoplexy were admitted to this Hospital.

Jones pointed out that the age and the sex made little difference in the death rate. Under sixty years of age 76.8 per cent of the males and 79.6 per cent of the females died, while over sixty years of age 75.7 per cent of the males and 82.4 per cent of the females died.

CONCLUSIONS

In this study of 801 cases of vascular accidents to the brain, the analysis

between 140 and 170 millimeters of mercury.

3. Of the 617 patients on whom a Wassermann test was performed, only 8.58 per cent had a positive Wassermann. Forty of the 53 cases that had a positive Wassermann died.

4. The hospital admissions of cases of apoplexy were least numerous in the months of July, August, and September, and most numerous in January.

5. The sex distribution in this series was 56.1 per cent males to 43.9 females.

6. Of the patients showing paralysis, 53.2 per cent had a lesion in the left cerebral hemisphere.

7. The mortality in this series for the five years was 78.6 per cent.

The author wishes to express his appreciation to Dr. William Browning and Dr. Arthur C. Brush for the opportunity of studying these cases.

Pernicious Anemia without Achlorhydria*†

Case Report

By EARLE A. HARVEY, M.D., and WILLIAM P. MURPHY, M.D.,
Boston, Massachusetts

CHANGES in the stomach or in its secretions have been noted as a common finding in pernicious anemia for many years. As early as 1860 Austin Flint¹ spoke of an absence of gastric secretion and mentioned degenerative changes in the gastric mucosa. In 1877 Fenwick² noted atrophy of the gastric mucous membrane. Achlorhydria was spoken of by Cahn and von Mering³ as early as 1886 and again by von Noorden⁴ in 1891. Since these early reports, the absence of free hydrochloric acid from the gastric juice and a low total or combined acidity has usually been considered to be a typical or even a constant finding in this disease.

Achlorhydria has been known to exist in some cases for years before clinical symptoms of the disease developed. Ivy, Morgan and Farrell⁵ cite records from 18 different authors totaling 36 such cases. Strandell⁶ cites 23 cases reported by 13 different authors. The achlorhydria is usually considered to be a permanent condition in this disease even after a good remission has been brought about with

liver treatment. Minot and Murphy⁷ have reported it present in 18 patients when gastric analysis was performed from two to twenty-two months after a remission had been produced with liver therapy. Brauch⁸ reported achylia to be present in five cases in remission after treatment with liver. Strandell⁹ found achylia still present in one patient after a remission in the disease of sixteen and one-half years' duration without liver treatment. Shaw¹⁰ and Heeres¹¹ each report the return of hydrochloric acid with improvement in the anemic condition in one case not treated with liver.

Many of the earlier reports of gastric analyses made in patients considered to have pernicious anemia show a fairly large number with free hydrochloric acid present in the gastric contents. Stockton¹² found that three out of nine patients examined had free acid. Friedenwald and Morrison¹³ reported that 14 of 76 cases examined had free acid present but found it diminished in all except four patients in whom the gastric juice was normal.

Later reports, however, have only rarely recorded a patient without achlorhydria, perhaps because of the introduction of better methods of diagnosis. Cabot¹⁴ reported only one of

*Received for publication September 29, 1932.

†From the Medical Clinic of the Peter Bent Brigham Hospital, Boston.

79 cases of pernicious anemia tested; Percy¹⁵ found only one such case of those tested in his series of 129 cases (he does not state the number tested); Levine and Ladd,¹⁶ in reviewing the histories of 150 cases of pernicious anemia, reported only one patient with an unquestioned diagnosis out of 107 cases tested, in whom free hydrochloric acid was found to be present. In the cases which showed no free acid, 14 had a total acidity between 20° and 30°, seven between 30° and 40°, and two between 60° and 70°. Carr¹⁷ reported tests in 53 patients, in three of whom small amounts of free acid were found. Panton, Maitland-Jones and Riddoch¹⁸ reported that two of 35 cases tested had small amount of free acid; Willson and Evans¹⁹ found achlorhydria in all of 111 cases tested, and Grinker²⁰ found hydrochloric acid present in three of 74 cases tested. Piney²¹ reported one case of subacute combined degeneration of the spinal cord in which free acid was present in the gastric secretion. No anemia was present, but viscosimetry showed the average volume of the red blood cells to be high and the diagnosis of pernicious anemia was later confirmed by history and by autopsy. Taubmann²² reported a typical case of pernicious anemia with free hydrochloric acid in the gastric juice. A remission of the disease occurred and the patient was discharged from the hospital with a red blood cell count of four million per cubic millimeter and a hemoglobin level of 93 per cent, although liver therapy was not used. One year later he reentered the hospital acutely ill and died. The cause of death was not known, although Minkowski²³ states

that it was probably not because of anemia. An autopsy was not performed.

The evidence as presented in the literature indicates that a disease condition typical of pernicious anemia in all essential respects, except that free hydrochloric acid is present in the gastric secretion, may occur. That such cases do occur is strong evidence against the etiological importance of achlorhydria in pernicious anemia. The work of Castle, Townsend and Heath²⁴ supplies further evidence to substantiate this idea. These same authors have also presented evidence of an alteration in the gastric contents which is more uniformly present than is achlorhydria and which they consider to be of greater etiological significance.

Because there is a paucity of reports of undoubted cases of pernicious anemia with free hydrochloric acid in the gastric contents, it seemed advisable to report the following case, giving the laboratory and clinical findings in considerable detail. The diagnosis is made more certain and the report more interesting by the typical, prompt and striking improvement in the blood following the institution of peroral liver therapy and again following the use of intramuscular injections of liver extract.

CASE REPORT

L.J.R., a 55-year-old, American-born housewife, entered the Peter Bent Brigham Hospital for the first time on July 15, 1930, complaining of jaundice, weakness and loss of weight.

Her illness dated from about February of the same year with the insidious onset of weakness, ease of fatigue, and loss of appetite. The weakness had steadily in-

creased and was accompanied by marked shortness of breath and forceful palpitation of the heart on moderate exertion. There followed subsequently swelling of the ankles, chilly sensations and anorexia, with nausea and vomiting at the sight of food, icterus, and the appearance of clay-colored stools. For a month before the present admission the patient had been troubled with dizzy spells and with a staggering gait. The fingers, feet and legs had felt numb and were often painful to pressure. Black and blue spots became evident following slight bruising. A persistently sore tongue developed. On June 5, 1930, she was seen in another Boston clinic at which time the following observations were made. The gastric contents showed free hydrochloric acid, the urine a slight trace of albumin with numerous white blood cells in the sediment. The blood showed a non-protein-nitrogen value of 25 milligrams per 100 c.c., a negative Wassermann reaction, 5.3 milligrams of bilirubin by the Van den Bergh test, 9.1 gm. of hemoglobin per 100 c.c., of blood, a red blood cell count of 1,680,000, and 3,800 white blood cells per cubic millimeter. Roentgen-ray studies of the gastrointestinal tract were interpreted as showing either a large diverticulum of the duodenum or a partial obstruction of the duodenum with dilatation. Intravenous cholecystograms showed no filling of the gall-bladder.

Thereafter until admission to this hospital the jaundice fluctuated in intensity and the weakness progressed.

The family history was irrelevant. The patient's first husband had died with pulmonary tuberculosis. Her second husband was living and well. The patient had always been strong, and except for the diseases of childhood and one cold each year, had suffered no ill health. The menstrual history was not unusual. There had been occasional slight bleeding from hemorrhoids. Nocturia, four to five times per night, had been present for many years. In 1925 a Bartholin's cyst had been removed; in 1927 an operation was performed for repair of the perineum and suspension of the uterus; and in 1929 another operation was done for repair of a postoperative ventral hernia and for bilateral inguinal herniae. Her nor-

mal weight was 175 pounds, but had decreased by about 25 pounds during the five months preceding the present hospital admission. A detailed dietary history failed to reveal evidence of a food deficiency.

Physical examination showed a large, well-developed woman lying comfortably in bed. She was mentally clear and coöperative. There was evidence of recent loss of weight. The hair was black with some graying and was normal in amount and texture. The skin showed a uniform brownish-yellow tint with several faint purpuric spots over the body. The pupils were equal, regular, and reacted normally to light and in accommodation. The sclerae were icteric. Ophthalmoscopic examination showed the optic discs to be normal in appearance. The left retina showed a small hemorrhage in the upper temporal quadrant and the right showed a small hemorrhage at the temporal side of the disc. The retinae were both pale but showed no areas of exudate. The retinal vessels appeared slightly larger than normal but showed no nicking, embedding, or tortuosity. The hearing was good. The mucous membranes of the mouth were pale and the teeth were all extracted. The tongue was smooth, clean, pale and slightly atrophic in appearance. It protruded in the midline without tremor. There were no areas of redness or of ulceration. There were loose folds of skin about the neck which suggested recent loss of weight. The thyroid gland was not palpable. The thorax was symmetrical and of normal appearance. Expansion was good and equal on both sides. Respirations were 20 per minute and of normal depth and character. The breasts were markedly atrophic. The heart was not enlarged. On auscultation a soft blowing systolic murmur was heard over the apex region. Examination of the heart was otherwise negative. The radial pulses were equal, and regular with a rate of 88 per minute. Palpation of the arterial vessel walls did not suggest sclerosis. There were many small prominent superficial veins below the knee and down the thigh. The blood pressure was 115 mm. of mercury systolic and 60 diastolic. The lungs were resonant throughout to percussion and tactile fremitus was normal. The voice and breath

sounds were normal and no râles were heard. The abdomen showed two midline scars. There was a small reducible right inguinal hernia. The abdominal reflexes were active. The lower edge of the liver was easily palpable three fingers' breadth beneath the costal margin. The gall-bladder, spleen, kidneys and bladder could not be felt. Rectal examination revealed small internal hemorrhoids on the left posterior wall, but none externally. Vaginal examination showed a slight cystocele. The cervix had a slight transverse laceration and the fundus of the uterus could not be felt. No adnexae felt. There was no enlargement of cervical, axillary, inguinal or epitrochlear glands. There was marked pallor of the fingers and nail beds. Dorsa of the wrists were heavily freckled. The biceps, triceps and radial-periosteal reflexes were equal and normal. No joint changes were noted. There was slight edema along the ankles and legs as high as the knee. There was a suggestion of positive Babinski and Oppenheim tests.

The knee jerks and Achilles reflexes were normal. The Romberg and Kernig tests were negative. There was paresthesia of the fingers of both hands. Vibration sense was decreased over the bony prominences of the arms and legs.

Clinical Laboratory Tests on Admission. The hemoglobin varied between 5.6 and 5.4 grams per 100 cubic centimeters. The red blood cells varied between 886,000 and 1,400,000 per cubic millimeter of blood as counted by various observers. They showed anisocytosis, poikilocytosis, and rare nucleated forms. There was a moderate number of macrocytes and microcytes. Slight polychromatophilia was noted. Hematocrit determination showed 16.2 per cent cells and 83.8 per cent plasma. The individual cell volume was 13.5 by 10^{-11} cubic centimeters. The average mean diameter of the red blood cells by the method of Price-Jones was 8.7μ . The fragility of the red blood cells was tested on two occasions and found to be within normal limits.

Preformed creatinine.....	1.43	Preformed creatinine.....	2.60
Cholesterol	143.0	Cholesterol	113.6
Blood iron.....	40.0	Blood iron.....	40.16

There was a definite leukopenia, the white blood cells varying from 3,500 to 4,800 per cubic millimeter. The differential white blood cell count was essentially normal except that the polymorphonuclear leukocytes showed characteristic hypersegmentation of the nuclei and the Arneth count showed a marked shift to the right with an Arneth index of fifteen.

Both the bleeding and the clotting time were normal. The icteric index was 15 and 25 on successive determinations. The Van den Bergh test gave a delayed direct reaction. Quantitative determination gave 4.8 Van den Bergh units or 2.4 milligrams of bilirubin per 100 cubic centimeters. Wassermann, Hinton, and modified Hinton tests were negative.

Gastric analysis done on several occasions showed the presence of adequate amounts of free hydrochloric acid as well as of pepsin and rennin. (See table 3*)

The basal metabolic rate was plus six. The electrocardiogram showed normal curves.

Urine studies were essentially negative. The test for Bence-Jones protein was nega-

tive. Phenolsulphonephthalein excretion was 32 per cent in two hours and ten minutes.

Stool studies did not reveal abnormalities. Careful search was made for ova and parasites.

Temperature, pulse and respirations were within normal limits on admission and remained within these limits during all periods except that preceding death.

Cholecystograms (intravenous) failed to show a normal gall-bladder shadow at ten, twelve and fourteen hours. The findings indicated a pathological gall-bladder.

The esophagus appeared normal by roentgen-ray examination. The stomach was low and hypotonic, showed vigorous peristalsis, a smooth outline, and no residue at six hours. The duodenal cap was large, and filled and emptied well. There was a large diverticulum in the second portion of the duodenum, and two other diverticuli at the duodeno-jejunal junction. There were also multiple diverticuli in the small bowel distal to this. Hypomotility was present, barium not having filled the cecum at six hours. The twenty-four hour examination showed a long atonic redundant colon. The cecum was fixed in the pelvis and the ascending colon was medial to the usual position. The diverticuli noted on the previous day were

*A more complete record of the results of observations of the blood may be seen in tables I and 2

empty. The roentgenological impression was diverticulosis.

Films of the long bones showed an irregular thickening of the cortex of the left fibula and a lesser amount of thickening on the right. The bones all appeared slightly

a day. Vomiting ceased. Following this therapy she had a typical and fairly satisfactory reticulocyte response reaching a peak of 19.3 per cent on the tenth day after starting liver therapy. The reticulocyte response is shown on chart 1.

TABLE III
GASTRIC ANALYSIS

	Residue	Benzidene	Reaction	Free HCl	Total Acid	Rennin
Fasting spec., 13 c.c. pinkish mucoid fluid	1%	Negative	Neutral	0	6	1- 320
EWALD MEAL*:						
1st specimen: 7 c.c. bready grey fluid	3%	Positive	Acid	60	75	1- 640
2nd specimen: 9 c.c. bready greenish fluid	3%	"	"	6	10	1- 640
3rd specimen: 14 c.c. bready pale yellow fluid	2%	"	"	0	24	1- 640
4th specimen: 17 c.c. bready amber fluid	2%	"	"	0	10	1- 160
HISTAMINE†: 0.5 mg. intramuscularly						
5th specimen: 17 c.c. bready green fluid	2%	"	"	35	51	1-1280
6th specimen: 14 c.c. cloudy green fluid	2%	"	"	52	86	1-1280
7th specimen: 30 c.c. cloudy green fluid	2%	"	"	77	96	1-2560
8th specimen: 15 c.c. hazy green fluid	2%	"	"	73	82	1-2560

*The Ewald meal consisted of 60 gms. of bread and 200 c.c. water. The first and second specimens were obtained at twenty-minute intervals, the third and fourth at forty-minute intervals.

†Histamine was given intramuscularly and specimens obtained every fifteen minutes. Difficulty was experienced in obtaining second, third and fourth specimens so that 10 c.c. of water was introduced into the stomach through Rehfuess tube and washed back and forth through tube. This procedure undoubtedly accounts for the low figures obtained in titrating specimens against tenth-normal sodium hydroxide. Pepsin was positive in all specimens as determined by the ordinary test with Mett's tube in dilute hydrochloric acid. Rennin was positive in all specimens in dilutions noted in table. This analysis was done on January 7, 1931. Gastric analyses were done on four other widely separated occasions and agreed with the essential findings noted above. The slightly positive benzidene tests are accounted for by trauma to the gastric mucosa.

decalcified. No localized areas of bone destruction were seen, except possibly on the styloid process of the right ulna where the bone appeared somewhat thinner than usual.

Progress Notes. On July 24 the patient began the ingestion of 240 grams of raw liver pulp daily. (See table 4 for complete record of treatments.) Much of the liver pulp was vomited, and on July 27 the liver pulp was discontinued and she was given daily liver extract No. 343 (N.N.R.), the amount derived from 800 grams of liver. This was well taken with the addition of twelve minims of tincture of belladonna three times

During the patient's stay in the hospital she continued to make excellent clinical improvement. The red blood cell count increased from about one million at the time of admission to two million on August 16, 1930, twenty-one days after liver extract therapy was begun. The patient continued to take daily liver extract prepared from 800 grams of liver. She was then discharged from the hospital and seen at weekly intervals, the blood showing continued, gradual improvement until the hemoglobin was 12.6 grams per 100 cubic centimeters and the red blood cells 4,230,000

per cubic millimeter on October 4, 1930. For the next two months the blood picture remained about constant. The following month there was a definite fall in the red blood cell count and hemoglobin, although she had taken extract prepared from 400

to 600 grams of liver daily. During the six months following discharge from the hospital the neurological signs became progressively more marked. The patient staggered while walking. The numbness and tingling in the hands and feet seemed on the

RETICULOCYTE RESPONSE FOLLOWING LIVER THERAPY.

*Partially vomited and refused.

**Prepared from 800 grams of raw liver. Given daily.

whole to become more severe and constant in spite of the improvement in the blood picture. She complained bitterly of coldness and stiffness of the extremities. The fingers were clumsy so that she was unable to put on gloves without assistance.

The patient's failure to make complete recovery was thought to be partly due to the gall-bladder disease that had been suspected during her first admission to the hospital. She entered the medical service for the second time. Intravenous cholecystograms were repeated and failed to show a gall-bladder shadow. Cholecystectomy was advised and the patient was transferred to the surgical service. On January 17, 1931,* under avertin and ether anesthesia, the gall-bladder was removed in the usual manner. The liver was involved in a diffuse perihepatitis. The pathological specimen showed a gall-bladder 15 centimeters in length and 6 centimeters in diameter. The surface was smooth except where it had been detached from its bed. On opening the gall-bladder a considerable quantity of poorly concentrated bile escaped. There was a solitary stone measuring 3.8 by 2.8 by 2 centimeters. This had a rusty color and a slightly roughened surface. Within the gall-bladder was a small amount of scaly material of about the same color. The mucosa was not injected and of quite normal appearance. A few strands of fibrous tissue were seen in some areas but these were not prominent. Microscopic section of the gall-bladder showed moderate fibrosis with chronic inflammation. Culture of the bile and wall of the gall-bladder showed no growth. The pathological diagnosis was chronic cholecystitis and cholelithiasis. The patient made an uneventful postoperative recovery except for slight vomiting on the first and second days. Following the operation the hemoglobin dropped to 10.5 grams per 100 cubic centimeters of blood and the red blood cells to 2,930,000 per cubic millimeter. Liver extract was given and there was a slight reticulocyte rise reaching a peak of 4.2 per cent on the sixth day following

operation (see table 1). A rapid recovery in the blood picture was noted (see chart 2) reaching a peak on February 7, 1931. The patient was still weak and unable to walk alone. She was discharged with instructions to continue to take daily the liver extract prepared from 800 gm. of liver. On February 9, 1931, she became quite constipated and developed an attack of vomiting which lasted about twenty-four hours. She returned to the hospital for observation on February 21, 1931, at which time her blood showed 13.4 grams of hemoglobin per 100 cubic centimeters of blood and 3,560,000 red blood cells per cubic millimeter. There was little or no change in the chemical tests of the blood. The Arneth count showed a shift toward normal with an index of 40. She was weak and unable to walk. She was advised to continue to take daily liver extract prepared from 600 gm. of liver. On March 13, 1931, there were 12.7 grams of hemoglobin per 100 cubic centimeters of blood and 3,460,000 red blood cells per cubic millimeter. On several occasions she was troubled with a slight diarrhea. On the whole her general condition grew gradually worse after leaving the hospital. The neurological symptoms showed little or no improvement, although she was able to walk with assistance. The blood picture was not satisfactory but showed some improvement so that the red and white blood cells appeared more normal.

During the months of March and April her health continued to fail. There was progressive weakness in the legs. The numbness and tingling involved both upper and lower extremities and was constant. There was edema of both legs. Her appetite failed. She was troubled much with diarrhea and reported that the liver extract passed through the bowel unchanged. On occasions there was a sensation as though the abdomen were being distended with gas. In May 1931, she was unable to walk without assistance and finally was confined to bed. She developed mental changes, becoming more irritable and having periods during which she would scream almost constantly. On May 17, 1931, she was seen by one of us (W.P.M.), who found the blood pressure 86 mm. of mercury systolic

*Operation was performed by Dr. John Homans of the surgical staff of the Peter Bent Brigham Hospital.

and 55 diastolic. The heart sounds were barely audible and the pulse weak. There was marked edema of the extremities and definite icterus. She was incontinent and unable to move the lower extremities. A

tests were poorly executed. There was definite impaired pain, temperature, vibratory, tactile and position sense in the legs. The reflexes were increased in both arms and markedly exaggerated in both legs. An

CHART II

trophic ulcer was present over the lower back. She entered the hospital for the third time on May 19, 1931. Physical examination showed the sclerae slightly icteric and the mucous membrane pale. The arms and legs were spastic. Hands and fingers were clumsy. Finger to nose, and heel to knee

unsustained patellar and ankle clonus was present. Positive bilateral Babinski and Oppenheim tests were observed with brief patellar and ankle clonus. The hemoglobin was 7.7 grams per 100 c.c. of blood with 1,820,000 red blood cells per cubic millimeter. Intramuscular liver extract was given with a definite reticulocyte response

reaching a peak of 13.7 per cent on the sixth day of treatment.²⁵ The red blood cell count increased approximately two million in the following month. Although the blood made a definite response, the trophic ulcer gradually enlarged in size and depth. A rise in temperature occurred with leukocytosis; she gradually became weaker and died on June 28, 1931.

POSTMORTEM EXAMINATION

A complete necropsy was performed four hours after death on a white woman who was well developed but poorly nourished. She appeared older than her stated age of 56 years. The hair was black, streaked with grey and of normal texture. The eyes were blue, the pupils were unequal, the right measuring 4 mm. and the left 3 mm. in their respective diameters. The left pupil was irregular and eccentrically placed, being above the center of the iris. A decubitus ulcer measuring 8 by 14 cm. in diameter and extending down to the bone was found over the right and left trochanters. Further exploration of the ulceration in the region of the right trochanter revealed a cellulitis extending between the gluteal muscles to the sacrum. The ulceration over the left trochanter was continuous with a cellulitis which extended down the thigh to the prepatellar bursa and also involved this structure. The muscles underlying the needle puncture marks in the left gluteal region showed no evidence of inflammation. On the right side the muscles were involved in the inflammatory process already described. There was marked edema of the left foot and leg. The left femoral and iliac veins were filled by a laminated thrombus. The subcutaneous fat which remained was of a lemon yellow color. The pectoral muscles were atrophied.

The pathological changes in the heart, lungs, spleen, intestines, adrenals and genitourinary organs were irrelevant to her anemic condition other than for a slight fatty degeneration of the heart muscle seen in the interventricular septum and columnae carneae.

The liver weighed 2260 grams, was of a pale yellow-brown color with prominent liver markings. It was softer in consistency

than normal and very fragile. The former gall-bladder bed was well healed.

The pancreas was of normal color and size but was slightly softer than usual.

The stomach was of average size, had a fairly well preserved mucosa which was thrown into the usual folds. The mucosa showed no evidence of atrophy, ulceration, or tumor.

The entire marrow, exposed from the middle of the shaft of the femur to the articular end was of a deep red color and none of the fatty marrow usually seen was apparent.

The cord was of normal size and the meninges were free from exudate. Cross sections of the cord at the time of the post mortem showed no changes which were recognized on gross inspection. The superior longitudinal and the right lateral sinus contained an antemortem thrombus. The meninges were free from exudate. Morbid changes of the brain were found neither before nor after fixation.

The culture made of heart's blood taken from the right auricle contained *Staphylococcus aureus hemolyticus*.

Microscopic Examination. The minor pathological changes which were found in the heart, lungs, kidneys, spleen, adrenal glands, aorta and brain were irrelevant to the anemic condition.

The sections taken from the fundic, cardiac and pyloric areas of the stomach showed a mucosa of average width for these respective areas. The parietal cells were present in large numbers and were well preserved. The sections from the pylorus contained the usual deep mucus-secreting glands. There was no atrophy, ulceration of the mucosa, or evidence of a malignant new growth.

The section of muscle fibers taken from the left gluteal region at the site of liver extract injection showed atrophy but there was no inflammatory reaction and no cellular infiltration.

The liver showed a marked periportal fatty infiltration.

The pancreas showed a replacement of some of the acinar structures by fat cells.

The sections of bone marrow taken from the femur showed a marked replacement of

the fatty marrow by a highly cellular tissue. Many of these cells were identified as belonging to the granulocytic series, although lymphocytes and plasma cells were fairly numerous. There were also immature cells which could not be definitely identified. Mature and immature eosinophiles were numerous among the granulocytic cells. Occasionally a basophile was seen. Megakaryocytes, frequently of small size, were scattered throughout. Scattered among the granulocytic and immature cells were clusters of cells representing erythropoietic centers, most of the cells of which were well differentiated and not of the undifferentiated megaloblastic type seen in pernicious anemia. Occasionally a small amount of brownish pigment was present but nowhere was it abundant. The blood vessels throughout were engorged. The histology of the marrow was consistent with what is seen in the remission period in pernicious anemia or following the response to liver therapy.

Sections were taken from the cervical, dorsal, and lumbar regions of the spinal cord. They all showed marked degeneration of the nerve fibers without extensive cellular reaction or gliosis. The areas of degeneration were not sharply outlined but corresponded with the areas ascribed to the following nerve fascicles, gracilis, cuneatus, dorsal and ventral spinocerebellar, posterior spinothalamic and spinotectal, lateral cerebrospinal and rubrospinal. There was no apparent degeneration of the grey matter of the cord and the ganglion cells were well preserved. There was no inflammatory reaction in the pia arachnoid or dura. The ganglion cells of two dorsal root ganglia were well preserved.

Dr. Schulz' summary of the findings follows.*

The postmortem examination revealed extensive ulcerations of the sacrum with an extension of the cellulitis to the hip, thigh, and prepatellar bursa. Death, at least in part, was due to this condition. The thrombophlebitis and the thrombosis of the superior and lateral sinuses were additional important factors in the causation of death.

*We are indebted to Dr. R. Z. Schulz for permission to record his summary of the postmortem findings.

The anemic condition was rather puzzling. Such possible causes as malignant tumors of epithelial origin, particularly carcinoma of the stomach, sarcomatous tumors and leukemia, could all be ruled out.

The cord changes were those found in pernicious anemia, and these changes may be considered a positive factor in favor of the diagnosis of pernicious anemia. The hyperplastic red blood elements in the bone marrow were of a character consistent with a spontaneous or induced remission in this disease. The absence of another etiological factor to account for the anemia was also circumstantial evidence favoring the diagnosis. The blood changes observed on clinical examination and the response of these to intramuscular liver therapy were characteristic of pernicious anemia.

On the other hand the stomach showed none of the atrophy usually found in pernicious anemia; the acid-secreting cells were numerous and well preserved and the other glandular elements showed no degeneration or atrophy. These findings, together with the presence of free hydrochloric acid reported clinically, constituted the chief factors which were not characteristic of pernicious anemia.

There have, however, been a number of cases of pernicious anemia reported in which hydrochloric acid was present in the stomach and others in which it was absent but reappeared to a slight extent after treatment. The poor response to oral administration of liver extract in this case may have been due to the presence of free hydrochloric acid as suggested by Dr. Christian. Since the etiology of pernicious anemia is at present disputed and since the disease is diagnosed by a combination of symptoms together with the exclusion of known causes of anemia, it is our opinion that this case should be classed with the group of pernicious anemia. Whether it is one of the closely allied conditions cannot be ruled out from the postmortem findings. We, therefore, are recording it under the diagnosis of pernicious anemia.

COMMENT

The case presented is that of a patient with a blood picture and symptoms entirely compatible with a diag-

nosis of pernicious anemia, but with free hydrochloric acid, as well as rennin and pepsin in the gastric contents. A response of the reticulocytes and red blood cells occurred as the result of the ingestion of liver extract similar to that which would be expected in a case of pernicious anemia complicated by disease of the gall-bladder. Subsequently a relapse occurred during a period in which a rather large amount of liver extract was being ingested although, owing to a severe diarrhea, it was probably not being absorbed for use in the formation of blood cells. Dr. Christian has suggested a possible destructive action of the hydrochloric acid of the stomach on the active substance in liver extract. The blood, however, again improved following the intramuscular injection of a liver extract. There is undoubtedly evidence in this case of the retarding influence of complicating factors (gall-bladder disease with liver damage, diverticulo-

sis and diarrhea) in the subnormal response of the reticulocytes to liver therapy, the incomplete response of the red blood cells to a rather large intake of liver extract, and the unsatisfactory course of the disease. Of what etiological significance these same complications are is a matter for speculation.

The possible importance of disease of the gall-bladder or liver in the occurrence of pernicious anemia has been suggested by several observers, notably Lord Dawson of Penn.,²⁶ Harris,²⁷ Jones²⁸ and others. Although Castle and his co-workers have demonstrated the absence in the gastric secretions in pernicious anemia of a substance or function which is present in the normal stomach it would seem possible in view of the inconstancy of the achlorhydria that the disturbances in the biliary system or liver may sometimes be of even more immediate etiological importance than are the gastric changes.

Standardization of Diabetics with Diet and Insulin*

By JOSEPH T. BEARDWOOD, JR., A.B., M.D., F.A.C.P.,
Philadelphia, Pennsylvania

ONE hesitates to use the term "standardization" in relation to the treatment of disease. We rightly should consider each patient as an individual and adapt our treatment accordingly.

In the management of diabetes the term "standardization", however, is used to indicate two necessary steps in treatment. The first is the control of the disease, by which is meant the reduction of the blood sugar to normal levels, with or without insulin, with the patient on a maintenance diet. A diet containing a properly balanced proportion of carbohydrate, protein, and fat, and sufficient total calories to enable the patient to carry on his or her daily activities without loss of weight below a certain predetermined standard.

Of greater importance than the control of the disease is the second step which includes the proper education of these diabetics and their instruction in diet and hygiene, so that they are able properly to care for themselves at home. Unless this is done, the patient is discharged from the hospital faced with the choice of either eating the same meal day after day or of sitting

down to each meal in fear and confusion.

This is by far the most important step in the standardization of these patients, and unless they are satisfactorily educated the temporary control of the situation is valueless, and they return again and again in various stages of decompensation of the insulinogenic system until severe coma or some other preventable complication causes a fatal termination.

The diabetic who is taught diet calculation, a few simple laboratory examinations, and the importance of diabetic hygiene is able to adapt himself to his surroundings and to lead a normal type of life.

The use of a subnormal caloric diet, or the so-called "test diet", has largely been discarded because this involves frequent changes of diet and also of insulin which tend to confuse the patient. These individuals must be discharged on a diet which is adequate calorically for their daily needs. As this can usually be calculated accurately in advance, it is far better to place the patients on this as their initial diet and readjust the insulin dosage to care for it if necessary, rather than to waste time by gradually increasing the diet as the patient's tolerance warrants.

The term "diabetic diet" is a poor

*Presented before the Main Line County Medical Society, Haverford, Pa., March 12, 1932.

one and should be avoided as, with the exception of foods with a very high carbohydrate content, such as sugar, honey, candy, pastry and the like, there are really no foods that a diabetic may not include in his menu if proper allowance is made for the amount of carbohydrate, protein, and fat which they contain.

In constructing the diet of the diabetic there are certain fundamental facts which must be borne in mind.

First, it is generally agreed that the diabetic should have a lower caloric diet than his normal diet. It has been found that a diet which allows 30 calories per kilogram of body weight per day is satisfactory for patients engaged in ordinary occupation. In cases in which the patient must do hard physical labor it may be necessary to increase this to 40 or 45 calories per kilogram of body weight per day, but it has been our experience that these instances are rather infrequent.

Second, it has been shown that 0.7 to 1.0 gram of protein per kilogram of body weight per day is required to maintain a nitrogen balance and 1.0 gram per kilogram is a satisfactory allowance for the average diabetic.

Third, the carbohydrate and fat must be so adjusted that there will be sufficient carbohydrate to completely burn the fatty acid derived from the fat in order to avoid the danger of acidosis from the diet itself. This fortunately can be determined beforehand by the use of Woodyatt and Schaeffer's ketogenic and antiketogenic ratio.

There are three schools of thought in regard to the exact carbohydrate allowance. These are briefly:

(A). *The Low Carbohydrate and*

High Fat Diet. The advocates of this diet claim for it the advantage of requiring a lower insulin dosage. Its theoretical disadvantages are that it gives a very low margin of safety as far as the ketogenic and antiketogenic balance is concerned, and that it tends to produce a lipemia and subsequent arteriosclerosis. There is, moreover, the clinical disadvantage that a diet low in carbohydrate is not a very palatable one for the average person and so its use adds another temptation to break the routine.

(B). *The High Carbohydrate Diet.* In this diet, first advocated by Sansum and his co-workers, the patients are allowed 200 gm. and upward of carbohydrate a day. Indeed their carbohydrate allowance may differ but little from a so-called normal diet. Such a diet has the advantage of being palatable and easy to accommodate to the menu of the rest of the family. It also, by tending to do away with a lipemia, lessens the patient's chances of developing acidosis and arteriosclerosis. It has the distinct disadvantage that larger doses of insulin are required.

(C). *The Moderately High Carbohydrate Diet.* We have found this diet, which is advocated by Joslin and others, to be the most satisfactory. The formula which we have used in most of these cases is:

1½ to 2 grams of carbohydrate per kilogram of body weight per day. 1 gm. of protein per kilogram of body weight per day.

Fat qs. to make 30 calories per kilogram of body weight per day.

This allowance, of course, is based on ideal weight and for the average

individual means a daily allowance of over 100 gm. of carbohydrate per day. The figures given above are for cases in adults.

If, after three to five days on such

and caloric allowance per kilogram, because of the nutritional needs that go with bodily development. The following table¹ we have found useful as a guide in these cases:

TABLE I

Age	2	4	6	8	12
Carbohydrate (per kilogram of body weight per day)	10-12 gm.	7-9 gm.	4-6 gm.	3-5 gm.	2.5-3 gm.
Protein (per kilogram of body weight per day)	4.5 gm.	4 gm.	4 gm.	3 gm.	2.5 gm.
Calories (per kilogram of body weight per day)	90	80	75	65	55

a "maintenance diet", the blood sugar is still above normal, insulin is indicated.

It might not be amiss to consider at this point what a normal blood sugar value should be. It has been shown that elderly diabetics with sclerosis of the coronary arteries do not stand well attempts to depress the blood sugar level too low and frequently develop cardiac symptoms. A safe figure to take as "low normal" is one-half the patient's age plus 100 (expressed in milligrams per 100 c.c. of blood).

Many elderly diabetics past middle life do better if the fasting blood sugar is .014 or .015 per cent.

Diabetes in children is an acute disease. The onset is usually abrupt, the disease severe and the margin of safety between coma and hypoglycemia is small. To compensate for this, however, children seem to stand both coma and hypoglycemia better than adults and may recover promptly from a degree of each which would be fatal to adults.

These little patients, of course, require a larger carbohydrate, protein,

As stated above, if after three to five days on a "maintenance diet" the patient fails to show a marked change towards normal, insulin is indicated.

In a recent series of two hundred cases at the Diabetic Clinic at the Presbyterian Hospital 50 per cent required insulin. In a like number of private patients 46.2 per cent required insulin.

It need scarcely be stated that insulin is for all practical purposes inactive if given by mouth, by rectum, by inunction, by inhalation, by nasal tampon, by duodenal tube, or sublingually, or that there is no substitute which can be given by mouth for insulin.

The exact dose of insulin required in any given case is impossible to foretell and must be arrived at through careful attention to the laboratory findings. It is, of course, safer to adjust the insulin dose by blood sugar determination than by urinalysis.

A method which we have found satisfactory in determining the initial dose is to start with:

10 units a day if blood sugar is below 200
20 units a day if blood sugar is between 200-250

30 units a day if blood sugar is between

250-300

40 units a day if blood sugar is above 300

This scale, of course, must be adjusted according to developments and is no criterion of the final maintenance dose. If one were compelled to state the dose of insulin in any given case the answer would be "enough to control blood sugar."

If only up to 15 units are required, it can be given in one dose before breakfast. If more than 15 units and less than 40 units are required, it can be given in equal doses before breakfast and before dinner at night. If more than 40 units are required, it may be given before each meal, although it is safer to give larger doses before breakfast and supper and a smaller dose before lunch. Frequently it may be necessary to give a fourth dose at midnight and a fifth dose at 3 a.m.

The site of injection, of course, should be varied, and the smallest volume of insulin used, although the U-20 is probably the best strength to use routinely.

There are two types of reactions which are seen with the use of insulin. The first of these is the protein reaction. This may vary from a mild localized reaction to a rather severe generalized urticaria. Protein reactions are comparatively infrequent but they occur often enough for us to be on our guard against them. In many cases they can be avoided by changing the brand of insulin which is used.

The second and more common reaction is the hypoglycemic reaction or insulin shock, which results when the dose of insulin given is too large to be

balanced by the carbohydrate available at the moment in the body.

Insulin reactions usually develop from thirty minutes to three hours after the injection is given, although we sometimes note a delayed reaction occurring six to ten hours after the last administration.

The usual symptoms of insulin shock are inward tremors, hunger, nervousness, sweating, rapid pulse, subnormal temperature, diplopia, amnesia and coma. While these are the usual symptoms, it must be emphasized that any unusual emotional or nervous symptoms developing in a patient taking insulin should be regarded with suspicion. I will cite one instance of this:

This patient was a thin man of about 110 pounds in weight, whose blood pressure was seldom above 115 mm. of mercury, a man whose usual demeanor was mild and who was careful never to offend his friends or neighbors. One night, immediately after dinner, he got up from the table and staggered up the stairs complaining about the furnishings of the house, about his neighbors and bragging about his own importance. Upon reaching his bedroom he began to move the furniture about, displacing many pieces which ordinarily he could not have so much as budged. He became more and more abusive and finally his wife had to call in two of the neighbors to control him. A neighborhood physician was called, who gave him one-quarter grain of morphine, without diminishing his enthusiasm or strength. When I was called to see him he had struggled with these two husky young neighbors until they were practically ex-

hausted. We induced him to drink orange juice and gave him adrenalin by hypodermic. Shortly following this treatment he became rational again and expressed surprise at his former attitude.

Attacks of this type constitute a recognized form of insulin shock, and unless we are on our guard they may be mistaken for hysterical episodes and the treatment be misdirected.

Insulin shock is a condition not to be regarded lightly nor to be induced if it can be avoided. There have been recent reports of patients who have died of coronary attacks as a result of insulin shock. In elderly diabetics, par-

ticularly, every precaution should be taken to prevent the occurrence of all hypoglycemic reactions.

In conclusion, if there is any doubt as to whether a patient is in diabetic coma or is suffering from insulin shock the case should be considered as one of hypoglycemia and glucose should be administered by mouth or vein. If the case should prove to be one of diabetic coma little damage will have been done. If, however, it is one of hypoglycemia a life may have been saved.

Insulin Hypoglycemia*†

Two Cases with Convulsions; One Necropsy Report

By BYRON D. BOWEN, M.D., F.A.C.P., and GILBERT BECK, M.D.,
Buffalo, New York

THE reaction of the body to hypoglycemia, caused by unbuffered insulinism of endogenous or exogenous source, constitutes a recent chapter in medicine. This communication deals chiefly with this response as it occurs in the treatment of diabetes with insulin.

We have divided the insulin reaction into two phases, largely for the sake of convenience of description. The first is characterized by nervousness, perspiration, pallor, tremor, palpitation, weakness, hunger, and a peculiar sense of "goneness". The second indicates a disturbance of the central nervous system and presents a wide variety of symptoms. Of these the most frequently observed are diplopia, paresthesias particularly of the face and tongue, mental confusion, drowsiness, ataxia often simulating that of alcoholic intoxication, a vacuous, staring countenance, amnesia, and coma from which the patient cannot be aroused. Other manifestations less frequently encountered are dysarthria,

mixing of words, strabismus, hemianopia, loss of sphincter control, automatism, crying and singing, negativism, excitement or anger, giddiness, vomiting, garrulity, apraxia, aphasia, hemiparesis, temporary incorrigibility, behavior defects, tonic and clonic spasms of the extremities, opisthotonos and epileptiform convulsions. Many variations and combinations of these may occur in a reaction. The manifestations do not appear in any fixed type of sequence; nor does any one patient always exhibit the same type of reaction. The usual prodromal symptoms of the first phase may apparently be absent in some cases, or at least they are so brief in duration as to escape the attention of the patient. People accustomed to being about patients who are taking insulin can, however, often detect the characteristic countenance or behavior before the patient himself is aware of his state.

We present résumés of the following illustrative cases.

(1) A school teacher took her usual dose of insulin but did not eat her regular breakfast because she was not at home. While standing before her class she suddenly lost equilibrium, pitched forward, and was later admitted to hospital with a gash over one eye.

(2) A man, who had been taking insulin without trouble for three years, went to an

*Presented in abstract form before the Section of Medicine, New York State Medical Society, Buffalo, New York, May 25, 1932.

†From The Buffalo General Hospital and School of Medicine, The University of Buffalo.

entertainment at his club. He took his regular dose of insulin, 18 units, just before departing from home. The dinner was delayed for over an hour and he did not care to ask for food. During the first course he felt giddy, collapsed and vomited several times. He was quite confused when admitted to hospital. There he behaved queerly, became very intimate and called one of us, with whom contact had always been formal, by his first name.

(3) A woman, who had been under treatment for nine years, usually knew when a reaction was coming on, yet could not bring herself to take the sugar which she always kept in her handbag. She was once taken to the police station on the charge of intoxication.

(4) A young man took his usual dose of insulin in the early morning and returned to bed. As it was Sunday the family slept late. He was found later in a convulsive state, but he promptly responded to glucose given intravenously.

(5) A man of thirty took his usual dose of insulin and his breakfast, shoveled considerable snow, and went to his business. At 1 p.m. he was found asleep by the police in his parked automobile. He was carried to a doctor's office in a state of coma and was given glucose intravenously. This immediately brought him out of the coma. He remembered nothing for at least an hour previous to this experience. Later he recalled that he was driving his automobile about four miles distant from the place where he was found, but he could recollect nothing which had occurred between that time and his recovery. He apparently drove this distance successfully while in an "automatic" state, resembling a fugue.

(6) A woman of sixty-two, who had been under insulin treatment for eight years, developed headache, difficulty of speech, and vomiting soon after breakfast. Six months prior to the present attack, she had had a right sided hemiplegia which had left but little residual damage. In the present attack coma followed closely after the symptoms which have been described, and when she was seen thirty minutes after the onset she was completely unconscious, with stertorous breathing and a sharp deviation of

the eyes to the left. The pupils were not dilated. Her blood pressure was lower than usual, 150 mm. of mercury systolic and 80 mm. diastolic. Unfortunately, a blood sugar determination could not be made. Ten grams of glucose in a 50 per cent solution were administered intravenously. Fifteen minutes later there was no change in her condition. However, within the next hour she gradually regained consciousness; occasionally she awoke momentarily and stared at those in the room. Two hours later she was normal again and able to take food. Then it was discovered that she had fever and a "grippe" infection, which had probably been the cause of the vomiting attack. Hypoglycemia was the probable cause of her symptoms. The family stated that she ate candy during the premonitory stage, but the patient had no recollection of anything from breakfast to lunch time.

In the insulin treatment of diabetes it is often necessary to give rather large doses in order to keep the patient's urine reasonably free from sugar. It is often a most difficult problem to achieve this in a patient in whom the diabetes is severe. Variations in the concentration of blood sugar are marked during the twenty-four hours, and the administration of insulin must be so planned as to counterbalance them. Since an attempt is always made to return even a severe diabetic patient to his normal position in society, it is often impossible for him to keep either on a perfectly standardized program or to keep the level of his physical exercise constant. Unusual muscular activity is one of the most common causes of insulin reactions. Hypoglycemia occurs very frequently on Sundays or holidays, when a patient's usual program is interfered with by the irregularity of meals and exercise.

Fatal Cases of Insulin Hypoglyce-

mia. Considering the above mentioned difficulties and the alarming symptoms which may be produced by insulin, it is rather interesting that so few reports of fatal cases have appeared in the literature.

JOSLIN¹ reports the following four cases that have come to his attention:

(1) A woman of 51 with gangrene and sepsis, who was seen in consultation, had received 240 units of insulin daily. She was unconscious and her blood sugar was 15 mgs. per 100 c.c. Glucose brought her out of coma twice, but she later succumbed. Insulin might have been but a secondary cause of death in her case.

(2) A woman, who apparently became alarmed at her symptoms, injected 122 units of insulin on her own responsibility during one night. She died in spite of glucose injected intravenously and subcutaneously.

(3) A man of 20, who had been living quite carelessly, took large doses of insulin to counteract his dietary indiscretions. He became comatose rather suddenly one evening and was given 60 units of insulin during the night. In the morning his blood sugar was too low to read. He died about fifteen hours after the inception of symptoms.

(4)² A girl of 14 ate less than her usual meal one evening. At 2 a.m. she was found in a convulsive state. During the succeeding fifteen hours, 300 units of insulin were administered. She died a day later in a state of tetanic convulsions.

HEIMANN-TROSJEN AND HIRSCH-KAUFFMANN³: A girl of eight, whose diabetes was severe and difficult to control, was admitted to hospital with convulsions. She was taking 56 units of insulin daily. Her blood sugar on admission was 20 mgs. per 100 c.c. The convulsions temporarily disappeared following the intravenous injection of two grams of glucose. Later on the same amount of glucose failed to relieve them. She was unconscious for twelve hours before death occurred. During this period convulsions occurred frequently. Glucose (107 grams) was given intravenously, intraperitoneally, and by gavage. The greater part of the glucose, however, was administered after the convulsions had been recurring for at

least six hours. The blood sugar, when taken an hour after a glucose injection and two hours before death, was 52 mgs. per 100 c.c. The necropsy, forty-eight hours post mortem, showed status thymico lymphaticus, enlarged Peyer's patches, colloid goiter, an adenoma of the cortex of the adrenals, and cysts of the ovaries. The central nervous system was not examined.

CAMPBELL AND MACLEOD⁴: (1) A habitual drunkard, who was refused insulin at the Toronto General Hospital, was treated elsewhere. He took his usual morning insulin, 30 units, but not feeling inclined to eat he proceeded with his day's activities. About midday he collapsed and was taken to hospital. Upon admission he was cyanosed, had edema of the lungs, and died before glucose could be administered. There was no necropsy, so the exact nature of his death was unknown, although hypoglycemia seemed a likely cause.

(2) A patient, whose insulin dosage was 40 units, had a gastrointestinal upset and took an additional 10 units of insulin. Shortly after, she recognized symptoms of hypoglycemia, took orange juice, and summoned her physician. He advised that more antidote be taken, but the suggestion was unheeded. The patient died in collapse shortly after.

PEMBERTON⁵: The patient had tuberculosis and diabetes. In the first attack of hypoglycemia there was muscular rigidity, opisthotonos and vomiting, which lasted five minutes. The second attack was ushered in by a period of physical and mental excitement, which was followed by muscular flaccidity and a semicomatose state. The eye balls showed pendulous movements. The corneal and abdominal reflexes were absent. There was a bilateral ankle clonus and Babinski response. The patient died a few moments later. Necropsy done the following day showed caseous pulmonary tuberculosis and fibrosis of the pancreas. The brain was described as being definitely wet.

MEMBREZ AND RAZDOLSKY⁶ (Non-diabetic patients who were given insulin and glucose):

(1) A very emaciated man of 50 years was admitted to the surgical service. He was given 40 grams of glucose intravenously and 0.5 c.c. of insulin (units not stated). The

following morning he received a blood transfusion of 500 c.c. and on that evening 40 grams of glucose intravenously and 1 c.c. of insulin. One and one-half hours later he felt chilly, became pale and later had fever. He was very weak, had a small pulse, perspired, and developed tonic spasms of the hands. Coma soon occurred. He was given injections of camphor, digitalis, and epinephrine, which brought no improvement. The next day his condition was considered grave. He was given 1,000 c.c. of salt solution intravenously and another blood transfusion of 500 c.c. Examination at this time showed his pupils to be dilated and his eyes staring. The knee jerks were active; a double Babinski response was present, the left being more active than the right. The right abdominal reflex was greater than the left. There was rigidity of the neck and of the muscles of the extremities. The spinal fluid, obtained by cisterna puncture, was clear and came out in drops. Sugar in the spinal fluid was 78 mgs. and the blood sugar 178 mgs. (It is not stated whether these tests were simultaneous, but they were done on the same day, four days after the insulin was injected.) The following day the patient was conscious and would raise his hands after commands. There was still some muscular rigidity and there was incontinence of the bladder. Since he did not improve, he was given 0.5 c.c. of insulin without glucose the following day. In two hours the patient was again comatose, but had no convulsions. He died in a short time of cardiac failure.

Necropsy Report. Acino-nodular and ulcero-fibrotic pulmonary tuberculosis; passive congestion of the liver, spleen, kidneys, meninges and spinal cord; hyperemia and edema of the meninges.

(2) A woman of 50 was admitted to the surgical service because of symptoms of intestinal obstruction. At operation a tumor of the intestine was found and an entero-anastomosis was done. She was in good condition on the fifth day following operation. Five hundred c.c. of a 10 per cent solution of glucose intravenously and 0.5 c.c. of insulin were given. That night she developed tonic contractions of the fingers, her jaws were set, eyes were turned to the right and upward, and the pupils did not react to light.

There was rigidity of the neck and other muscles. The tendon reflexes of the upper extremities were increased and those of the lower extremities diminished. The protective reflexes were absent. Coma followed. She was given 500 c.c. of glucose solution subcutaneously. Later on she became conscious, but remained very weak. The next day the pupils were equal, speech was slow and weak. A positive Oppenheim response was present on the left. The following day she received 600 c.c. of glucose solution subcutaneously and 0.5 c.c. of insulin. Her condition remained satisfactory for the next week, when nausea and vomiting appeared. She was then given 500 c.c. of 10 per cent solution of glucose intravenously and 0.5 c.c. of insulin. Three hours later she became very weak and had cramps in the hands; in six hours she was unconscious, perspired profusely and died the following morning of gradually increasing heart failure.

Necropsy Report. A well-built woman. Carcinoma and stricture of the intestine; metastases in the ovaries and omentum; edema of the brain.

WHITE AND SMITH[†]:* A boy of eight, who had been diabetic for four years, had been taking insulin for three years. In July 1930, he developed whooping cough. The insulin dosage had to be increased from 9 to 34 units daily. On August 17 a mild insulin reaction occurred, so the insulin was reduced to 28 units. On the evening of August 21 he was awakened by a paroxysm of cough. He cried out and complained that he was unable to see. The blood sugar was not taken, although an insulin reaction was suspected. He was immediately given, by mouth, 120 grams of orange juice and 10 grams of glucose, but restlessness and noisiness continued. One hour later he vomited. Throughout the night, glucose by mouth was given at frequent intervals and he received two injections of epinephrine 1-1,000 (0.3 c.c.). The symptoms did not change. He vomited again and by morning he was irrational. At 8 a.m. he was restless, his eyes were wide open and his face was ex-

*Drs. Priscilla White and Bernard Smith kindly furnished us with the data of this case.

pressionless. He did not seem to comprehend. The rectal temperature was 105.0° F. He was then given 10 grams of glucose intravenously. The blood sugar at 10 a.m. was 250 mgs. He received 10 grams of glucose intravenously again, and at 11 a.m. the blood sugar was 580 mgs. Insulin, 12 units, was given upon the receipt of this report. Physical examination showed no abnormal neurological signs. The temperature remained high and the clinical state did not change. At 7 p.m. the spinal fluid showed some increase in pressure, but was clear and showed no increase of cells. At 9 p.m. he had mild convulsive twitchings. His blood sugar was 110 mgs. Ten grams of glucose were again given intravenously. The following day examination by a neurologist showed only an overfilling and pulsation of the retinal veins, an absence of the knee and ankle jerks, and a questionable right Babinski response. In the opinion of the examiner the condition resembled cerebral edema more closely than anything else. That evening he had a convulsion lasting one and one-half minutes; his body was rigid, the head was retracted, eyes were open, the hands were clenched and he foamed at the mouth. Another shorter convulsion came on during the night. The temperature continued high, 104.0°-105.0° F. At 11:30 the next morning he had a series of convulsions, one every 10-15 minutes. They started in the right arm; the mouth and eyes were drawn to the left. At 12:30 the convulsions were occurring every 2-5 minutes, but became less frequent before death, which occurred at 2:55 p.m.

Necropsy Report. "The brain shows marked thickening of the arachnoid and dilation of the arachnoidal vessels. There are scattered foci of degeneration with edema, scattered lymphocytes and oligodendroglia. In many places there is marked ependymal edema, and in rare foci dislodgement of the ependyma. In one of these foci there is a slight amount of pigmentation."

ALLAN AND WILDER⁸: A child of four received 95 units of insulin over a period of fifteen hours because of diabetic coma. The child retained consciousness, sat up in bed,

later became unconscious. Twenty units insulin were given but unconsciousness

continued. Six and one-half hours later hypoglycemia was suspected. Glucose intravenously, subcutaneously, and by rectum was administered immediately, but death occurred soon afterwards.

ROSENDAHL⁹: A severely emaciated diabetic patient with bilateral pulmonary tuberculosis. The first attack came on following two units of insulin, but subsequent attacks appeared after insulin was discontinued, in spite of increasing the diet. The patient was hypoglycemic at the time of death.

Necropsy Report. A completely sclerotic pancreas with calculi in the ducts. No island tissue was found. The liver showed a slight cirrhosis. The brain was not sectioned.

WOHLWILL¹⁰: (1) A woman of 62, who had been diabetic for at least two years, was admitted to hospital with an abscess of the breast, which had developed within three days. During this period she had received 100 units of insulin daily. Upon admission she was in deep coma, and also presented weakness of the left lower face. The diagnosis at first was a cerebral accident, but later this was changed to hyperinsulinism. She expired on the fourth day after admission.

Necropsy Report. The pancreas contained a considerable amount of fat. Cystopyelonephritis and mastitis were found. The brain was dry and brittle; otherwise, no pathological changes were discovered in the central nervous system. The facial weakness could not be accounted for.

(2) A woman of 29, who was known to have had diabetes for fifteen months, was admitted to hospital in typical diabetic coma. On the first day 135 units of insulin were given; on the second day, 70 units, and on each of the third and fourth days, 90 units. Consciousness returned on the fourth day, but she was completely disoriented. The breathing continued to be labored and the breath was described as uremic. Under treatment the blood sugar dropped from 462 mgs. to 65 mgs. and the glycosuria completely disappeared. The mode of death was not mentioned in the author's report.

Necropsy Report. Typical glycogenic degeneration of the kidneys. Extensive pulmonary emphysema. The brain was described as dry, but not as brittle as in the first case.

There was a generalized ganglion cell change which resembled the severe degenerative change of Nissl. There was a marked reaction of the glia, varying from a disappearance to a pyknotic change in the nuclei and the loss of the staining affinity of the processes of these cells. Many ameboid glia cells were scattered throughout the nervous tissue. In a few areas an unusual change in the axis cylinders was seen. This consisted in a swelling of the fiber and a dulling of its staining quality. The author questions whether this change might not have occurred after death.

COMMENT

We have included these two cases in this report because they were listed by Wohlwill as caused by insulin overdosage. The clinical data of both cases are incomplete, but the first obviously was complicated by a pyemic process and the second might have had concomitant uremia.

Early in the insulin era it was soon learned that emaciated diabetics, who were then so common, were sensitive to even small doses of insulin. Wood-yatt¹¹ mentions the development of hypoglycemic convulsions in such a patient who was receiving a diet and calculated doses of insulin. The blood sugar was too low to read. The patient died in coma in spite of restored glycemia and glycosuria. Williams¹² had a similar experience with one patient. He has kindly written us that he knows of two other patients in his vicinity who have succumbed to insulin hypoglycemia.

Gammon and Tenery¹³ have recently reviewed the subject of spontaneous hypoglycemia. Of the twenty cases classified as hyperinsulinism, due to adenoma or carcinoma of the islands of Langerhans, five have died. The following patients were necropsied:

THALHIMER AND MURPHY¹⁴: Carcinoma of the islands of Langerhans. The patient had frequently recurring convulsions followed by coma. Death occurred while the patient was in coma. *Necropsy Report*. The leptomeninges and the convexity of the brain showed slight or moderate swelling and moderate congestion of the vessels. Careful section of the brain showed no other abnormality.

MCCLENAHAN AND NORRIS¹⁵: The patient died in hypoglycemic coma in spite of large amounts of glucose which did not effectively raise the blood sugar. *Necropsy Report*. An adenoma of the islands of Langerhans. The brain showed perivascular round cell accumulations.

NADLER AND WOLFER¹⁶: Extensive primary carcinoma of the liver was found. Glucose was withheld at the final attack, at which time the blood sugar reached 13 mgs. per 100 c.c. Cheyne-Stokes respirations appeared and death occurred in coma two and one-half hours after the inception of the attack. This patient had had many attacks and his blood sugar had been very low, but convulsions had never occurred. *Necropsy Report*. (Dr. F. D. Gunn) The brain showed no macroscopic edema.

CASE REPORTS

Case I. F.W., a restaurant owner, aged 32. In February 1930, he was first admitted to hospital in diabetic coma. He had had diabetic symptoms for a month prior to this admission. He was discharged in two weeks on a diet of 1700 calories and 100 units of insulin daily. He was seen but once after his discharge, when he was given an increase of diet and advised to reduce his insulin gradually.

On June 1 we were summoned to his home in the country because he was again in coma. It was learned that he had been drinking heavily. The evening before he had complained of dizziness and nausea. Nevertheless, he had taken his evening dose of insulin and had gone to his room; it was not determined whether the evening meal had been taken. Later he was found in a semicomatose state, breathing slowly and perspiring heavily. He was given 30 units of insulin but no food. At midnight he was given 20 additional units, as his friend stated that he

was getting restless. Shortly afterwards he lapsed into unconsciousness. He had a convulsion during the early morning hours. When one of us (B.D.B.) saw him at 9 a.m. he was very restless, excited, and incorrigible. It was necessary for his attendants to restrain him. It was estimated that he had received from 70 to 100 units of insulin since the night before and that no food had been given. He was given 20 grams of glucose intravenously without change in his clinical condition. A half hour later his blood sugar was taken, which proved to contain 98 mgs. per 100 c.c. Then 30 additional grams of glucose were given intravenously. At twelve o'clock the ambulance doctor gave him 20 additional grams. As soon as he was admitted to hospital he received 20 more, at which time he showed some signs of waking up when stimulated. Further attempts to give glucose intravenously were unsuccessful, because he was unmanageable. The following note was made in the afternoon. "The patient is very much confused, but not delirious. His remarks are stereotyped, often short phrases which are repeated frequently. He lapses into sleep after being aroused. The neurological examination is negative." At 9 p.m. he was again given 20 grams of glucose intravenously. He then was beginning to take some fluid by mouth. His blood sugar, one-half hour later, was 308 mgs. per 100 c.c. His bladder was extremely distended and it was necessary to catheterize him. It required three men to hold him down during this procedure. He was then given 10 units of insulin every three hours, followed by 200 c.c. of orange juice by mouth. The following morning his mentality seemed clearer and his comprehension better. His blood sugar was 222 mgs. per 100 c.c. It was necessary to continue the glucose intravenously because it was impossible to get him to take the orange juice. By evening he recognized some of his friends. On the morning of June 3 he was mentally clear, but slow. He was able to take food. It was then learned from friends that in August 1929, before the onset of diabetic symptoms, he had an attack of repeated epileptiform convulsions, which came on while driving an automobile and while on his feet. He had been drinking

heavily before the present attack. He was discharged on June 6, at which time his mental condition, as far as memory, insight, and judgment were concerned, was good. His neurological examination remained negative.

Comment. Alcoholic intoxication did not seem to account for his reaction. It seems probable, on the other hand, that because of the large amount of insulin which he had had and the extreme rarity of true epilepsy in the diabetic, his symptoms were related largely to hypoglycemia.

Case II. E.D., a boy of 16, who had been under our observation since a few weeks following the inception of diabetes three years before, was brought to hospital March 21, 1931, in "status epilepticus". He had been a faithful patient and had visited the out-patient clinic two weeks previously, when it was found that his blood sugar was 54 mgs. per 100 c.c. at noon. His insulin dosage was then decreased from 32 units daily to 28; his diet was unaltered—135 grams of carbohydrate, 60 grams of protein, and 140 grams of fat. He had had no insulin reactions recently. Both of the patient's parents were deaf and dumb, but he was normal in all respects and got along very well at school. It was learned that on March 20 he roller-skated from 8 to 10 p.m., during which time he fell on his left shoulder and side of his face, producing only a minor skin abrasion on his forehead. Upon arrival home his arms and jaws twitched. The parents thought that diabetic coma was impending and gave him 36 units of insulin. He continued to twitch in his sleep all night, vomited a few times, and refused food. Because he was not improved by morning 18 units of insulin were given at 8 a.m. and repeated at 10 a.m. He had about six convulsions during the day and, according to the father's statement, was a "little unconscious". During a period of two hours after admission he had a series of about fifty major convulsions with the following sequence: cessation of breathing, cyanosis, turning of eyes to the left with nystagmus, wrinkling of forehead, twitching of the right side of face, tongue moving in and out, rigidity of

arms with hands forcibly adducted at the wrists, rigidity and extension of the legs, flaccidity and occasional clonic spasms of the entire body. In the short interim between attacks he remained totally unconscious. His blood sugar on admission was 43 mgs. He was given 170 c.c. of a 50 per cent solution of glucose intravenously during the first four hours after admission, but the convulsions did not cease until sodium luminal 0.12 grain was given intravenously. His blood sugar an hour after the last injection of glucose was 46 mgs. per 100 c.c. Glucose intravenously was continued at intervals all through the night. Total night amount, 110 c.c. of 50 per cent solution. There was occasional emesis, but consciousness was not regained. Spinal fluids, obtained on the evening of admission and the next morning, were tinged with blood; they were not under pressure. The glucose content of the first fluid was 80 mgs. and of the second, 111 mgs. per 100 c.c. The chloride content of the second was 816 mgs. per 100 c.c. The record of the temperature, pulse, respiration, and blood pressure are shown on the accompanying chart. The day after admission the red cells were 4,300,000 per cu. mm., hemoglobin, 70 per cent, leukocytes, 12,000, with 81 per cent of polymorphonuclears. On March 22 he had two convulsions fifteen minutes apart. Sequence: dilatation of the pupils, turning of the eyes to the left, severe twitching of the right face, twitching of the left thumb and the left arm, elevation of the left arm to a right-angled position and, finally, a sharp contraction of both pupils to pin point size. During the following three days he showed no signs of regaining consciousness. His temperature, pulse rate, and respiration rate rose. On March 23 signs suggesting meningeal "irritation" developed—questionably positive Kernig and Brudzinski signs, but no rigidity of the neck. There was an absence of the deep reflexes as well as of the plantar responses. On March 24 two cisterna and two lumbar punctures were done; very little spinal fluid could be obtained and that was again slightly bloody (traumatic?). Insulin, glucose and physiological saline solution subcutaneously were kept up during March 22, 23, and 24. He died on March 25.

Necropsy. (Dr. Kornel Terplan)*

General. The body is that of a slender, well-developed boy of 16 with very little adipose tissue. There are small excoriations of the skin on the right temple and the right occipital region. Upon examination underneath these abrasions no hemorrhage or alteration of tissue is found. There is no fracture of the skull or injury to the dura mater.

Brain. The pachymeninges above the cerebrum are markedly distended. The brain is pressed closely to them and shows a very extensive degree of swelling. The veins in the leptomeninges are distinctly injected. The sulci are entirely obscured and the gyri greatly enlarged and flattened. The brain is heavy—weight, 1535 grams. On cross section there is a very marked hyperemia and extensive edema in all parts of the cerebrum and cerebellum. The tonsils of the latter are, also, distinctly swollen. The cerebellar leptomeninges, in the posterior part of the tuber vermis, show a small intrameningeal suffusion. The ventricles are distinctly diminished in size, being compressed by the swollen brain substance. They contain almost no spinal fluid.

Spinal Cord. There are free hemorrhages on the posterior aspect of the pachymeninges in the fat tissue, but no free hematoma. The pachymeninges and cord are both distended and closely attached. There are small subdural hemorrhages along the spinal cord (cisterna puncture). The leptomeninges show no distinct sign of fresh hemorrhage. Sections of the spinal cord reveal a very marked edema. The leptomeninges are distinctly injected.

Spinal Fluid. (Cisterna puncture). Very small amount, blood tinged. Chloride content, 845 mgs. per 100 c.c.

Heart and Aorta. Normal size. There is a very slight fatty change in the intima of the ascending aorta and in the branches of the left coronary artery.

Pancreas. Rather narrow and small. Weight, 34 grams. Shows distinct hyperemia.

Suprarenals. Very large, showing considerable amount of lipoid in the cortex.

*To be reported elsewhere in more detail, together with the histologic findings.

THE NATURE OF THE HYPOGLYCEMIC REACTION

A low blood sugar is the usual accompaniment of the insulin reaction both clinically and experimentally, although good clinical observers have reported similar reactions in patients receiving insulin which have occurred

at a time when the blood sugar was well above the hypoglycemic level. John¹⁷ found hypoglycemia in only 54 per cent of his patients during reactions. The remainder had either normal blood sugar levels or hyperglycemia. In our experience an unequivocal reaction has never been observed in

the absence of hypoglycemia. On the other hand, we have frequently observed blood sugar readings below 60 mgs. without symptoms; one obese youth had a blood sugar of 26 mgs., yet had no complaints. Macleod¹⁸ observed an asymptomatic hypoglycemia in animals that had previously been well fed.

The similarity between the early symptoms of the insulin reaction and the epinephrine reaction was commented upon by several workers, but it was not until Cannon¹⁹ and his co-workers brought forth physiological evidence of an epinephrine discharge during hypoglycemia that this relationship was clearly established. Cannon showed that cardiac acceleration of the denervated hearts of animals occurred coincidentally with insulin hypoglycemia and that the cardiac rate fell promptly after the administration of glucose. This acceleration did not occur in the denervated hearts of the suprarenalectomized animals. Other evidences of epinephrine discharge during hypoglycemia are contained in the work of Abe, Houssay et al, and of Kahn.²⁰ The following symptoms, pallor, sweating, tachycardia and dilatation of the pupils, are evidence of a discharge of sympathetic impulses which is produced by epinephrine action. Cannon¹⁹ believes that this discharge is a protective mechanism which attempts to compensate for hypoglycemia by mobilizing glycogen from the liver.

The second phase of the reaction is of greater moment. The symptoms point to a disturbance of the central nervous system and often are of a nature indicating a focal disorder. The

nature of this mechanism is not understood. The Toronto physiologists early observed that the venous blood of hypoglycemic animals seemed darker than normal, which suggested that anoxemia might be the cause of the symptoms since convulsions are known to occur in asphyxia. Olmsted and Taylor²¹ investigated this phase of the problem, but found only a slight fall of the oxygen saturation of the arterial blood in dogs preceding insulin convulsions. They, moreover, were not able to duplicate these results in rabbits.

In our fatal case an extreme edema of the brain and spinal cord was found. Four of the six reported necropsies on patients who had died of hypoglycemia showed some degree of cerebral edema, though, judging from the reports, this was much less extensive than the edema found in our patient. Schereschewsky, Mogilnitzky and Gorjaewa²² seem to be the only ones who have made anatomical observations of the central nervous system in animals with induced hypoglycemia. They report hyperemia, edema, and hemorrhages of the brain in dogs that had received huge doses of insulin.

These findings suggest that hypoglycemia may be accompanied by a disturbance of the water or of the electrolyte balance. In this connection other observations offer some support to such a relationship. Olmsted and Taylor²¹ found that the oxygen capacity of the blood in decapitated and decerebrated cats indicated that the blood was most concentrated at the time when the blood sugar reached its lowest level. Rathery and Sigwald²³ studied the effect of insulin hypogly-

cemia in twelve dogs. They report a constant elevation of the plasma chlorides and a decrease in the spinal fluid pressure. Drabkin and Shilkret²⁴ found that convulsions did not occur in dogs that were made hypoglycemic by the injection of large doses of insulin if they had previously been dehydrated by water deprivation for several days. They, also, report that insulin increased the existing anhydremia. Drabkin and Ravdin²⁵ observed that the cerebrospinal fluid pressure of hydrated dogs that had received large doses of insulin, rose as the blood sugar fell and as the blood became concentrated. The intravenous administration of a hypertonic solution of sodium arabinatę to hydrated dogs, during a period when severe insulin convulsions were present, resulted in a temporary return of the concentration of the blood toward normal. The convulsions disappeared temporarily (30-45 minutes) even though severe hypoglycemia remained. They suggest that the mechanism in the production of convulsions proceeds in the following cycle: hypoglycemia→anhydremia→rise in cerebrospinal fluid pressure→convulsions. They removed both stellate ganglia from three hydrated dogs. In these, insulin failed to produce convulsions and hypoglycemia was appreciably delayed and its magnitude reduced. Also, neither anhydremia nor rise in the spinal fluid pressure occurred in these dogs. McQuarrie and Peeler²⁶ observed that convulsions may be induced in epileptic children by hydration produced by the ingestion of water and the injection of pitressin. This offers further evidence that cerebral hydration is a factor in the cause of

convulsions. Weir, Larson and Rowntree²⁷ injected pituitrin in antidiuretic doses and simultaneously gave large amounts of water, 50 c.c. per kilogram per hour, by stomach tube to dogs. The symptoms which followed—asthenia, restlessness, diarrhea, nausea and vomiting, tremor, salivation, twitchings of the muscles, ataxia, tonic and clonic convulsions, and stupor or coma—are largely referable to disturbance of the central nervous system. This disturbance is possibly hydration.

Olmsted and Logan²⁸ found that typical insulin convulsions could be induced in decerebrated cats, but not in decapitated cats, even though in the latter the blood sugar was maintained at a hypoglycemic level. In hypophysectomized-decerebrated cats the blood sugar fell rather rapidly after insulin, and convulsions ensued promptly; while in decerebrated cats, whose hypophysis was left intact, the blood sugar was found to be more resistant to the action of insulin. Cannon²⁹ has suggested that this effect is caused by an injury to the hypothalamic region which is produced by the operation of low-decerebration. Houssay and Bissotti,³⁰ however, have also called attention to the extreme sensitivity of hypophyseoprival dogs to insulin. Such animals, receiving doses of insulin that had no effect on control animals, died from hypoglycemia. Spontaneous hypoglycemia crises also occurred in these dogs. Olmsted and Taylor³¹ showed that typical hypoglycemic convulsions could be produced in decapitated cats by actively induced respirations and that these animals would have violent convulsions following the slightest stim-

ulus. This irritability disappeared after the injection of glucose. It would seem, then, that the factor responsible for the convulsions which are associated with hypoglycemia may act on the spinal cord as well as the mid-brain.

The more pronounced symptoms of the insulin reaction, which we have spoken of as the second phase, indicate a disturbance of the central nervous system. This disturbance is associated with a hypoglycemia and it seems evident that it is caused either by the hypoglycemia or by secondary changes, possibly physico-chemical in nature, which accompany it. The use of glucose intravenously in patients showing this phase of the reaction acts specifically and promptly if the symptoms have been of short duration. The fatal case that we are reporting and a number of those contained in the literature, demonstrate that the reaction within the nervous system may go to a point which is not reversible by the intravenous administration of glucose.

Lennox³¹ determined the fasting respiratory quotients of the brain, arm and leg by means of analyses of the O_2 and CO_2 contents of the regional arterial and venous blood. The average quotient for the brain was 0.95, for the arm, 0.86, and for the leg, 0.72. He also found that the difference in the venous and arterial blood sugar paralleled the respiratory quotients. These studies, in his opinion, suggest that the disappearance of glucose from the blood is greater in its passage through the brain than through the extremities. Myerson and Halloran³² made a similar study on psychotic patients with identical results. It would

appear from these observations that the brain required glucose in its metabolism to a greater extent than other tissues.

The retardation of an appreciable rise of the blood sugar after the intravenous administration of glucose in patients who had previously received large doses of insulin, strongly suggests that there is a mechanism of insulin storage in the body. Our two cases as well as others reported in the literature would seem to demonstrate such a protective phenomenon.

SUMMARY

We have been able to collect twenty fatal cases of hypoglycemia produced by the artificial injection of insulin. This number includes our own case and nineteen which we have found in the literature.

The cases of two diabetic patients with insulin hypoglycemia, which had been produced by the erroneous administration of large doses of insulin, have been reported. Both manifested symptoms referable to the central nervous system. The fatal case showed an extreme edema of the brain and spinal cord and a very small amount of spinal fluid at necropsy.

Suggestive evidence that the cerebral symptoms of the hypoglycemic reaction are caused by or related to a hydration of the central nervous system has been collated.

The mechanism of the relationship of this possible hydration to hypoglycemia is not understood.

Changes in the central nervous system, which are related primarily to hypoglycemia, may be irreversible if the restoration of normal or hyperglycemia is delayed. Patients manifesting

cerebral symptoms of an insulin reaction, in our opinion, are better treated by the prompt use of glucose intravenously rather than by the less dependable method of the use of carbohydrate orally.

The behavior of the blood sugar after the intravenous administration of glucose to patients who have received large doses of insulin, suggests that there is a mechanism of insulin storage in the body.

The Incidence of Tuberculosis in Diabetes*†

By LOUIS I. KRAMER, M.D., and HERMAN A. LAWSON, M.D.,
Providence, Rhode Island

THE patient with diabetes who attempts to give himself the best care is surrounded by restrictions and must always exercise considerable self-denial. He must be scrupulous in the care of his feet and regard seriously any skin infection no matter how trivial it may seem. He must exercise the greatest care to avoid contracting the ordinary acute infections, such as the common cold, grippe, and gastroenteritis. If he is intelligent his happiness is clouded by the fear of premature arteriosclerosis with all of its sad complications, such as retinitis, coronary disease, gangrene, etc. In the list of dangers which may threaten the diabetic must be included pulmonary tuberculosis inasmuch as some writers find evidence that the diabetic may be unduly susceptible to this disease.

Joslin,¹ in his textbook, states that in his experience tuberculosis in diabetics seldom occurs in private practice today. Charles Montgomery² believes that there is no conclusive proof that tuberculosis is more common in diabetics than in the rest of the population of like age period. Boswell³ states that he too finds no greater incidence of tuberculosis among diabetics than among non-diabetics of like age period.

J. H. Musser, Jr.⁴ states: "This combination of disease is rather unusual as tuberculosis is not more frequent in the diabetic than in the normal individual".

There are others, however, who do not hold to this comforting opinion. Griesinger⁵ more than 70 years ago reported 250 cases of diabetes with 42 per cent showing tuberculosis. Windle⁶ found 50 per cent of 327 cases to have died of tuberculosis. Fitz⁷ quotes Copeland and Bardsley in the early nineteenth century to the effect "that tuberculosis occurred so frequently in diabetics as to be a sign of this disease". These statistics and opinions, of course, are influenced by the much greater frequency of tuberculosis in the general population at that time and also by the poor treatment which was given to diabetics at that time. Fitz and Murphy⁸ in 37 cases of diabetes examined postmortem found pulmonary tuberculosis to have been the cause of death in 19 per cent. Perhaps the most discouraging experience has been that reported by Sosman and Steidl⁹ in 1927. These workers made 261 separate roentgen-ray examinations of the chest in 182 consecutive cases of diabetes. These examinations revealed tuberculosis in 9 per cent of the cases. This was not, however, the usual apical type of tuberculosis but was of

*Received for publication October 22, 1932.

†From Diabetic Clinic, Medical Dept., Rhode Island Hospital.

such a characteristic appearance that at the Peter Bent Brigham Hospital it is spoken of as "diabetic tuberculosis". "It is bronchopneumonic in type, usually around the hila and deep in the lungs, strongly suggesting the type of tuberculosis seen in children or non-sensitized persons." It was usually accompanied by little or no physical signs. Sosman and Steidl regard this type of tuberculosis as a new infection and not the reactivation of an old infection. They found the prognosis uniformly bad.

More recently from the Mayo Clinic Adams¹⁰ reported the following: "Among the first thousand cases of diabetes studied after 1922, there were ten cases with signs of active pulmonary tuberculosis. Of these ten, seven are now dead in spite of the most careful treatment of the two diseases. Fourteen more of these first thousand developed active pulmonary tuberculosis after their first visit to the clinic." They concluded from these data that active pulmonary tuberculosis is a less common but more serious complication of diabetes than acidosis or gangrene. They find that tuberculosis is not as common as has been supposed.

"In the Peter Bent Brigham Hospital⁷ and its out-door department, from October 1, 1922 to January 1, 1929 there appeared 1,529 patients with diabetes." Of these, 35 had developed subsequent tuberculosis. "Joslin reports 43 cases of tuberculosis among his last published 3,000 cases." The combined number of these cases—Mayo Clinic, Brigham Hospital, and Joslin's—totals 5,500. This gives an incidence of 1.8 per cent of the total. Of the Brigham cases reported from

October 1922 to January 1929, 86 per cent are dead. Fitz tabulated as follows the duration of life in diabetics after tuberculosis is recognized (30 fatal cases):

- (1) One year or less—19 cases—63 per cent;
- (2) More than one year and less than three years—7 cases—23 per cent;
- (3) More than three years—4 cases—14 per cent.

We, in the diabetic clinic of the Rhode Island Hospital, have been interested in determining how frequently our patients are afflicted by tuberculosis, and our interest was increased especially by the report of Sosman and Steidl regarding the high incidence of a highly fatal type of tuberculosis. This clinic comprises 500 active diabetic cases who are seen at varying intervals. In general these people are of a poorer class such as one would expect to see in a free clinic, and as a group are probably comparable to the type of patients seen at the Brigham Hospital. They include people of various nationalities and of varying degrees of intelligence and coöperation. The disease in these patients is naturally of every degree of severity. We have available the roentgen-ray findings in 408 patients. We think it is noteworthy that in not a single case have we found the hilum type of tuberculosis described by Sosman and Steidl. We have found five active cases of tuberculosis in this group and are watching closely one patient whom we consider a potential case. In addition, two patients have been treated in the clinic who have inactive tuberculosis of the ordinary apical type. In both

of these patients the tuberculosis was present before the development of diabetes. Both of these patients are alive and well, one of them in spite of a severe diabetes which is well controlled. The patient whom we regard as a potential case of tuberculosis is a young

man of 26 years of age, with severe diabetes who has reported undoubted hemoptysis. This patient also has a history of pleuritis sicca on several occasions in the past and also of gross hemoptysis four or five years ago. In spite of this history he has none of the ordinary symptoms of tuberculosis and physical examination is negative. A single examination of the sputum

FIG. 1. Case W. H., February 1932.

man of 26 years of age, with severe diabetes who has reported undoubted hemoptysis. This patient also has a history of pleuritis sicca on several occasions in the past and also of gross hemoptysis four or five years ago. In spite of this history he has none of the ordinary symptoms of tuberculosis and physical examination is negative. A single examination of the sputum

costophrenic sinus is shallow. There is definite density of the structures in the region of the lung roots. There is abnormal density of lung markings in the midportion of the right lung. There are many small ring-like shadows in the lower lobe of the right lung suggesting dilated bronchi." Roentgen-ray examination made in February 1932 was reported as fol-

lows: "Examination of the chest shows generalized increased markings throughout the lung fields. There appears to be some beading of the markings upward into the apex. There is

CASE I

E. R., female, age 31, duration of diabetes nine years, of tuberculosis three years and ten months. X-ray findings in June 1928 were as follows: "There is an area of mottled dullness projecting outward from the

FIG. 2. Case II, July 1929.

a small area of dullness in the fourth interspace anteriorly. There are numerous small dense calcified areas in the region of the lung roots, particularly in the left, suggestive of previous healed infection." The roentgen-ray of the chest of this patient is shown in figure 1.

A brief résumé of our five active cases is as follows:

region of the great vessels into the right axilla and at the level of the second and third right anterior ribs. There is a large ring-like shadow in the second interspace probably due to a large cavity. Findings in this area suggest a lung abscess but could be due to a tuberculous process. There is dullness also in the lower lobe of the left lung just above the diaphragm shadow. No evidence of fluid in the left chest. The dullness in the left lower lobe could be due to tuberculosis. The dullness could be due to

consolidation also". This patient was treated very successfully by pneumothorax. She was discharged from the sanatorium within a few months and is doing very well. She is afebrile, has no cough or sputum and the disease is apparently arrested.

revealed scattered tuberculosis in the greater part of both lungs and a cavity in the left lung. The patient is afebrile, but has a persistently positive sputum. His general condition seems to be very good. "However, his prognosis can only be considered fair

FIG. 3. Case III, February 1930.

CASE II

J. H., male, age 64, duration of diabetes four years, of tuberculosis three years. Roentgen-ray findings July 17, 1929 (figure 2) were as follows: "There is a marked cloudiness and infiltration at the left top and right mid-chest and also definite mottling in the left base consistent with tuberculosis." The patient is in a sanatorium. The findings two years later, June 1931,

because of the danger of a generalized dissemination of the disease from the open cavity. He is sugar free or occasionally has a very slight trace of sugar in the urine on an ordinary diabetic diet without insulin."

CASE III

J. H., male negro, age 37, duration of diabetes seven years, of tuberculosis ten months. Roentgen-ray on February 18,

1930 and January 2, 1931 showed negative lung fields (figure 3). The patient, however, continued to feel badly, losing weight, etc., and another roentgen-ray taken July 1, 1931 showed the following (figure 4): "Examination of the chest shows extensive mottled dullness on the right between the

and is doing fairly well for a bilateral case. The outlook is still uncertain."

CASE IV

V. C., male, age 54, duration of diabetes six years, positive evidence of tuberculosis June 1932 when he began to complain of

FIG. 4. Case III, July 1931.

third and fourth ribs anteriorly. The findings are those usually seen with a tuberculous process. The entire left lung is clear." He, too, is at present in a sanatorium. The latest report from the sanatorium is as follows: "In regard to the case of J. H., would say that he is taking 70 units of insulin daily, and usually has only a trace of sugar in his urine. He is a bilateral case and has not been given pneumothorax. He has gained ten pounds since admission

cough, loss of weight, and fatigue. His diabetes is of a mild nature. He is on a house diet excluding sweets, without insulin. He is at present in the Charles V. Chapin Hospital in the tuberculosis ward and is doing very well. He is afebrile and has shown only one positive sputum. Earlier in the course of his diabetes the chest roentgen-ray findings were negative, but a second roentgen-ray in June 1932 showed a tuberculous infection in the right upper lobe.

CASE V

B. C., age 50, duration of diabetes two years, of tuberculosis about fourteen months. Patient has family history of tuberculosis. Routine roentgen-ray examination in May 1931 was reported as follows: "Examination of the chest shows definite, fine increased density scattered throughout both

creased density of the bronchial markings, but no definite evidence of tuberculosis." She continued to feel well after the diabetic condition was brought under control and felt well until May 1932 when she complained of pain in her chest, weakness, loss of ten pounds weight and of a generally run-down condition. She was admitted to

FIG. 5. Case V, May 1931.

lung fields, slightly more in the right than the left. The appearance is suggestive of infection of the lungs, possibly tuberculosis." (Figure 5). Physical examination and sputum were negative. The patient remained in bed all summer under the care of her family physician who completely disregarded the diabetic condition and gave her a high calory diet without insulin. She returned to the clinic in December 1931 with marked glycosuria and a fasting blood sugar of 250 mg. per 100 c.c. She had lost nine pounds in weight; we attributed this loss to the uncontrolled diabetes. Roentgen-ray at that time was reported as follows: "Examination of the chest shows some in-

the tuberculosis ward of the Charles V. Chapin Hospital and was discharged from there June 1, 1932, with the diagnosis of healed tuberculosis. She has remained in good condition since then.

SUMMARY AND CONCLUSIONS

1. In our clinic comprising 500 active diabetic patients, 408, or 81.6 per cent, unselected cases have had roentgen-ray examination of the lungs.

2. Five, or 1.2 per cent, showed positive roentgen-ray evidence of tuberculosis.

3. The prognosis in one case is unfavorable or uncertain, but in the remaining four it is good.

4. It is of interest to note that none of our active cases has shown the serious type of tuberculosis described by Sosman and Steidl.

5. The incidence of tuberculosis in our group corresponds closely to that noted in other recently published statistics.

6. All of our cases of active tuber-

culosis seen since this study was undertaken are alive. The longest duration of the tuberculous infection in this group is three years and ten months.

7. In our experience tuberculosis has not occurred any more frequently in diabetics than in non-diabetics. In those cases in whom tuberculosis has developed it has not run a more unfavorable course than in non-diabetics.

Primary Hypochromic Anemia*

Its Importance in Medical and Surgical Diagnosis

By JOHN E. WALKER, M.D., F.A.C.P., *Opelika, Alabama*

HYPOCHROMIC anemia in adults is generally considered as secondary to some other disease process, such as hemorrhage, malignancy, infection, or nephritis. This view has prevailed so long that "hypochromic anemia" and "secondary anemia" are often used as synonymous terms. In recent years, however, a type of hypochromic anemia has been recognized as an independent disease. The condition may be referred to as primary hypochromic anemia. It occurs almost exclusively in women. Achlorhydria is nearly always present. One of the most characteristic features of the disease is a rapid, almost dramatic, response to iron therapy in massive doses. Its recognition is of great importance, not only because it requires a specific type of therapy, but also because of the possibility of its confusion with anemia due to chronic hemorrhage. The common assumption that a "cause" must be found for every case of hypochromic anemia is erroneous and may lead to ineffective treatment.

Textbooks of medicine contain no description of primary hypochromic anemia. Likewise, the special treatises on hematology do not describe it, ex-

cept that Naegeli¹ gives a short account of its essential features, calling it "chronic chlorosis". Knud Faber² accurately described the disease in 1913. Recent interest, however, dates from the paper published in 1929 by Kaznelson, Reimann, and Weiner.³ They refer to it as achylic chloranemia. Other terms that have been used are chronic hypochromic anemia (Altshuller⁴), chlorotic anemia with achlorhydria (McCann and Dye⁵), achylic anemia (Schulten⁶), essential hypochromic anemia (Schulten⁷), hypochromic anemia with achlorhydria (Waugh⁸), idiopathic hypochromemia (Mills⁹), idiopathic secondary anemia (Watkins¹⁰), chronic chlorosis and chlorotic anemia (Mettier and Minot¹¹), chronic microcytic anemia (Witts¹²). I prefer the term primary hypochromic anemia as introduced by Dameshek.¹³ The condition is obviously not chlorosis. The age distribution is entirely different. Moreover, chlorosis was frequently accompanied by hyperacidity. The hyperacidity was sometimes so marked in chlorosis that the possibility of an accompanying peptic ulcer was considered (Rosenow¹⁴).

I have recently encountered four patients with primary hypochromic anemia. The case histories of two of them are below.

*Received for publication September 29, 1932

CASE I

C. M., female, aged 41, ambulant, first seen January 24, 1931, complaining of general weakness. Her general health had been good prior to the present illness. There had been two attacks of influenza, eleven and two years ago respectively. The patient had been married for twenty years. One child was living and well. The menses were regular, lasted three to four days, and were described as being profuse.

The onset of the present illness had been gradual. About three years ago she began to tire easily. This had increased, until recently any exertion caused shortness of breath. The tongue had become markedly sore, off and on during the illness. There had been aching in both thighs extending to the knees. The appetite had been good. Patient stated she had been told that all of her trouble was due to excessive loss of blood at the menstrual periods and that no improvement could be expected without an operation to correct this abnormality.

Examination showed a pale, middle-aged woman, 63 inches high and weighing 129 pounds. The sclerae were clear. The tongue was smooth, red, and showed a few superficial ulcerations at the margins. The general physical examination revealed no abnormality. The liver and spleen were not palpable. The reflexes were normal. The vibratory sense was not impaired. The uterus was retroverted, otherwise there was no pelvic abnormality. Fluoroscopic examination of the heart, lungs, and stomach showed no abnormality.

Laboratory Examination: Blood hemoglobin, 48 per cent (Newcomer-Klett glass standard, 15.3 gms. per 100 c.c. being considered 100 per cent); red blood cells, 3,520,000 per cubic millimeter; color index, 0.7; white blood cells, 5,550 per cubic millimeter; neutrophils, 62 per cent; eosinophiles 4 per cent; basophiles, 1 per cent; lymphocytes, 30 per cent; monocytes, 3 per cent. There was moderate poikilocytosis and anisocytosis, microcytes being especially numerous. The red blood cells were obviously hypochromic. There was no evident abnormality of the platelets. On two examinations there was no free hydrochloric acid in the gastric contents after an Ewald meal, and

the total acidity was 11 per cent. There was no lactic acid nor occult blood. The urine contained no urobilinogen (Ehrlich's aldehyde reagent) and was otherwise normal. There was no occult blood in the stools and no parasites nor ova. The blood serum was pale; icterus index six. The Wassermann reaction was negative.

The patient was given nine Blaud's pills (U. S. P.) a day and forty drops of dilute hydrochloric acid after each meal. In addition, a diet was prescribed which included fresh lean meat, green vegetables, cooked fruit, and fresh fruit each day.

The hemoglobin increased to 83 per cent in four weeks and to 90 per cent in six weeks. The symptoms disappeared entirely. The pills were then reduced to three a day, but the patient, against advice, left them off entirely. After three months without iron, the hemoglobin had decreased to 70 per cent. The pills were then resumed, nine a day. At the end of four additional months the hemoglobin was 111 per cent. Four months later she had again relapsed, hemoglobin 73 per cent. Patient stated that she saw no need of regular visits for hemoglobin determinations and dosage adjustment, for she had learned when to take iron merely from her subjective sensations.

CASE II

C. H., female, age 40, ambulant, was first seen March 3, 1932, complaining of stomach trouble and prolonged slight elevation of temperature. The patient had been married twelve years; there had been no pregnancies. Four years before an operation had been performed for the removal of an ovarian tumor. The past history had otherwise been uneventful.

The patient attributes the onset of the present illness to an attack of influenza two years ago. Since then she has had frequent afternoon elevation of temperature reaching from 99½ degrees to 100½ degrees. This has led to her supervision as a tuberculosis suspect. She has gradually developed marked shortness of breath. She has vomited frequently on slight provocation. There is an almost constant feeling of discomfort in the epigastrium, amounting almost to pain. Abdominal flatulence has been marked. There

have been two recent attacks of diarrhea. The patient has lost her appetite for meat and has eaten very little meat during the past three years. The menses are regular and profuse.

Examination: The patient was an extremely pallid woman; weight 111 pounds and height 62 inches. The tongue was smooth and pale. The general physical examination revealed no abnormality. The pelvic organs were normal. Reflexes were normal; vibration well perceived. Fluoroscopic examination of heart, lungs and stomach showed no abnormality. Electrocardiograph was normal.

Laboratory Examination: Hemoglobin, 30 per cent; red blood cells, 2,670,000 per cubic millimeter; color index 0.6; white blood cells 2,800 per cubic millimeter; neutrophils, 56 per cent; basophils, 1 per cent; lymphocytes, 20 per cent; monocytes, 9 per cent. One normoblast seen in counting 100 leukocytes. Slight poikilocytosis was present, and marked anisocytosis with microcytes predominating. Marked hypochromia. The platelets appear normal. Gastric contents: no free hydrochloric acid; total acidity, 6 per cent; no blood or lactic acid. Icterus index, 6. The urine contained no albumin, sugar, casts, or urobilinogen. There was no occult blood, nor any parasites or ova in the stools. The Wassermann and Kahn reactions were negative.

Exactly the same treatment was given as in Case I, except that the Bland's pills were increased to 12 a day. Three weeks later the hemoglobin was 60 per cent; after six weeks it was 80 per cent, and after nine weeks, 93 per cent. The leukocytes never increased above 4,000. There was no further gastric distress or fever after the hemoglobin reached 60 per cent.

The other two patients were also women, aged 35 and 38 years respectively. Both had achlorhydria. The hemoglobin of one was 60 per cent, and of the other 63 per cent. Both improved rapidly on 9 Bland's pills a day.

ETIOLOGY

The etiology of the condition is obscure. It is probable that the achlorhydria and the anemia are both the result of a constitutional defect, rather than that the anemia is a result of the achlorhydria. Dameshek¹⁸ suggests that the disease is possibly related to the deficient gastric digestion of organic iron. Many of these patients, like Case II above, give a history of eating very little meat. This aversion, however, may be a simple result of the achlorhydria, and is not necessarily concerned in the etiology of the condition. Certainly, large quantities of meat in the form of liver, as used in the treatment of pernicious anemia, have no influence on the condition.

Although primary hypochromic anemia and pernicious anemia have dissimilar blood pictures and require entirely different types of therapy, there appears to be a link between the two diseases. Schulten calls attention to the fact that primary hypochromic anemia and pernicious anemia may occur in different members of the same family. He also cites from the literature two instances of individuals with primary hypochromic anemia who later developed pernicious anemia. Dameshek has seen a similar change from one type to the other.

One of the most surprising features of this newly recognized disease is its great incidence. It is unquestionably far more common than pernicious anemia. Wits estimates that among every 100 persons with achlorhydria, there will be 20 individuals with primary hypochromic anemia and 10 with pernicious anemia. My own four cases were encountered among 250 consecu-

tive ambulant patients. Among these patients there was not a single case of pernicious anemia. While women greatly predominate, men are not immune to primary hypochromic anemia. One of the seven cases reported by Dameshek was a man. Fourteen per cent of the 117 cases studied by Witts¹² were in men.

About half the cases occur between the ages of 30 and 42 years. The disease becomes much less frequent after the menopause, although it does not disappear entirely. One of the Mills⁹ patients was 58 years old, and another 61. Strauss¹⁵ has observed three instances in pregnancy. Mills believes that pregnancy is merely a complication of the disease and does not play any part in its etiology.

SYMPTOMS

The symptoms consist as a rule of the usual symptoms of anemia, namely, shortness of breath, palpitation, weakness and dizziness. These symptoms are sometimes surprisingly slight considering the degree of anemia. In addition, there may be numbness and tingling of the extremities. Gastric complaints, such as loss of appetite, and diarrhea are frequent. Many of the patients give a history of profuse menstrual periods. Long continued low fever may occur, as in pernicious anemia. This fever may cause tuberculosis to be suspected, as in Case II above. Aching in the limbs and joints is frequent.

EXAMINATION

The patients appear very pale. The pallor, often alabastrine, contrasts with the yellowish tint of pernicious anemia.

The tongue is red in a large proportion of the cases. Typical Hunterian glossitis may be present. Koilonychia (spoon-shaped nails) is often marked. The spleen is sometimes palpable. Achlorhydria is present in almost all of the patients, though the finding is not as absolute as in pernicious anemia. Dameshek has noted postero-lateral sclerosis, though this is rare.

The hemoglobin may be as low as 15 per cent (Dameshek¹³). The color index is much below 1.0, but the red cells are as a rule more reduced than in the figures given for chlorosis. Microcytes predominate. This is obvious not only from the examination of the smear, but has been shown by careful measurements of the diameters of the red cells by McCann and Dye⁶ and by Schulten.⁷ There is considerable poikilocytosis and anisocytosis. Nucleated red cells are rare. Leukopenia is present as a rule. The icterus index is low, and the urine contains no more than a trace of urobilin, if any.

DIAGNOSIS

The blood picture of primary hypochromic anemia sharply separates it from pernicious anemia. Unlike pernicious anemia, however, the blood picture of primary hypochromic anemia is not pathognomonic. Knowledge of the primary form of hypochromic anemia in no way eliminates the necessity of a very thorough examination for known causes of secondary hypochromic anemia, such as infections, nephritis, occult malignancy, or occult hemorrhage. The leukopenia helps to rule out subacute bacterial endocarditis. The stools should invariably be examined for occult blood, and roentgenological

examination of the gastrointestinal tract is desirable. Achlorhydria helps to establish the diagnosis of primary hypochromic anemia if there is no reason to suspect gastric carcinoma. Failure to improve under proper treatment should cause early splenic anemia to be suspected.

The greatest difficulty lies in distinguishing between primary hypochromic anemia and the anemia of menorrhagia, particularly since profuse menstrual periods may occur in the former disease. If there is no obvious gynecological lesion, operation or roentgen-ray sterilization should certainly be delayed until after a therapeutic test with iron, since such a test at the most requires only four to six weeks. In my opinion, some of the anemias attributed to functional menorrhagia and submitted to roentgen-ray sterilization are in reality instances of primary hypochromic anemia. This error is all the more common on account of the prevalent belief already mentioned that hypochromic anemia is always secondary to some other process such as hemorrhage. Likewise, recognition of this disease renders caution necessary in attributing anemia to doubtful bleeding from hemorrhoids.

TREATMENT

The essential feature of treatment is the use of iron in large doses. The usual small doses of iron are without effect. The form of the iron is immaterial, if the dosage is large enough. There are three forms in use, any one of which is satisfactory.

1. Bland's pills, U.S.P. The dose is 9 to 12 five-grain pills a day. The

pills should be freshly prepared so as to guard against failure of disintegration. (Each pill contains 30 mg. of Fe as FeCO_3). Vallet's mass, U.S.P. (17 per cent Fe as FeCO_3), may also be used in doses of 60 grains a day.

2. Iron and ammonium citrate, U.S.P. (17 per cent Fe), is an inexpensive preparation. It can be easily prescribed in 25 per cent aqueous solution, and given diluted in milk or water in the dosage of two drams of this solution three times a day. To prevent any possibility of diarrhea, Minot and Castle recommend beginning with one-half dram doses and increasing to two drams three times a day.

3. Reduced iron is the favorite preparation in Germany.⁷ It is given in doses of 6 to 10 grams daily.

It is useless to give proprietary preparations of iron and it is needless to give iron by injections.

There is some difference of opinion as to whether copper enhances the effect of the iron. Mills⁹ is of the opinion that it does, and he gave daily 1/16 grain of copper carbonate (2.1 mg. Cu) in 90 grains of Bland's mass. One of the patients observed by Dameshek likewise failed to show satisfactory improvement until a daily dose of 0.1 gram copper sulfate (23 mg. Cu) was added to the iron. The other six cases observed by Dameshek¹³ improved satisfactorily on iron alone.

Considerable weight must be given to the findings of Mills. His observations were apparently well controlled. Five of his patients were kept for many months on 60 grains of Bland's mass daily, without improvement. Prompt improvement occurred when

copper was added. Witts,¹² however, is emphatic in his belief that copper plays no part in the improvement, for the iron preparation used by him was practically free of copper, containing only 0.01 mg. of Cu in the daily dose. This quantity of copper is less than that in the ordinary diet. The Bland's pills used by me were likewise prepared from a very pure form of ferrous sulfate (Merck, granular, U.S.P., X), the daily dose of 12 pills containing only 0.1 mg. Cu. The iron preparation used by McCann and Dye contained 0.36 mg. Cu in the daily dose.

It appears then that improvement in most instances is satisfactory without the addition of copper. Whether the improvement will be accelerated by the addition of copper requires more study before being accepted as a proved fact. So far, there has been no evidence that arsenic is an aid in this type of anemia.

In addition to iron, I gave my patients hydrochloric acid, principally on account of the evidence presented by Mettier and Minot¹¹ that iron is better absorbed from an acid medium. This addition does not seem to be essential, though it will have the same effect in relieving gastric symptoms as in achlorhydria from other causes.

The iron therapy must be continued in full dose until the hemoglobin reaches 85 per cent to 90 per cent. Then the dose may be reduced to about one-fourth of the previous amount. This dosage must be continued indefinitely in order to prevent relapse, unless the patient can report for hemoglobin estimations every few months. A marked tendency toward relapse is one of the features of the disease. Some of these patients finally learn

themselves to know when they need iron.

Minot and Castle¹⁶ call attention to the fact that the best results are obtained when patients receive a proper diet as well as specific therapy. Such a diet will include fresh and cooked fruits, green vegetables and ample animal proteins, particularly meat.

As a rule, six to eight weeks of intensive iron therapy is required to bring the hemoglobin up to 85 per cent or 90 per cent. My cases required about 40 days for the hemoglobin to increase to 85 per cent or 90 per cent. Dameshek¹⁸ reported a case with an initial hemoglobin of 15 per cent which increased to 77 per cent in seven weeks, and to 88 per cent after an additional seven weeks.

SUMMARY

Primary hypochromic anemia is an independent disease entity occurring principally in women between the ages of 30 and 42 years. Achlorhydria is almost always present. The blood findings are in no essential way different from those in anemia resulting from malignancy, infection, nephritis, or chronic hemorrhage. A thorough search for such well established causes of hypochromic anemia should always be made. Knowledge of primary hypochromic anemia should, however, prevent a hasty attribution of anemia to such causes as functional menorrhagia or hemorrhoids. In case of doubt, the patient should be submitted to therapeutic test before radical procedures are performed.

One of the most characteristic features of the disease is a rapid thera-

examination of the gastrointestinal tract is desirable. Achlorhydria helps to establish the diagnosis of primary hypochromic anemia if there is no reason to suspect gastric carcinoma. Failure to improve under proper treatment should cause early splenic anemia to be suspected.

The greatest difficulty lies in distinguishing between primary hypochromic anemia and the anemia of menorrhagia, particularly since profuse menstrual periods may occur in the former disease. If there is no obvious gynecological lesion, operation or roentgen-ray sterilization should certainly be delayed until after a therapeutic test with iron, since such a test at the most requires only four to six weeks. In my opinion, some of the anemias attributed to functional menorrhagia and submitted to roentgen-ray sterilization are in reality instances of primary hypochromic anemia. This error is all the more common on account of the prevalent belief already mentioned that hypochromic anemia is always secondary to some other process such as hemorrhage. Likewise, recognition of this disease renders caution necessary in attributing anemia to doubtful bleeding from hemorrhoids.

TREATMENT

The Effect of Liver Therapy on the Neurologic Aspects of Pernicious Anemia*†

By PAUL H. GARVEY, M.D., PAUL M. LEVIN, M.D., and
ERASTUS I. GULLER, M.D., *Rochester, New York*

THE treatment of pernicious anemia with liver, introduced by Minot and Murphy¹ in 1926, after the experimental work of Whipple and his associates, has had a remarkable effect on the clinical course of the disease. The response of the nervous manifestations has been discussed by various authors with considerable difference of opinion. This is due partly to the use of different criteria in evaluating the results of treatment. Some observers have relied on improvement of symptoms not necessarily dependent upon structural restoration, while others have based their conclusions on the rigid interpretation of abnormal neurologic signs. Another cause for confusion is the presentation of one or several improved cases, with the exclusion of less favorable ones. A survey of reports of this type may lead to an unwarranted degree of optimism.

It is the purpose of this paper to present the results of a study of 47 cases of pernicious anemia admitted to the Strong Memorial and Rochester

Municipal Hospitals since the opening of these institutions in 1926. The diagnoses were established by the usual criteria. Only those cases were included in which adequate follow-up examinations were made.

The treatment consisted of the daily administration of liver or liver extract by mouth without significant periods of interruption. The average duration of treatment in the entire series was 25 months. One of the patients first took liver in 1924 upon the suggestion of Dr. Joseph Roby of Rochester as the result of the experimental work of Whipple. Another patient has been taking desiccated hog's stomach instead of a preparation of liver. As the result obtained in this case is similar to those observed in the remainder of the series, we have included it with the rest. Patients with severe neurologic symptoms received brewer's yeast and cod liver oil in addition to liver therapy. This was suggested by the case report by Conner² and later by the experimental work of Castle³ and of Mellanby.⁴ Approximately half of the patients took dilute hydrochloric

Of the total of 47 cases, 29 presented both symptoms and signs of spinal cord degeneration, 10 had symptoms but no

†From the Department of Medicine, University of Rochester School of Medicine, and the Medical Clinic of the Strong Memorial and Rochester Municipal Hospitals.

signs of nervous system involvement, and three had no indication of this complication. The remaining five patients had prominent psychic disorders and are considered solely from this aspect; their period of observation was too short to judge the effect of liver on their cord symptoms. In 40 patients, treatment was regular and uninterrupted; this was adequate in 25 cases, as indicated by a consistent maintenance of the blood level at four million or more red blood cells per cubic millimeter; in the remaining 15 cases, the average blood count was below this level, usually due to an inadequate intake of liver preparations.

RESULTS OF LIVER THERAPY

In the evaluation of the therapeutic results obtained by the use of liver, two criteria must be employed. First, and perhaps most important from a clinical standpoint, is the degree of symptomatic relief expressed by the comfort and rehabilitation of the patient. Second, progress or regression of the degenerative process in the nervous system must be measured by signs which depend solely upon structural change within that system.

It is a generally accepted fact that certain nervous symptoms respond favorably in a majority of patients. Most notable among these are paresthesia and ataxia. In 24 of the adequately treated patients who complained of paresthesias, 14 reported that this symptom improved or disappeared. It remained unchanged in four. In six of the patients the paresthesias became more severe, in parallel with signs of a steady progression of the cord degeneration. In the poorly

treated group the proportion of patients whose paresthesias improved is smaller. It is interesting that one of the patients described the replacement of soreness of the tongue by a disagreeable sensation of numbness.

Ataxia was a prominent feature in 14 of the well treated cases. In six of these cases there was improvement in this symptom. In some instances the amelioration was striking, in four ataxia became definitely worse, and in four others it was unchanged. Of four inadequately treated patients the ataxia improved in one, and remained stationary or progressed in three.

In gross contrast to the fairly favorable influence of treatment on symptoms, the objective examination of the nervous system in our series indicated a progression of the cord degeneration in 10 of 17 well treated cases. All but one of these showed extension of the process to the lateral columns. The course in patients with blood counts above five million did not differ from that in the others of this group. In six of the cases the abnormal signs remained unchanged. Demonstrable improvement occurred in only one case in which there was a return of joint sensibility without return of perception of vibration or change in reflexes. Of 10 patients who received inadequate treatment the signs progressed in eight and remained stationary in two. One patient of this group developed paraplegia in flexion, a condition described in this disease by Hall and Hirsch.⁵

The possibility of the prevention of cord degeneration by the use of liver is supported by our data. At the time of the original examination the neurologic findings were normal in 19 pa-

tients. Of the nine who were satisfactorily treated, only one developed pathologic signs, while this occurred in five of the ten poorly treated patients.

The following case illustrates progression of cord degeneration under treatment.

CASE I

L.G., male, aged 63, was referred by Dr. C. P. Thomas for a neurological examination, November 12, 1929. He complained of mental depression and of numbness and tingling in the hands and feet. The family history is of unusual interest in that his brother, R. G., aged 58, died three months previously of a progressive cord degeneration associated with pernicious anemia. R.G. was first examined by one of us when his symptoms were identical with those of his brother; liver treatment was instituted at this time.

The present illness of L. G. began five months previously with mild mental depression. This was accompanied after two months by persistent paresthesias in the hands and feet and impairment of skilled movements of the hands. There was no disturbance of the gait. Slight soreness of the tongue had been present at times.

On examination, the patient was a well nourished man of ruddy complexion. He was mentally clear. The expression and general behavior indicated considerable anxiety. The neurologic examination was negative except for slight awkwardness in buttoning the clothes. This was the only evidence of incoördination. Detailed examination of deep sensibility revealed no abnormalities in either the upper or lower extremities. The tendon reflexes, plantar reflex, gait and station were all normal.

The general physical examination was negative except for slight papillary atrophy of the tongue.

The laboratory findings were: Blood hemoglobin 86 per cent; red blood cells 4,500,000 per cubic millimeter; white blood cells 6,000 per cubic millimeter. The blood smear at the time of this examination was not definitely abnormal. A gastric analysis revealed the absence of free hydrochloric

acid in the fasting specimen and also in those taken after the test meal. The urine and stool examinations were negative. The cerebrospinal fluid was normal. The blood and spinal fluid Wassermann tests were negative.

The diagnosis was pernicious anemia with early subacute combined degeneration. Liver treatment and diet rich in vitamins were instituted. The patient was again seen on May 22, 1931. He complained of weakness of the legs,² difficulty in walking, girdle sensation and constipation; these symptoms had developed since the preceding fall. The paresthesias were more severe. The examination showed increased tendon reflexes in the upper extremities with a bilateral Hoffmann sign. The legs were weak but he was able to walk unassisted though with an ataxic gait. The knee jerks were present and about normal. The Achilles reflexes were lost. A Babinski sign was present on the left. Position sense of the toes was greatly impaired and vibratory sensation was lost over the bony prominences of the pelvis and lower extremities. He was unable to stand in the Romberg position without falling.

His condition has progressed further so that at the present time he is unable to walk unless assisted by two persons. The ataxia of the hands has become more marked and he is unable to write. Paresthesias likewise have increased.

Since November 1929 he has taken six vials of liver extract daily and also fresh liver twice a week without interruption. Blood counts were done at intervals of a month. The hemoglobin has varied between 95 and 110 per cent; the average red blood cell count was 4.1 million per cubic millimeter. The color index has been persistently over 1.0 and the smears have shown definite anisocytosis and poikilocytosis.

COMMENT

In this case the diagnosis was made shortly after the onset of nervous symptoms and before the characteristic blood picture of pernicious anemia had developed. Treatment was started before objective evidence of cord degeneration was present except

for impairment of skilled movements of the hands. The patient appreciated the similarity of his condition to that of his deceased brother and realized the necessity for continuous treatment. In spite of this the course was slowly but steadily progressive.

The improvement of ataxia under liver therapy has been noted. Most authors are agreed that the favorable response of this symptom is not usually paralleled by improvement of deep sensibility. In fact, the ataxia may at times improve in the face of actual progression of the spinal cord lesion as evidenced by increasing sensory and motor disturbances. Analysis of our series shows that deep sensibility returned in only one of the six patients in whom ataxia improved. Improvement in strength and muscle re-education, as suggested by many authors, are probably important in the correction of this symptom.

CASE II

M. N., a housewife, aged 56, was admitted to the Strong Memorial Hospital October 22, 1929 and discharged four days later. She complained chiefly of numbness and tingling of the hands and feet. The past and family histories were irrelevant. The present illness began two years previously with extreme weakness. She was confined to bed for three weeks with gradual but not complete return of strength. A short time later she complained of a sensation of swelling of the legs which was slowly replaced by a feeling of numbness and tingling below the knees. In December 1928 numbness and tingling of the hands and soreness of the tongue became troublesome symptoms. For six months prior to entry she had been unaware of the position of her feet and had been unable to walk or stand unless assisted.

Examination: Mentally clear. The skin and mucous membranes had good color. The tongue was very red and sore, and

there was slight atrophy of the papillae along the edges. The cranial nerves were normal. The strength of the upper extremities was fairly good. The tendon reflexes in the upper extremities were not elicited. There was a considerable degree of ataxia with both hands, by the finger to nose test. Vibratory sensation was diminished over the wrists. Sense of motion and position of the fingers was lost in one hand (presumably the right). The knee and Achilles reflexes were absent. The plantar response was flexion on both sides. There was loss of sense of motion and of position of the feet and toes. Vibratory sensation was lost over the bony prominences of the pelvis and lower extremities. The legs were extremely ataxic. Examination of superficial sensibility showed a diminution of tactile and thermal sensation below the knees. The general physical examination was negative. The laboratory findings were: Blood hemoglobin 86 per cent; red blood cells 3,590,000 per cubic millimeter; white blood cells 8,600 per cubic millimeter. The differential count was as follows: Polymorphonuclear neutrophils 67 per cent; large and small lymphocytes 26 per cent; large mononuclears and transitionals 5 per cent; eosinophiles 1 per cent; basophiles 1 per cent. In the smear the red blood cells were large and stained deeply. There were moderate variations in size and shape. The platelets were normal. The chemical examination of the blood plasma showed non-protein-nitrogen 24 mg. per 100 c.c., sugar 74.9 mg. per 100 c.c.; icterus index 8. A gastric analysis revealed the absence of free hydrochloric acid in both the fasting specimen and in those taken after the test meal. Urine examination: clear; acid; sp. gr. 1.015; albumin 0; sugar 0; urobilin 0; micro, occasional cast and 10-14 white blood cells per high power field. The cerebrospinal fluid was clear; pressure 125 millimeters of water; normal dynamics; 4 cells per cubic millimeter; Pandy test negative; gold sol curve 0001100000. The blood and spinal fluid Wassermann tests were negative.

The diagnosis was pernicious anemia with subacute combined degeneration of the cord. The patient was advised to take liver, high

vitamin diet and was instructed regarding Fraenkel exercises.

After leaving the hospital the patient took uncooked fetal calves' liver for a period of four weeks. Three weeks after starting treatment she stated that, whereas previously she was unaware of the position of her lower extremities, "feeling" had returned. In May 1931 she was able to walk with the aid of a cane and in September she was able to get along without a cane, climb stairs and do her housework. The numbness and tingling of the lower forearms, hands, legs, and feet persisted and became even more marked in the upper extremities. She was unable to pick up or hold small objects with the hands. The soreness of the mouth completely disappeared under treatment.

The treatment consisted of uncooked fetal calves' liver, about three and one-half pounds per week, for a period of four weeks. The same amount of uncooked calves' liver was then taken for a period of six months and since then she has taken one vial of liver extract three times a day. She has also taken considerable amounts of cod liver oil which she thinks has been a factor in her general improvement. In addition to the medical treatment, systematic muscle coordination exercises were employed.

Neurological Examination: December 1931. Her general health was excellent and there was no evidence of anemia. The cranial nerves were normal. The strength of the upper extremities was very good. The biceps and triceps reflexes were present but diminished. Hoffmann's thumb sign was absent. There was no ataxia by the finger to nose test except of the right hand when the eyes were closed. Vibratory sensation was diminished over the wrists, especially the right. Sense of motion and position of the fingers was present in the left hand and absent on the right. The knee jerks were increased on both sides. The Achilles reflexes were present but diminished. A bilateral Babinski sign was present. Sense of motion and position of the toes was lost in both feet. Vibratory sensation was lost over the bony prominences of the lower extremities. Ataxia of both legs was present by the heel to knee test and was more

pronounced with the eyes closed. She walked with a slightly ataxic gait. The Romberg sign was positive. The chief disturbance in superficial sensibility was a diminution of pain and tactile sensation over the lower forearms and hands. The hemoglobin was 75 per cent and the red blood cells numbered 4,500,000.

COMMENT

This case illustrates several points. First, a considerable degree of functional recovery may occur in the absence of improvement of the neurologic signs. However, there is a possibility that postural sensibility partially returned as judged by the patient's descriptions, although the usual clinical tests failed to detect this. Second, while apparent improvement is taking place, evidence of increasing cord degeneration may occur, as shown by the appearance of a bilateral Babinski sign. Several observers have described cases of this type in which decrease of ataxia is accompanied by so-called improvement of the tendon reflexes. It is apparent that this phenomenon probably represents a progression of the spinal cord degeneration rather than a regression.

EFFECTS OF CESSATION OF LIVER TREATMENT

Six cases discontinued treatment for periods varying from four months to three years. In one, the signs and symptoms remained stationary over a period of three years without liver. In two, mild symptoms occurred during the relapse and improved under further treatment. In two others more severe neurologic manifestations followed the cessation of treatment and progressed in spite of a satisfactory regenerative response of the blood to further administration of liver. The sixth patient, in whom there were signs of posterior column involvement, showed progressive neurologic manifestations after a four month lapse of treatment notwithstanding the per-

sistence of high blood levels during this period (blood hemoglobin 105 per cent; red blood cells 5,400,000 per cubic millimeter).

Psychoses. Prominent psychotic manifestations were present in five patients. In two, there was a state of confusion; these patients responded well to treatment. The symptoms were more severe in three patients, who progressed in spite of fairly high blood levels and died three to five months after the onset of the psychoses.

DISCUSSION

Mention has been made previously of the conflicting opinions expressed by various authors concerning the effects of liver on the neurologic manifestations of pernicious anemia. This diversity, it was noted, may be partly explained by a difference in the criteria employed in determining the efficacy of treatment. Confusion still exists, however, when objective phenomena alone are considered. Curschmann⁶ has expressed himself definitely as denying any beneficial influence whatever of liver upon the spinal cord changes of the disease. He makes the statement "I have as yet not seen a single case of pernicious anemia in which the spinal symptoms, especially the sensory, motor and reflex disturbances, have been improved by liver treatment". In contrast are Ungley and Suzman⁷, who claim that, provided the treatment be adequate, considerable improvement in the neurologic lesion may be confidently expected. They found that vibration and joint sense returned in a number of their cases and that a Babinski sign disappeared in five out of nine cases. They con-

cluded that "all signs and symptoms of cord involvement may disappear."

A number of other authors have taken intermediate positions. Smithburn and Zerfas⁸, in a report based on a study of 115 cases of pernicious anemia, concluded that "improvement may occur in the neural and psychic changes" but also that "changes may develop for the first time or may steadily progress" during adequate treatment with liver extract. Needles⁹ has recently reported a series of 25 cases of pernicious anemia complicated by subacute combined degeneration, 11 of whom received adequate liver treatment. Signs of subacute combined degeneration appeared in five despite therapy, in four they remained stationary, while in two there was some evidence of improvement. In the two cases in which improvement occurred it concerned symptoms rather than signs.

In our series of 40 patients of pernicious anemia who received uninterrupted treatment with liver for an average period of 25 months, 27 patients presented signs of cord degeneration. Of these the treatment was adequate in 17 and in 10 the treatment was insufficient to maintain the proper blood levels. Of the well treated group subjective improvement, excluding the effect on paresthesias, occurred in six cases while evidence of favorable improvement on the neural process occurred in but one. As has been noted, in this case the improvement consisted of a return of joint sense in the lower extremities without return of vibration sensibility or change in the reflexes. In 10 of the 17 patients who received adequate

treatment there was objective evidence of progression of the cord degeneration, while in six the signs remained stationary. Of the patients who at their first examination presented no evidence of cord involvement, further observation showed that only one of nine well treated cases, and five of 10 poorly treated ones developed signs of cord degeneration.

While the number of patients studied in this group does not justify definite conclusions, certain deductions may be entertained. In the majority of cases of this series the spinal cord degeneration associated with pernicious anemia has progressed in spite of liver therapy. The rapidity of progression was variable. In some patients the degenerative process seemed to progress relentlessly; while in others, perhaps the majority, the progress of the neural changes was retarded. That improvement in cord changes is unusual is not surprising when one considers the character of the lesion and the inability of axis cylinders once destroyed to regenerate. Davison¹⁰, in an interesting histopathologic study of the cords of 17 cases of pernicious anemia with subacute combined degeneration, found progressive glial changes in the seven cases which were treated with liver. The untreated cases observed prior to the institution of liver treatment failed to show this glial reaction. The myelin sheaths and the axis cylinders in treated cases were not different from those in the untreated ones. He assumed that liver therapy caused a reduction in the amount or in the strength of the hypothetical toxin and therefore allowed the glia to proliferate and replace the damaged tissue.

It has not been definitely decided whether the axis cylinder or the myelin sheath is primarily affected in combined degeneration of the cord associated with pernicious anemia. While both structures are eventually destroyed, some investigators believe that the myelin sheath is affected first. If this is correct, institution of treatment may lead to functional restoration of the partly damaged nerve fiber. In this connection we may refer to Case II. This patient noted that the sense of position of her extremities improved to a certain degree several weeks after she began liver treatment. It is difficult to ascribe this partial return of position sense to any other factor but liver treatment.

CONSTITUTIONAL FACTORS

It is recognized that there is a definite tendency for pernicious anemia to occur in several members of a family. It is also a common observation that the disease occurs more frequently in individuals of a certain constitutional type. Among the characteristics of this type are fair complexion and premature graying of the hair. That there may be a familial tendency to the development of severe nervous manifestations is suggested by the patient presented as Case I and his brother who is mentioned there. In both, the initial symptoms and the clinical courses were similar. Symptoms began at relatively high blood levels and the cord degeneration progressed in spite of continuous treatment.

TREATMENT

Several factors must be considered in the treatment of pernicious anemia

accompanied by nervous manifestations. To be effective it should be given before degenerative changes in the cord are well established. We feel that treatment begun at this time is of value in the majority of patients, in the prevention of serious cord lesions. Certain patients, however, fail to respond in a favorable manner; in these the cord degeneration progresses in spite of persistent treatment.

Continued treatment appears advisable, as its interruption in several cases has been followed by aggravation of signs and symptoms referable to the nervous system. In one case, after liver was discontinued for a period of four months, the patient returned with more pronounced neurologic symptoms and signs although her red blood cell count was 5,400,000 and her blood hemoglobin 105 per cent.

The opinion has been expressed that whole liver is more effective in the treatment of subacute combined degeneration than liver extract. As all the patients in our series received both forms of treatment, we are unable to draw conclusions regarding their relative merits. The use of concentrated vitamin preparations has furnished no definite evidence of their value.

CONCLUSIONS

The use of liver is the most important measure in the treatment of pernicious anemia in all of its manifestations. Favorable effects have been noted in the amelioration of neurologic symptoms and possibly in a prevention or retardation of the spinal cord degeneration. In our opinion improvement in neurologic signs is unusual.

Cinchophen Hypersensitiveness*†

A Report of Four Cases and a Review

By CHARLES L. SHORT, M.D., and WALTER BAUER, M.D., F.A.C.P.,
Boston, Massachusetts

INTRODUCTION

ALTHOUGH cinchophen and its compounds have been used in medicine for about twenty-four years, only recently have possible dangers from this drug been at all well known to the profession. While scattered reports of comparatively mild toxic side-actions are found in the literature from 1913 on, Worster-Drought's¹ case (published in 1923) of toxic hepatitis due to atophan was the first to call attention to this most serious complication of cinchophen therapy. Three years later, Evans,² Glover,³ and Willcox⁴ added additional cases to the British literature. In this country, Miss F. M. Painter, Assistant Editor of the Case Records of the Massachusetts General Hospital, observed from 1922 on several fatal cases of liver atrophy apparently following the use of weldona (a proprietary antirheumatic containing cinchophen). This observation was referred to by Cabot,⁵ who did not recognize cinchophen as the offending agent in the

preparation. In the last five years, reports of cases of liver damage in patients who had taken cinchophen have increased in an alarming fashion. Rabinowitz⁶ in 1930 was able to collect 50 such cases, with 25 deaths and 20 autopsies. It is probable, of course, that many of these cases are not reported and that many more patients with liver atrophy of apparently unknown etiology would, on careful questioning, have revealed the previous use of the drug. In view of these facts, the therapeutic use of cinchophen may well be again evaluated, as the number of reported cases would seem to preclude mere coincidence.

The lesion produced in the liver is not distinctive. It resembles very closely acute yellow atrophy due to other agents or of unknown etiology, or, when destruction is not so complete, the subacute yellow atrophy or toxic cirrhosis of Mallory.⁷ The wide variation in the dosage of the drug necessary to produce liver damage would seem to indicate that certain individuals have an idiosyncrasy or hypersusceptibility, while others enjoy a relative immunity and are able to take large doses over a long period with impunity.

It is proposed in this paper to review, not the more serious cases of

*Received for publication July 6, 1932.

†From the Medical Clinic of the Massachusetts General Hospital. (This is publication No. 8 of the Robert W. Lovett Memorial for the study of crippling disease, Harvard Medical School, Boston, Massachusetts).

liver damage due to cinchophen, but cases, principally of skin manifestations, which seem to demonstrate a true allergic reaction to the drug. It is believed that a review and analysis of these relatively minor complications may aid in the elucidation of the hepatic reactions. Four cases personally observed are also presented, one of them demonstrating a marked hypersusceptibility to cinchophen and to its compounds in a hypersensitive individual who also gave altered responses to a variety of other agents.

PHARMACOLOGY

Cinchophen, or phenyl-quinoline-carboxylic acid, was first used therapeutically under the name of atophan by Nicolaier and Dohrn⁸ in 1908. Several compounds of this drug have also been introduced, the most commonly employed being neocinchophen (tolsin, novatophan) or the ethyl ester of methyl cinchophen. The combination of iodine with cinchophen has been held, without clear evidence, to be especially efficacious in the treatment of rheumatic diseases, resulting in the sale of two proprietary remedies: oxyl-iodid, said to be the hydro-iodid of cinchophen, and farastan, or mono-iodo-cinchophen. Atophanyl, diiodoatophan, biloptin, quinophan, agotan, phenoquam, leucotropin, fantan, iriphan and weldona are listed by Rabinowitz⁶ as congeners of cinchophen. In addition it is probable that cinchophen or its derivatives make up a part of a large number of popular remedies for arthritis, thus adding a dangerous unknown quantity to the widespread use of the drug.

The actions of cinchophen and neo-

cinchophen resemble very closely those of the salicylates. Hanzlik⁹ has summarized the literature in a review published in 1926. Briefly, the actions include:

1. An increase in uric acid excretion through direct action on kidney permeability;
2. An antipyretic effect, not gained through depression of the metabolism, but through sweating and peripheral vasodilatation;
3. Analgesia, of unknown cause;
4. Depression of the leukocytes in rheumatic fever.

There is no definite evidence of a choloretic or antichemotic action, and any antiphlogistic effect is doubtful, unless perhaps through alteration in permeability of the capillaries or articular tissue or both, which might facilitate absorption. There are no data as to whether, as in the case of the salicylates, these drugs exert a depressant action on the streptococcus immune bodies; but Derick et al¹⁰ have shown that neocinchophen will nearly completely inhibit the formation of circulating antibodies in serum sickness due to horse serum. Cinchophen and neocinchophen are equally effective with the salicylates in relieving the symptoms of rheumatic fever. They are likewise not to be regarded in any way as specific in this disease, but represent a fortunate combination of analgesia and antipyresis. The analgesic action of the cinchophen compounds has been extended to other diseases causing long-continued pain, notably chronic arthritis, again without evidence of any specific effect on its course and with such improvement as occurs prob-

ably attributable to more normal use of the joints.

Both cinchophen and neocinchophen are but slightly soluble in water. The acidity of the former produces some irritation in the throat and stomach. It is probable that absorption of these drugs is nearly complete in the intestinal tract. The exact mode of excretion is not known, but the prevailing evidence goes to show that they are largely destroyed in the body with only slightly changed oxidation products being discovered in small amounts in the urine. Recently Lichtman¹¹ has found that in normal subjects, following the ingestion of 0.1 to 0.9 grams of cinchophen, amounts up to 21 per cent of oxy-cinchophen, 2 (ortho-hydroxy)-phenyl-quinoline-4-carboxylic acid, appear in the urine in the course of twenty-four hours. Excretion of this substance begins in two to three hours and is usually complete in twenty-four. He believes that oxy-cinchophen represents an intermediary product in the destruction of cinchophen by the liver. He has devised a simple colorimetric method for its quantitative determination in the urine. The results may be interpreted as a test for liver function, an increased excretion showing an interference in the catabolism of cinchophen beyond the stage of oxy-cinchophen due to diseased liver cells. In view of what is known concerning the effects of cinchophen upon the liver, we would be reluctant to advocate the use of this test, although the author has as yet observed no deleterious action in cases of hepatic disease.

The usual dosage of cinchophen and its compounds is from 22.5 to 45.0

grains (1.5 to 3.0 grams) daily. It has been found that from 10.0 to 13.0 grams of cinchophen and 11.0 to 16.0 grams of neocinchophen are necessary for complete effect, similar to salicylization in rheumatic fever. By this is understood the production of the so-called "toxic effect", with manifestations similar to those of salicylism.

As mentioned above, however, besides these therapeutic effects, there are side-actions of cinchophen and its derivatives which are often of grave danger to the patient. As yet, there has been no adequate pharmacological explanation of them. Splitting of the quinolin nucleus to liberate the benzene ring has been suggested by Ross¹² and others, but argued against by Sutton,¹³ Sherwood¹⁴ and Sollmann,¹⁵ since most of the benzene derivatives and the phenols do not injure the liver in overdoses. Furthermore, liver damage is as marked following the administration of aliphatic compounds, such as chloroform and carbon tetrachloride, and of phosphorus. The nitrobenzene compounds which might be produced by the oxidation of the quinolin nucleus are believed by Sutton¹³ and Sherwood¹⁴ to be responsible, in cases showing liver damage. Nitrophenols and nitrobenzenes all produce hepatic injury in certain cases. The failure of the kidney to excrete these substances and the existence of previous liver damage are postulated as adjuvant factors. So far, only theorizing is possible since objective evidence from experimentation is lacking, although a start has been made recently by Churchill and Van Wagoner.¹⁶ These authors have given massive doses of

cinchophen to dogs, with death resulting in three weeks. Autopsies showed varying degrees of liver necrosis, and impaired liver function was demonstrated during life by the bromsulfalein test and by diminution in urea formation. Two other dogs, with kidney damage created by a method of clamping the renal artery, have been given a dosage corresponding to the one used therapeutically in man. These animals have shown similar impairment in liver function, but were alive at the time of publication. These results may well represent a cumulative toxic action. Reichle,¹⁷ using rats, found that parenteral and enteral administration of cinchophen did not cause histologic changes characteristic of cinchophen poisoning in man. The livers of some of the animals were first depleted of glycogen by starvation, or were injured by carbon tetrachloride.

EXTRA-HEPATIC REACTIONS

A few cases have been reported showing toxic signs and symptoms which do not follow directly upon liver damage nor can be justly included in the group due to idiosyncrasy or allergic reactions, which we shall describe below. Kidney damage following full therapeutic or "toxic" dosage of cinchophen, demonstrated by the appearance of albumin, casts and white cells in the urine and diminished phthalein output, has been reported by Hanzlik.¹⁸ A similar action on the kidneys by the salicylates has been described. Schroeder¹⁹ mentions two cases of albuminuria following atophan administration. A tubular type of renal degeneration accompanying acute yellow atrophy has been noted at autopsy by several

observers (Evans,² Reichle,²⁰ Rake,²¹ Loewenthal,²² Sutton¹³). Beaver and Robertson,²³ in a recent review of the postmortem changes in fatal cinchophen hepatitis, expressed the belief that the pathologic changes were primarily in the liver and that "fatty changes in the heart and kidneys, mild fat necrosis of the pancreas, mucosal and serosal hemorrhages were . . . secondary to the toxic disturbances concomitant with atrophy of the liver". One case of acute pancreatitis has been reported by Petty²⁴ in a patient who took a "whole tubeful" of atophan for neuralgia. Laparotomy confirmed the diagnosis of pancreatitis; the liver appeared normal; the patient recovered. Coincidence, of course, cannot be excluded in this single case. Cases showing nausea, vomiting, and diarrhea without obvious liver damage or allergic manifestations may be accounted for by local irritation of the gastrointestinal tract.

ALLERGIC MANIFESTATIONS

Four cases personally observed showing typical symptoms of drug allergy are presented below. They are also included in the table which summarizes all the similar cases discovered in the literature.

CASE I

(No. 38 in the table) *Chronic arthritis; urticaria and bronchitis following the use of cinchophen.*

B. R., a Polish housewife, aged 35, was admitted to the medical service of the Massachusetts General Hospital on September 4, 1931, complaining of arthritis of ten months' duration, associated with severe sore throats for which a tonsillectomy had been performed two months before. No history of allergic disease in the patient or in her family was obtained, except for asthma in

an uncle. Examination disclosed only moderate joint changes characteristic of atrophic (rheumatoid) arthritis. The urine and blood were essentially normal. There was no eosinophilia.

Treatment was begun on September 9 with cinchophen 22.5 grains (1.5 grams) daily. Generalized urticaria developed nine days later on September 18, and the drug was discontinued the following day, after a total dosage of 225 grains (15 grams). The urticaria, along with a blotchy, itching erythema, gradually subsided in the course of the next week. During this period, her arthritis seemed definitely improved, but she was bothered by a non-productive cough, which lasted for about three weeks. There were no abnormal physical signs in the lungs, and a roentgenogram of the chest taken on October 6 was negative. On September 21, two days after discontinuing the cinchophen, the icteric index and quantitative Van den Bergh tests were within normal limits. Further treatment was carried on by a series of nine intravenous injections of mixed typhoid-paratyphoid vaccine with improvement in her arthritis and no untoward effect except for the development of herpes labialis on October 4, following the third injection. From then on, the progress of the patient was uneventful. When seen on January 18, 1932, four months after her skin reaction to cinchophen, she was nearly free from arthritis, and intradermal tests with a 1/500 solution of cinchophen were negative.

COMMENT

In this case, there is no evidence of an acquired sensitivity, unless we consider that the ingestion of 15 grams over nine days before symptoms began was sufficient to produce it. It is quite possible that the patient had received the drug in the course of the treatment of her arthritis before coming to the hospital. The "bronchitis", which lasted about three weeks, corresponds to that observed in two of Schilling's³⁷ cases (Nos. 28 and 30 in the table) and may well be an allergic manifestation. In contrast to Case III (see below), mixed typhoid vaccine intravenously caused no urticarial response. No evidence of liver damage could be obtained by the usual tests.

CASE II

(No. 39 in the table) Gout; urticaria and epigastric distress following the use of farastan (mono-iodo-cinchophen).

M. I., an Italian fisherman, aged 54, was admitted to the medical service of the Massachusetts General Hospital on December 3, 1931, complaining of inflammation of the right wrist of five weeks' duration. During the past two years he had had two attacks of pain, swelling and redness of the great toes of each foot, with complete freedom from symptoms between the attacks. Ten days before admission, a physician had given him farastan (mono-iodo-cinchophen), 22.5 grains (1.5 grams) daily for four days, a total dosage of 90 grains (6 grams). The use of the drug was then discontinued on account of epigastric distress, and three days later generalized urticaria had appeared, which had continued until admission.

The past history included gonorrhea twenty-four years before, and malaria in 1914. There was no family history of gout and none of allergic disease in patient or family.

Examination showed itching, erythematous areas over thighs, arms, palms and soles, with several wheals. Swelling, tenderness, and pain on motion were present in the right wrist.

The urine and blood were negative, with no eosinophilia. The non-protein-nitrogen was 29 milligrams and the uric acid 5.2 milligrams per 100 cubic centimeters of blood. No pus could be expressed from the prostate. Roentgen examination showed abscessed teeth, but no changes characteristic of gout in the hands or feet.

After admission, the rash lasted three days, accompanied by epigastric distress and pain on swallowing. December 5, eight days after omission of the drug, the liver function (Rosenthal), the icteric index and the quantitative Van den Bergh tests were all normal. Carbohydrates were forced in the patient's diet, to guard against possible liver damage from cinchophen. While on the ward, his right wrist improved, but he developed a dusky, tender swelling of the right second metatarso-phalangeal joint. A diagnosis of gout was made, a low purine diet instituted and the abscessed teeth re-

moved. By discharge on December 23, the arthritis had greatly improved.

The patient was seen in the out-patient department on January 30, 1932, about two months after his skin reaction, and was found to be nearly symptom-free. Intradermal tests with a 1/500 solution of cinchophen were negative.

COMMENT

This case is quite similar to Case I in the absence of direct proof of acquired sensitivity (although it is quite probable that he had received similar treatment in his previous attacks), in negative tests for disturbance in liver function and in negative skin reactions.

CASE III

(No. 40 in the table) Chronic arthritis; cinchophen used once without reaction, but six months later, its administration followed by urticaria and fever, with a similar response to repeated small doses; patient hypersensitive to a variety of other agents.

H. D., a white, married, native cook, aged 57, was admitted to the medical service of the Massachusetts General Hospital on October 11, 1930, complaining of arthritis of one year's duration. Her past history included chronic constipation, frequent sore throats, and double oophorectomy and appendectomy fifteen years before. There was no family history of allergic disease, except for occasional attacks of urticaria in a sister, but the patient herself had had one attack of urticaria ten years before, mild and of brief duration, without known cause.

At the onset of her illness, one year before admission, she had taken a proprietary drug (eucophen) up to a total dosage of about 30 grains (2.0 grams) of cinchophen, without toxic symptoms. Six months before admission, she took during a single week about 69 grains (4.6 grams) of oxyl-iodid, a proprietary compound said to be the hydro-iodid of phenylcinchoninic acid, containing 33 per cent iodine and 67 per cent cinchophen. The next day, shortly after taking one capsule containing 3 grains (0.2 gram), she was seized with chills, fever, generalized aching and severe urticaria, lasting thirty-six hours. From then on, although omitting the drug, she continued

to have intermittent, frequent attacks of urticaria, without relationship to exacerbations of her arthritis, which became worse.

Examination on admission showed weight loss, arteriosclerosis of retinal and peripheral vessels, enlargement of the heart to the left with accentuation of the aortic second sound and a blood pressure of 175 millimeters of mercury systolic and 100 diastolic. Moderately severe atrophic (rheumatoid) arthritis involved especially the hands, wrists and knees.

Laboratory tests revealed normal findings in the blood (including absence of eosinophilia), pyuria, a negative Hinton test, and normal values for blood non-protein-nitrogen, blood uric acid, icteric index, gastric acidity and basal metabolism. A quantitative Van den Bergh test was normal. Roentgenogram disclosed changes in the joints consistent with atrophic arthritis; a low position of the colon; and essentially negative teeth, sinuses and gall-bladder. Intradermal and scratch tests with the common food and dust allergens were negative.

Treatment was started with a high vitamin diet, salicylates, measures against constipation and renal lavage for pyelitis. A sample of "proteose", isolated from the urine during an attack of urticaria according to the method of Oriel and Barber⁴² gave positive local and focal reactions. In the course of the next two months, desensitization was attempted with small doses of this "proteose". During this treatment, the patient's urticaria lessened and her arthritis improved, but not without one or two severe urticarial attacks apparently due to overdosage with the "proteose".

January 14, 1931, she was given 7.5 grains (0.5 gram) of farastan (mono-iodo-phen). At this time, we were unaware that her previous urticaria had been caused by cinchophen. Four hours later she had a shaking chill, arthralgia, and cyanosis of the extremities, followed by fever, which had risen to 104° F. Ten hours after administration of this drug, the white blood count was 5,800 and the urine examination negative. In the course of the next hours, her temperature returned to normal, but severe generalized urticaria appeared, gradually subsiding in forty-eight hours. No

other cause for her fever and urticaria was found. Her joints seemed definitely improved following this reaction.

January 19, five days later, she was again given 7.5 grains (0.5 gram) of farastan with an exactly similar reaction, including chills, fever to 102° F. and urticaria, of like duration. The joints again seemed to be improved. In order to test the patient's sensitivity to iodine, Lugol's solution, 10 minims thrice daily was administered for a day without reaction. In the course of the next two weeks, she was given two intravenous injections of mixed typhoid-paratyphoid vaccine (15 and 20 million organisms respectively). A rise in temperature of about two degrees was secured with each injection followed by urticaria of about forty-eight hours' duration. The joints showed marked improvement after these reactions.

March 16, two months after her reaction to this drug, scratch tests with farastan in powder form and dissolved in N/10 sodium hydroxide were negative. Ten days later, the patient was given 7.5 grains (0.5 gram) of cinchophen with an ensuing reaction almost exactly similar in character and duration to that obtained after farastan, with a temperature rise to 104° F., urticaria lasting forty-eight hours and improvement in her arthritis. (Figure 1) Three days after the administration of cinchophen, Van den Bergh's test was negative for bilirubinemia.

April 9, a liver function test was done

by Rosenthal's method, resulting in no retention of the dye in thirty minutes. This test was followed by a reaction milder, though similar to those obtained with cinchophen, starting about three hours after the administration of the bromsulfalein. Three days later, scratch tests with cinchophen in dilutions of 1/50 and 1/500 and bromsulfalein in dilutions of 1/20 and 1/200 were negative. Just before her discharge on April 14, attempted transfer of the patient's sensitivity to the skin of two normal subjects by intradermal injection of her serum (Prausnitz-Küstner reaction) was unsuccessful, using cinchophen in a dilution of 1/500. During her hospital stay, she received methyl salicylate (externally), sodium salicylate, luminal, aspirin, Lugol's solution and amidopyrin without untoward effect.

The patient's course was then followed in the out-patient department. April 25, one month after her last reaction to cinchophen, intradermal tests with a 1/500 solution of cinchophen were negative. About June 1, she had an attack of urticaria lasting twenty-four hours accompanied by a gastric upset but without chill or fever. Its cause was unknown. About July 20, she sunburned her legs severely, with a resulting inflammatory edema lasting a week. This was also followed by urticaria lasting two days, and by marked improvement in her arthritis.

October 18, 1931, the patient was brought into the hospital again for a treatment with general diathermy. This consisted in ele-

FIG. 1. Temperature chart of Case III, following the ingestion of 0.5 gram of cinchophen.

vating her temperature to about 104° for four hours, by means of the passage of a high frequency alternating current through her body, with insulation to prevent the loss of heat. The method has been described by Neymann⁴³ and others. Urticaria began about four hours after the patient's temperature had reached 104° and continued for about thirty-six hours. Improvement in the joints was not so marked as following previous febrile attacks.

January 8, 1932, ten months after her last attack of urticaria due to cinchophen, intradermal tests with a 1/500 dilution of cinchophen were again negative.

COMMENT

This patient well illustrates an acquired sensitivity to cinchophen, since her urticaria first appeared following her second course of treatment with this drug. She seems to have developed an increasing sensitiveness; she did not react at all to the first course of two grams, she reacted in the second course only after the administration of 4.8 grams, and thereafter she showed an immediate, accelerated reaction within five hours after the ingestion of 0.5 gram. The duration (eight months) of her urticaria, which evidently began as an allergic drug reaction, is unusual. Perhaps she became sensitive to new extrinsic or to intrinsic (bacterial) allergens. Her febrile manifestations were not unusual. Coca⁴⁴ mentions fever as one of the most frequent symptoms of drug allergy, with temperatures of 104-106° F. frequently recorded. In Menninger's⁴⁵ cases of skin eruptions due to phenobarbital, 51 per cent showed febrile responses. Twenty-five per cent of the cases included in the table experienced a rise in temperature.

It is of interest that this patient showed multiple sensitivity, with identical reactions, to oxyl-iodid, farastan, atophan and brom-sulfalein. The common factor in the first three must of course be the cinchophen group. The last is not closely related chemically to the others, but it also is taken up and disposed of by the hepatic cells. In a survey of the larger series of cases ⁴⁶, ⁴⁷, ⁴⁸, ⁴⁹ in the American literature in which the Rosenthal test was used, a total of 473

patients, no reports of general reactions were found. The urticarial response is probably, then, one dependent upon an unusually hypersensitive individual. We do not consider the urticaria following fever from typhoid vaccine, sunburn, and general diathermy to represent a true allergic reaction, but believe that it may well follow the release of histamine-like substances from damaged cells.

CASE IV

"Neuralgia"; urticaria and liver damage, following the use of atophan; death from sepsis; autopsy.

C. G., an American housewife, aged 60, was admitted to the medical service of the Massachusetts General Hospital on December 28, 1931, complaining of vomiting and chilliness for twelve hours.

The past history included dyspnea on exertion, chronic cough, occasional edema of the ankles and much "gas" for several years. She had suffered from "neuralgia" of the left arm for fifteen years.

About four weeks before admission, she burned her left shoulder with an electric pad. Atophan was incidentally prescribed for relief of her neuralgic pain and in the course of the next two weeks she received about 200 grains (13 grams) of this drug. At the end of this time the use of the drug was discontinued following the appearance of generalized urticaria which persisted for a week. The burn had diminished in size but was not completely healed. For twelve hours before admission, she had vomited continually, and had had chilly sensations.

Examination showed a granulating wound on the left shoulder, the heart slightly enlarged, a systolic murmur, no jaundice, and the liver edge not palpable, although liver dullness continued for about an inch below the costal margin.

Laboratory tests revealed a negative urine, red blood cell count of 3,700,000, hemoglobin 60 per cent (Tallquist), and white blood cell count 20,000 with 92 per cent polymorphonuclear cells and no eosinophils.

The temperature ranged from 102° to 103° F. and the pulse was 110.

During the next two days she continued to vomit. December 30, the quantitative Van den Bergh showed 3.7 milligrams bili-

rubin per 100 cubic centimeters of blood and a liver function test (Rosenthal) disclosed 38 per cent retention at the end of a half hour. A probable diagnosis of acute yellow atrophy of the liver due to cinchophen was made. During the next week, the patient was treated with intravenous glucose and seemed to improve. Her vomiting ceased but she continued to run a fever of 101° to 102° F. and pulse of 100. There was still no definite clinical jaundice and the liver was unchanged in size on physical examination.

January 8, 1932, phlebitis of the left antecubital vein developed and the next day an indurated, red, non-tender mass the size of an egg appeared in the left axilla. This was treated by poulticing. January 10, she suddenly became dyspneic, her pulse rate rose to 150, and signs of consolidation appeared at the left base. Her temperature mounted to 105° F. and the patient died the next day. Pulmonary infarction was believed to be the most likely cause of death. Autopsy revealed a large sub-pectoral abscess on the left, pneumonia, and signs of a generalized sepsis. Grossly, the liver showed no evidence of acute yellow atrophy. Microscopically, central necrosis was found, with a few other scattered areas of hepatic cell destruction. It was believed that the histologic picture in the liver was compatible with either sepsis or cinchophen poisoning.

COMMENT

In this patient, the first sign of idiosyncrasy to the drug was the development of urticaria following the administration of 13 grams of atophan over two weeks. We have no knowledge as to whether she had previously been exposed to cinchophen, but believe it quite likely in the course of a painful illness lasting fifteen years. Prompt omission of the drug did not prevent the development of liver damage, manifesting itself clinically about two weeks later. Although she showed unmistakable signs of hepatitis due to cinchophen early in the course of her illness, the sepsis which developed was responsible for her death, and the histologic findings in the liver were equivocal in nature. Perhaps her resistance to infection was lowered by the hepatic injury. This

would be in accordance with frequent clinical observations.

DISCUSSION

In the table are summarized 41 cases of allergic reactions to cinchophen and its compounds, including all the cases which were found in the literature and the four presented in this paper. We have used only cases in which full reports are given and have therefore omitted mere references to this condition. We have also omitted 25 cases of urticaria occurring in the course of the use of farastan and reported without details in a combined series^{50, 51} of 1389 cases, (an incidence of 1.7 per cent).

The average age of the tabulated cases was 49, a figure perhaps influenced by the fact that the cases treated were largely sufferers from chronic arthritis or gout. Twenty-five, or 61 per cent, were in females and 39 per cent in males. The amount of the drug used before symptoms appeared varied from one gram to 115 grams, the average being 16.6 grams. The duration of administration was two weeks or less in all but five instances, with 5.3 days as an average.

Thirty-five of the 41 cases used cinchophen or atophan before symptoms began, two neocinchophen and two farastan. One patient was found sensitive to both atophan and novatophan and one (No. 40) to oxyl-iodid, farastan and cinchophen. In common with other drugs which often cause allergic skin manifestations, cinchophen and its compounds seem to be more prone to cause one type of dermatitis, although not to the exclusion of several others. In this series, the urticarial type, with erythema, wheals

TABLE I

Case Number	Author and Bibliography	Age	Sex	Preparation Used	Amount and Duration of Usage	Type of Dermatitis or Allergic Reaction	Other Symptoms	Dosage before Second Attack	Interval between Attacks	Nature of Second Attack	Remarks
1	De Oyarzabal ²¹	?	M	Neotophan	1.5 gms. (?) 12 hours	"Itching dermatitis, cecena-like."	None	Same	"Some months"	Same	
2	von Müller ²²	23	F	Atophan	6 gms. (?) "Several days"	Scarlatiniform, itching	Fever of 102°F.	Same	?	Same	Same experience repeated twice with same dosage, not with a smaller dose.
3	Phillips ²⁷	56	M	Atophan	20 gms. 10 days	Purpuric	None	8 gms.	7 days	Same	Repeated with soda bicarbonate; rash milder and lasted only 3-4 days.
4	Ibid ²⁷	45	M	Atophan	4 gms. 2 days	Urticaria	None	4 gms.	7 days	Same	
5	Ibid ²⁷	72	F	Atophan	1 gm. 6 hours	Urticaria	None	1 gm.	7 days	Same	
6	Ibid ²⁷	65	F	Atophan	45 gms. 1 month	Urticaria	None	2 gms.	7 days	Same	
7	Ibid ²⁷	53	F	Atophan	2 gms. 1 day	Scarlatiniform, itching	None	3 gms.	4 days	Fever 103°F., chill, no dermatitis	
8	Herrick ²³	38	F	Atophan	27 gms. 9 days	Scarlatiniform, generalized except face	Fever of 103°F., headache, vomiting, prostration	?	One month	Same	Atophan given a few months before without reaction.
9	Marañón ²⁹	?	M	Atophan	?	Erysipelas-like on head and neck	Chills, fever, depression, scanty urine with extraordinary proportions of uric acid	One tablet	"Few weeks"	Same	Atophan given a few months before without reaction.
10	Ibid ²⁹	?	?	Atophan	"One tablet"	Pruritus without eruption	Chills, fever, depression	1 gm.	One month	Same	Generalized pruritus, vomiting, fever of 100°F. accompanied the second attack.
11	Huber-Pestalozzi ²⁰	56	F	Atophan	17 gms. 18 days	Urticarial and scarlatiniform, generalized except face	None	1.5 gms.	Several days	Red, scaling plaques on face and neck with edema and fever of 101°F.	Six weeks later, similar reaction to 1 gm. of atophan. Atophan used for several years before without reaction.
12	Brammer ³¹	38	F	Atophan	20 gms. 10 days	Pruritus generalized	None	1 gm.	Several days	Red, scaling plaques on face and neck with edema and fever of 101°F.	
13	Kissmeyer ²²	70	M	Atophan	3 gms. 1 day	"Red spots" on face and neck, and edema	None	1.5 gms.	Several days	Red, scaling plaques on face and neck with edema and fever of 101°F.	

14	Thomson ¹³	30	F	Atophan	4.5 gms. 3 days	Scarlatiniform of face and neck	Slight malaise				Chronic nephritis and death en- sued, ? relationship to atophan.
15	Schroeder ¹⁰	37	M	Atophan	20 gms. 10 days	Generalized itching exanthem with edema	Fever, Albuminuria				
16	<i>Ibid</i> ¹⁰	46	M	Atophan	40 gms. 3 weeks	Multiform, itching, with wheals, edema, erythema, bullae	Albuminuria extra-systoles	1.5 gms.	6 months	Same, less severe	
17	<i>Ibid</i> ¹⁰	39	F	Atophan	?	Urticaria, edema	Palpitation, vomiting, rectal bleeding				Tracheotomy nearly necessary.
18	<i>Ibid</i> ¹⁰	50	F	Atophan	25.5 gms. 11 days	Generalized papular urticaria, edema	Fever of 101.5°F. bladder tetanus, laryngeal obstruction				
19	<i>Ibid</i> ¹⁰	38	F	Atophan	28.5 gms. 11 days	Papular with edema and itching, becom- ing purpuric	Fever of 100.5°				
20	<i>Ibid</i> ¹⁰	53	F	Atophan	39 gms. 15 days	"Reddish, itching exanthem"	None				
21	<i>Ibid</i> ¹⁰	57	F	Atophan	21 gms. 14 days	Papular, itching, with infiltration	Headache				Dermatitis following veronal 4 years before.
22	<i>Ibid</i> ¹⁰	34	F	Atophan	8 gms. 2 days	"Itching exanthem"	None	8 gms.	?	Same	Retested twice with same dos- age and result.
23	<i>Ibid</i> ¹⁰	44	F	Atophan and novatophan	21 gms. 8 days	Multiform, with urticaria, edema, papules, erythema	Pyrosis	24 gms.	18 days	Same, less severe	Novatophan used preceding sec- ond reaction.
24	Worster- Drought ¹	59	M	Atophan	16 gms. 12 days	Urticaria	None	0.5 gm.	3 weeks	Same, more severe	Second attack followed by jaun- dice for 3 weeks with recovery.
25	Scully ²⁴	48	M	Cinchophen	"One dose"	Vasomotor collapse	Tachycardia, chill, apprehension, low blood pressure	"One dose"	?	Same	Similar reaction 6 months be- fore after single tablet.
26	Barron ³⁵	44	M	Cinchophen	"2 tablets"	Syncope and vaso- motor collapse	None	"2 tab- lets"	3 months	Same, with erythema and edema	Urine contained albumin. Skin tests negative.
27	Boots and Miller ³⁶	?	M	Nco- cinchophen	2 gms. in single dose	Urticaria	Slight trace of albumin and casts 2 hours later				Patient known to have idiosyn- crasy for salicylates.
28	Schilling ³⁷	74	F	Atophan	1.5 gms. One day	Erythema, edema, itching, "aphthous" ulcers in mouth	None	0.3 gm.	2 years	Same, with dry bron- chitis but no erythema	Bronchitis lasted for weeks.
29	<i>Ibid</i> ³⁷	73	F	Atophan	15 gms. for 10 days	"Aphthous" ulcers in mouth	None				

TABLE I—Continued

Case Number	Author and Bibliography	Age	Sex	Preparation Used	Amount and Duration of Usage	Type of Dermatitis or Allergic Reaction	Other Symptoms	Dosage before Second Attack	Interval between Attacks	Nature of Second Attack	Remarks
30	<i>Ibid</i> ²⁷	?	F	Atophan	0.5 gms. in single dose	Edema of eyelids and "aphthous" ulcer in mouth	Fever and dry bronchitis				Given 1.5 gms. daily for 5 weeks following.
31	<i>Ibid</i> ²⁷	39	F	Atophan	1 gm. in single dose	Scarlatiniform	Circulatory collapse				Eruption occurred during jaundice along with attacks of angioneurotic edema of head, arms and larynx.
32	Sutton ²⁸	27	F	Cinchophen	37 gms., ? duration	Generalized, itching, papular	Jaundice, vomiting, fever. Death from acute yellow atrophy				Past history of asthma with positive skin tests. Six months later, skin tests positive for cinchophen.
33	Fink ²⁸	47	M	Cinchophen	14 gms. 4 weeks	Urticaria, purpura	Jaundice with recovery				Past history of urticaria due to strawberries. Father asthmatic. Six months later, skin tests positive for cinchophen.
34	<i>Ibid</i> ²⁸	54	M	Cinchophen	27 gms. 9 days	Urticaria	Latent jaundice				Farastan taken for one or two days a year before and discontinued on account of epigastric discomfort. Intradermal tests negative 3 weeks later.
35	Miller ²⁹	54	F	Farastan	10.5 gms. 7 days	Urticaria, edema, erythema; later morbilliform and papulo-vesicular	Nausea, anorexia, vertigo, confusion				Treated with intravenous glucose and intraduodenal magnesium sulfate.
36	Eimer ³⁰	52	M	Atophan	115 gms. 41 days	Morbilliform, purpuric	Severe jaundice with recovery				Drug contained in proprietary remedy for rheumatism.
37	Jr. Am. Med. Assoc. Bureau of Investigation ³¹	?	F	Cinchophen	One gm. or less in single dose	Bright red rash from waist up. Edema of tongue and throat	Circulatory collapse				Intradermal tests with 1/500 cinchophen negative 4 months later.
38	Authors' Cases	35	F	Cinchophen	15 gms. 10 days	Urticaria, erythema	Non-productive cough for 3 weeks				Intradermal tests with 1/500 cinchophen negative 2 months later.
39	<i>Ibid</i>	54	M	Farastan	6 gms. 4 days	Urticaria, erythema	Epigastric distress, pain on swallowing				Repeated twice with same result. Skin tests negative.
40	<i>Ibid</i>	57	F	Cinchophen oxyl-iodid Farastan	4.6 gms. 1 week	Urticaria; edema	Chills, fever	0.5 gm. of farastan	9 months	Same	Followed by fever, vomiting, jaundice and evidence of liver damage.
41	<i>Ibid</i>	60	F	Atophan	13 gms. 2 weeks	Urticaria	None				

or subcutaneous edema, was most frequently found, occurring in 16 cases. A scarlatiniform eruption was noted in six and a papular in five. Other types described included purpuric, morbilliform, vesicular and bullous lesions. Three cases cited by Schilling³⁷ showed "aphthous" ulcers in the mouth. As mentioned before, fever accompanied the dermatitis in about 25 per cent of the cases. Five showed various gastrointestinal symptoms (exclusive of jaundice), and in three, albuminuria was noted. In four cases, alarming syncope with vasomotor collapse took place, all recovering. Three of these also had skin eruptions. Rectal bleeding and bladder tenesmus were two other possibly allergic manifestations noted.

In view of the present conception expressed by Rackemann,⁵² that, "little doubt remains but that hypersensitiveness in man is acquired, just as typical anaphylaxis in animals is acquired," it is interesting that 14, or about a third of the cases, developed symptoms after exposure over a period of two days or less, many apparently showing an allergic type of response after a single administration of the drug. In only two of this group was a definite history obtained of a previous use of cinchophen unaccompanied by manifestations of hypersensitiveness. However, with the multitude of proprietary mixtures containing cinchophen and the propensity of sufferers from the arthritic diseases to sample many different remedies, it seems quite likely that previous exposure may have actually taken place without the observer's knowledge.

The mechanism of the acquisition

of hypersensitivity from simple non-protein substances such as cinchophen is as yet not completely understood, although some insight into this problem is given by the work of Landsteiner,⁵³ who has been able to combine many of these substances with homologous animal sera, and thus create compound proteins which have immunologic activity comparable to foreign serum. It is possible to suppose that some such combination may be formed in vivo. The patient might thus become sensitized shortly after the first administration of the drug. The variable, individual response to this sensitization would control not only the appearance or non-appearance of symptoms on further administration, but also their extent and duration when they do appear. In every case in which cinchophen was re-administered, an allergic type of response was elicited, often after a single dose. This reaction was essentially the same in most instances as the initial one, although in one case the dermatitis was absent in the second attack (fever and chill being the only manifestations), while, in another, only the second attack of vasomotor collapse was accompanied by an erythematous eruption. This constancy of response to re-administration (in two cases the patient was retested three times) would be fully compatible with a specific, acquired sensitivity.

Skin tests to cinchophen were negative in six cases, and positive in only two (Fink³⁸), both of these giving a previous history of allergy. Three additional cases (Nos. 21, 27 and 40), also gave a story of hypersensitivity in the past, the first to veronal, the second to salicylates, while the last had

had urticaria of unknown etiology. According to Zinsser,⁵⁴ positive skin reactions in drug sensitivity are not often obtained and "passive local homologous sensitizations by the Prausnitz-Küstner reaction have in general been negative."

In six of the 41 cases, the allergic manifestations were associated with evidence of liver damage. Three of these (Nos. 24, 33 and 34) showed evidence of mild liver involvement immediately following an attack of urticaria, in one (No. 34) a positive Van den Bergh test being the only clue. Worster-Drought's¹ classical case (No. 24), had urticaria following the ingestion of 16 grams in twelve days; three weeks later the patient took only 0.5 gram, with resultant more severe urticaria and jaundice lasting three weeks before recovery. In two other patients (Nos. 32 and 36), the skin eruption accompanied the severe jaundice, along with attacks of angio-neurotic edema in one (No. 32). Although the number of cases is not large, it is easy to see that dermatitis due to cinchophen may be followed by liver damage. Furthermore, as evidenced by cases 33, 34, and 41, immediate cessation of the drug may not prevent this more serious complication. However, as opposed to Worster-Drought's¹ one case where the premonitory urticaria was disregarded and jaundice followed the second administration of the drug, there are 18 other cases which were retested with the drug and Schilling's³⁷ patient (No. 30) to whom cinchophen was given for five weeks

following the appearance of allergic manifestations—all without evidence of hepatic injury. In three of our cases, tests for liver function were normal during or shortly following the appearance of the rash. It is impossible, then, to state that dermatitis occurring in the course of cinchophen administration is necessarily an ominous sign and that liver damage will follow. But we do wish to reemphasize that its appearance should call for immediate and final withdrawal of the drug, along with measures designed to protect the liver, such as the forcing of carbohydrate.

SUMMARY AND CONCLUSIONS

1. Four cases of allergic reactions to cinchophen and its derivatives are presented in detail, and 37 others are summarized from the literature.

2. The pharmacology and the therapeutic and toxic actions of this group of drugs are briefly reviewed.

3. Many cases appear to show an idiopathic, non-acquired sensitiveness, but previous use of the drug is not entirely ruled out.

4. Re-administration has invariably produced a similar allergic reaction, often following immediately upon the first dose.

5. While only six cases were associated with hepatic involvement, the appearance of dermatitis or other allergic manifestations is believed to indicate: first, the immediate and final withdrawal of the drug; second, the prophylactic administration of glucose for at least one week.

A Comparative Study of the Choleric Effect of Bile Salts and Oleic Acid and Bile Salts*†

By
REUBEN FINKELSTEIN, M.D., F.A.C.P., and EMANUEL W. LIPSCHUTZ, M.D.,
Brooklyn, New York

FOR the past year we have employed a mixture of oleic acid and bile salts for the treatment of patients suffering from various forms of gall-bladder disease. The results obtained, which were reported elsewhere¹⁵ were gratifying in a large number of cases. We then decided to undertake an experimental study of the choleric effect of bile salts and of oleic acid with bile salts to ascertain whether oleic acid which has a direct action on the gall-bladder also enhances the well known choleric effect of bile salts. Theoretically, as will be shown later, it appeared plausible that such would be the case. Dr. A. C. Ivy, in a communication to one of us (E.W.L.), encouraged the undertaking of this problem and referred to certain known factors by which he indicated the final outcome of the experiment.

Before proceeding, it is important to define the terms "choleric" and "cholagogue". The two terms are not interchangeable. The term "choleric" is applied to a substance that is capable of stimulating bile formation by the liver and its excretion from the liver.

The term "cholagogue" is used to describe a substance which stimulates the expulsion of bile through the bile passages and gall-bladder.

METHOD OF PROCEDURE

Thirty patients were used for this experiment, 18 women and 12 men, of ages between thirty and fifty years. Of these patients, eight suffered from chronic cholecystitis, two from cholelithiasis, four from duodenal ulcer, two from cholangitis and one from gastric ulcer. The remaining 13 patients on examination showed no gastrointestinal or gall-bladder disease and were admitted to the hospital for other conditions. Each patient was subjected to biliary drainages on three different days. The drainages were conducted over a period of three hours each day. On the first day no stimulation was used, on the second day bile salts were used and on the third day a mixture of oleic acid and bile salts was used. In this manner we were able to compare the quantities of bile collected in a definite period each day.

The Jutte duodenal tube was uniformly used in these experiments. This tube has a small metal tip, which facilitates its passage through the pylorus

*Received for publication June 3, 1932.

†From the Gastrointestinal Department of the Beth-El Hospital.

into the duodenum. It also has a number of perforations for a distance of about two inches at its distal end, thus permitting a more thorough collection of the duodenal contents than is possible with any other tube. To further minimize the possible loss of duodenal contents, the patient was kept in a modified Trendelenberg position throughout the three hour period. The position of the tube in each instance was ascertained by fluoroscopic observation. The time required for the passage of the tube with some manipulation under the fluoroscope was from ten to thirty minutes.

As soon as the tube was in the second portion of the duodenum, ten cubic centimeters of warm water were administered through it and the tube clamped off for a period of ten minutes, after which time it was connected to a drainage bottle and the duodenal contents collected for one hour. Then, second and third hourly specimens were collected separately in a similar manner. No suction was used. On the second day the same procedure was followed, but three grains of bile salts (sodium glycocholate and sodium taurocholate in equal parts) were dissolved in the ten cubic centimeters of warm water. On the third day, with the same procedure, six cubic centimeters of oleic acid, together with three grains of bile salts, were administered through the tube. In 10 of the 30 cases only two cubic centimeters of oleic acid were used with three grains of bile salts.

RESULTS

As shown by table 1, 17 of the 30 experiments showed that there was a

definite increase in the quantity of bile collected on the second day when bile salts were used to stimulate biliary secretion. The lowest increase was 13 per cent, and the highest 180 per cent, the average being 91.4 per cent. On the third day of the experiment when oleic acid was combined with the bile salts, there was a definite increase of bile collected during the three hour period in 25 of the 30 patients experimented upon. The lowest increase at this time was 17 per cent and the highest 444 per cent. The average increase amounted to 143.6 per cent. Increases less than 25 cubic centimeters were not included in these figures.

Gall-bladder bile, or so-called B-bile, was not obtained on the first and second days when only water and bile salts were used as stimulants. On the third day when oleic acid and the bile salts were injected into the duodenum, a dark heavy bile, B-bile, was recovered in all instances with the exception of the cases of two patients whose gall-bladders had previously been removed. The gall-bladder bile, or B-bile, recovered amounted to between 35 and 45 cubic centimeters and in each instance appeared from two to five minutes after the administration of the oleic acid and bile salts through the duodenal tube. In this connection, it is interesting to note that Lyon et al¹, in similar experiments employing sodium dehydrocholate, have reported that they have observed that this substance inhibits the gall-bladder emptying function.

As a general rule, the bile recovered on the third day of the experiment, throughout the entire three hour period, contained an increased amount of

bilirubin as shown by table 2 and also accordingly appeared to be much darker in color than the bile recovered during the similar period on the first two days. Ivy, in his Harvey lecture, New York City, on February 18, 1932, demonstrated that the gall-bladder does not empty at once when stimulated by cholecystokinin. Evidently a similar result follows when oleic acid is used as a gall-bladder stimulant and this may be the reason for the continued presence of darker bile in the three hourly specimens on the third day of the experiment.

In 10 subjects where only two cubic centimeters of oleic acid were used,

the quantities of bile recovered did not average any marked difference from those obtained where six cubic centimeters of oleic acid were used. B-bile appeared within the same period of time, thus demonstrating the marked cholagogue action of even small quantities of oleic acid.

Chart 1 shows graphically the response obtained on the second and third days when bile salts alone and oleic acid with bile salts, respectively, were used as compared with the first day of the experiment when only water was used. An analysis of the curves readily proves that the response to stimulation on the third day was

prompt, the largest hourly quantity being obtained within the first hour.

Table 2 shows some of the chemical and physical changes that occurred in the bile on the different days of the experiment. These figures are the averages for each of the three hour periods. Actually, the bile recovered

during each hour was tested separately and as a rule the dark, heavy B-bile, usually recovered during the first hour after the administration of oleic acid with bile salts on the third day, showed the highest figures in the cholesterol and bilirubin contents.

The specific gravity and total solids

were estimated in each of the specimens. These figures are of little value because of the cellular matter and duodenal debris found in bile obtained by the transduodenal method.

DISCUSSION

The fact that oleic acid causes the gall-bladder to contract and to empty has been amply demonstrated by the experiments of Copher and Kodama², Whitaker³, and Ivy⁴. Ivy and Oldberg⁵ have proved that a fatty acid coming in contact with the duodenal mucosa stimulates the formation of a hormone which causes the gall-bladder to contract and to expel most of its contents. They named this hormone "cholecystokinin". This work has recently been confirmed by Crandall.⁶ One of us (E. W. L.⁷) has shown roentgenologically, that five cubic centimeters of oleic acid, taken orally, will likewise cause a gall-bladder to expel most of its contents within two or three hours. Further work has shown that a similar result may be accomplished with the administration of two cubic centimeters of oleic acid. Stewart and Ryan,⁸ working with various drugs, corroborated these results only when oleic acid was used.

The choleric effect of bile salts has been amply proved by the physiologists of the latter part of the nineteenth and early part of the twentieth centuries. The literature is replete with evidence that the stimulating effect of bile salts upon the liver cells causes an increased production of bile.

Bayliss and Starling⁹ proved a number of years ago that the intravenous injection of secretin not only caused a copious secretion of pancreatic juice,

but also doubled the rate of flow of bile from the liver. Mellanby¹⁰ has shown that secretin stimulates bile formation indirectly by its action on the pancreas, i.e., pancreatic stimulation reflexly stimulates the liver. If the animal is depancreatized, injections of secretin fail to increase the flow of bile from the liver. Ivy¹¹ has shown that oleic acid stimulates the flow of pancreatic juice through an hormonal action. When oleic acid comes in contact with the duodenal mucosa it activates the production of secretin. In the light of the above knowledge it occurred to us that oleic acid should have a choleric effect. Our present study confirms this conclusion.

As to the method of recovering the bile, we find that our results compare favorably with the quantities shown in similar work done by Wakefield and his co-workers¹², on a group of six cases. The average amount of bile they recovered through the duodenal tube in a half-hour period, without stimulation, was 21.2 cubic centimeters. In our group of 30 cases the average half-hourly output, without stimulation, was 30.8 cubic centimeters. Following stimulation they found the average return of bile was 55.6 cubic centimeters per half hour. Our results show 59.1 cubic centimeters in the same period of time, with oleic acid and bile salts stimulation. McClure, Wetmore, and Reynolds¹³ believe that much of the bile excreted into the duodenum is lost because of the normal downward peristalsis and accordingly cannot be recovered by means of the duodenal tube. Okada et al ¹⁴ have concluded that 94 to 99 per cent of duodenal contents is re-

covered through the tube. While we cannot with reasonable certainty say what percentage of contents is actually recovered, we are inclined to concur with the opinion of the latter authors, judging by the relatively uniform quantities we recovered from individual subjects on the different days. There is no evidence in our results of daily gross fluctuations; only increases in quantities that were due to stimulation were noticed. In fact, after noting the quantities collected on the first and second days, we were able to predict approximately the results of the last day's draining. We believe that the patient's position during the drainage period and the type of tube used are factors of considerable importance. It does not seem plausible to assume that by virtue of some unknown coincidental factors, more bile found its way through the duodenal tube on the third day of the experiment, to give us persistent increased quantities in 83 per cent of our cases.

SUMMARY AND CONCLUSIONS

The comparative choleretic effect of bile salts and oleic acid and bile salts has been studied in a group of 30 subjects. In each case the bile was collected by means of a duodenal tube on three different days for three hourly periods. The first day served as a control day, when no stimulation was employed. On the second day three grains of bile salts were used for stimulation, and on the third day three grains of bile salts plus six cubic centimeters of oleic acid were used. In ten subjects, only two centimeters of oleic acid were used with three grains

of bile salts, to detect any possible alteration in the results obtained. The detailed technic is described. The quantities of bile drained on each day were noted, and examinations of the different samples of bile were made for possible chemical or physical changes. Less than 25 cubic centimeters was not considered a sufficient quantity to be accepted as an increase.

The following results were obtained:

1. In 17 patients, the quantity of bile collected was increased on the second day when bile salts stimulation was used. The lowest increase was 13 per cent, the highest 180 per cent, the average amounting to 91.4 per cent.

2. In 25 patients, the bile collected on the third day was increased when oleic acid and bile salts were used. The lowest increase was 17 per cent, the highest 444 per cent, the average increase amounting to 143.6 per cent. The ten cases receiving the smaller amount of oleic acid did not show any appreciable difference in the quantity of bile excreted, and were included in the above figures. Gall-bladder bile was obtained in every instance on the day when oleic acid had been used, with the exception of two cholecystectomized cases. The average quantity of this bile recovered was about 40 cubic centimeters.

3. Figure 1 shows graphically the response obtained after stimulation on the second and third days.

4. While some chemical and physical changes were noted in the different samples of bile, it is difficult to draw definite conclusions in view of the fact that the bile was obtained transduodenally.

As a result of this study, it may be concluded that oleic acid even in small quantities is not only a potent cholagogue but also definitely enhances the choleretic effect of bile salts.

We wish to acknowledge our thanks to Dr. Maurice Vaisberg and Dr. Harry Sherman for their kind assistance in these experiments, and to Mr. Kurt Heinhold for the chemical analysis of the various specimens.

Lobar Pneumonia*†

A Report of 2039 Cases

By OTIS S. WARR, M.D., F.A.C.P., and JACOB ALPERIN, A.B., M.D.,
Memphis, Tennessee

FROM January 1, 1916, to December 31, 1931, inclusive, 2039 cases of lobar pneumonia were observed in the Memphis General Hospital. Of this number, 517 occurred in white patients and 1522 in negroes. During this same period, the white patients comprised approximately one-third of the total discharges from the hospital but only one-fourth of the total number with pneumonia.

INCIDENCE

The morbidity of pneumonia, according to Blake,¹ depends upon the pathogenic properties of the organism, the opportunities for infection, and the factors of susceptibility and resistance. Since neither the Memphis City Board of Health nor the Tennessee State Board makes pneumonia a reportable disease, it is impossible to ascertain its true local incidence. It is well known that the number of cases varies greatly from year to year in all localities. This fact is strikingly illustrated

in chart 1. During the sixteen years covered in this study, the lowest incidence was in 1920, with 44 cases, and the highest in 1931, with 304 cases (chart 5). Thus, in 1920 the 44 cases represented 1 per cent of the total discharges, whereas the 304 cases in 1931 represented 2.8 per cent (chart 1-a).

Institutional statistics such as these offer the only means of estimating the incidence of pneumonia other than mortality tables. Since, as will be shown later, the death rate also varies widely from year to year, these mortality tables give only an approximate idea of the number of cases. The discrepancy is illustrated in a comparison of the incidence and death rate at the Memphis General Hospital with the mortality for the City and State (charts 1, 2, 3, 5).

Chart 1 shows the relative incidence of pneumonia among the rural and urban population for the State of Tennessee. Except for 1918, when there was a sharp rise, probably because of the influenza epidemic, there was only a slight variation in the mortality among the rural white and negro population and but little more among the urban whites. On the other hand, the rate was much higher and more variable among the urban negroes.

CHART 1

Lobar Pneumonia
Memphis General Hospital

CHART 1-a

CHART 2

The crowded, unhygienic living conditions of the urban negroes account not only for the higher incidence, but also for the higher death rate.

The importance of meteorological conditions as predisposing factors in the occurrence of pneumonia cannot be doubted, yet no one has been able to define this relation satisfactorily. Chart 6 shows a comparison between the pneumonia deaths in the Memphis General Hospital and in the City of Memphis, and the precipitation, relative humidity, days of possible sunshine, and the average mean monthly temperature.² In this series, as in many similar studies, no constant relation could be found between any of

CHART 3

the meteorological influences and the pneumonia deaths.

Economic conditions may have some effect upon the incidence of pneumonia. In computing the ratio of

among men because of their occupational exposure, yet the fatalities among the men and women were almost equal in the City of Memphis from 1921 to 1931, inclusive.

CHART 4

business failures per year³ with the pneumonia death rate in the City of Memphis, it was noted that the highest incidence of pneumonia seemed to follow the year of the greatest number of business failures. The comparison, however, is not sufficiently definite to be significant.

SEX

Usually the statement is made that lobar pneumonia is more prevalent

AGE

At what age do most cases of pneumonia occur? Of these 2039 patients, the majority were between twenty and forty years (chart 4). There seems to have been a marked discrepancy, however, between the age incidence and death rate at the General Hospital as compared with the mortality in the City of Memphis and State of Tennessee.^{4,5,6} The rising curve of the

death rate for lobar pneumonia after the fifth decade for the State undoubtedly means that many cases of lobular or terminal bronchopneumonia were included. The death rate for lobar pneumonia in the first decade in Memphis and Tennessee as reported is unusually high. Holt,⁷ in a study of 426 cases, found that over 90 per cent of

ally low, whereas in bronchiopneumonia, which is often secondary, it is always high, it is reasonable to assume that many cases reported as lobar were in reality bronchopneumonia.

PROGNOSTIC SIGNS

In the analysis of this series, an attempt was made to determine those

CHART 5

pneumonia which occurred in the first three years of life were bronchial in type. After the fourth year of life bronchopneumonia is more often secondary to some other condition. Of 3778 patients reported to the Memphis City Health Department as having died of lobar pneumonia, 1079, or almost one-third, were four years of age or under. Since the mortality from lobar pneumonia at this age is usu-

ally low, whereas in bronchiopneumonia, which is often secondary, it is always high, it is reasonable to assume that many cases reported as lobar were in reality bronchopneumonia.

data which would aid in predicting the most probable outcome of the average case. Many physicians have some particular sign or symptom upon which they rely for prognosis, while others maintain that it is almost impossible to foretell the course of any individual case. Loomis aptly stated, "There are some who have pneumonia whom we cannot cure, some whom we cannot kill, and some whom wise treatment

and good nursing will help to recover."

In the 2039 cases of lobar pneumonia of this series, the average height of the temperature, the systolic and diastolic blood pressure, the pulse pres-

a constant pulse rate of 120 or above as "toxic". Thus, pneumonia patients with a persistent tachycardia of 120 or over have a bad prognosis and require extraordinary care.

CHART 6

sure, and the urine tests varied but little between those who died and those who recovered (table 1). A persistently high pulse rate definitely stands out as a reliable indication of the severity of the disease. MacLachlan, Kastlin and Lynch⁸ confirm this and consider all cases of pneumonia with

Leukocyte Count. Of what prognostic aid is the white blood cell count? In actual figures, there was little difference in the count of those who recovered and those who died (table 1). However, when a comparison is made of the white blood cell count, taking into consideration the age of the pa-

tient, it is significant that at the age of twenty years and above, those with a count of 18,500 or below lived, whereas those with a count of above 18,500 died (chart 7). It must be understood that this is an average count

TABLE I
LOBAR PNEUMONIA, PROGNOSTIC SIGNS
(2039 cases)

	Cases <i>Recovered</i>	Cases <i>Died</i>
Average		
Temperature	101 degrees	102 degrees
Pulse	96	122
Blood pressure	108/61	110/63
Pulse pressure	47	47
Urine		
a. Albumin	38%	42%
b. Casts	18%	23%
White blood		
a. Cells	20,202	18,045
b. P.M.N.	82%	79%

and that some patients with a leukocytosis above this figure lived and some with a low count died. A very low leukocyte count signifies a poor response on the part of the patient and a bad prognosis. Finally, emphasis

mann test was 26 per cent, as compared with 27.1 per cent for the entire series. The difference is too slight to be significant.

Lobes Involved. A comparison of the involvement of the different lobes

CHART 8

should be placed on the fact that, in this series, during the period of life when lobar pneumonia is most common (twenty to forty years), the majority of the patients with a white cell count above 18,500 died.

Syphilis. What effect does syphilis have on the prognosis in lobar pneumonia? In this group, 458 patients, or 22.4 per cent, gave a positive Wassermann test. The mortality rate for the number with a positive Wasser-

mann test was 26 per cent, as compared with 27.1 per cent for the entire series. The difference is too slight to be significant.

may be seen in chart 8. Two or more lobes were affected in almost one-fourth of the series. The mortality was higher when the disease was present in both lungs than when two or more lobes of one lung were involved. The lower lobes were involved more than twice as often as the upper, and the right lower more than twice as often as the right upper.

Blood Cultures. Blood cultures were made in 281 cases. In 90, or 32 per

cent, a positive culture was reported. The mortality among those with a positive culture was 52.2 per cent, as compared with 24.2 per cent for those with a negative culture (table 2).

Sputum. The sputum was studied in 574 cases. The laboratory reported a

of early adult life. In this series, the greatest number of cases of Type I, like those of Types II and III, occurred between the third and fourth decades (chart 9).

Previous Attacks. Three hundred and thirty-five patients, or 16.4 per

TABLE II

Total	574	140		90	47	
Average			24.2%			52.2%
Blood culture taken in 281 cases: 32% positive blood cultures						

streptococcus in 49 of this number, and seven of these showed a positive blood culture. Although clinically these were cases of lobar pneumonia, objection might be raised to their inclusion in the series. Of the 426 cases showing a single type of pneumococcus, 180 were Type IV, 104 Type I, 73 Type III, and 69 Type II (table 2). It was interesting to observe the marked variation from year to year in the relative incidence, as well as the mortality of the different types.

It is generally conceded that Type I lobar pneumonia is primarily a disease

cent, gave a history of one or more previous attacks of pneumonia. The mortality of this group was 22.6 per cent, as compared with 28.3 per cent for the remainder of the series (table 3). It is thought by some that one attack predisposes to a second, yet the fact that the mortality was less among those who had previous attacks would indicate a certain amount of lasting immunity.

COMPLICATIONS

In table 4 are listed the most important complications recorded in this series.

CHART 9

LOBAR PNEUMONIA - TREATMENT

CHART 10

Empyema, as might be expected, ranks first. It developed in 53 cases, or 2.6 per cent of the entire number. ably larger number of effusions would have been found. *Pericarditis* was mentioned in only

TABLE III
LOBAR PNEUMONIA — MEMPHIS GENERAL HOSPITAL
(2039 cases)

Summary	No. of Cases	No. of Deaths	Mortality
Pneumonia cases	2,039	554	27.1%
Present attack	1,704	483	28.3%
Previous attack	335	76	22.6%
Positive Wassermann	458	121	26. %

Pleural effusion, on the other hand, was recorded in only 8 cases. There is no doubt that if more exploratory aspirations had been made, a considerable number of cases would have been found. Obviously, this is far too low. Autopsy records show that the incidence of pericarditis is second only to that of the pleural complications.

Doubtless it is overlooked more often than any other complication in pneumonia.

Multiple gastric ulcers complicated

treatment of this series of cases. The groups are too small to justify any conclusions for or against the use of any of these remedies. Nevertheless,

TABLE IV
LOBAR PNEUMONIA—MEMPHIS GENERAL HOSPITAL
(2039 cases)

Complications	Total Cases	Number Died	Mortality	Operative Mortality

one case. Death was caused by gastric hemorrhage, as shown at autopsy.

TREATMENT

In table 5 and chart 10 are listed the various remedies employed in the

it is interesting to consider the results obtained with some of the drugs most commonly employed.

Digitalis. It will be noted that digitalis alone or in combination with some other drug was used in 1231

cases. The average mortality for this group was 31.1 per cent. It was used alone in 745 cases, with a mortality of 22.5 per cent. The highest mortality, 58.2 per cent, occurred in the

Caffeine. Next to digitalis, caffeine seems to have been the most popular stimulant employed. It was used alone in 86 cases, one-half of whom died. When combined with some other

TABLE V
LOBAR PNEUMONIA—MEMPHIS GENERAL HOSPITAL
(2039 cases)

Treatment	Total Number Cases	Number Died	Mortality	Average Hosp. Stay of Those Who Recovered
Digitalis	745	168	22.5%	16.1 days
Dig. and quinine	128	38	29.6%	18.7 days
Dig. and caffeine	175	103	58.2%	21.1 days
Dig. and antiserum	15	7	46.6%	17.5 days
Dig. and pneu. antigen	55	13	23.6%	18.2 days
Dig. and strychnine	26	5	19.1%	12 days
Dig., caff. and quinine	36	20	55.5%	21.9 days
Dig., caffeine and strychnine	36	14	38.8%	17.3 days
Digitalis (alone or in combination)	1231	383	31.1%	17 days
Quinine	44	6	13.6%	14.8 days
Quinine (in some combination)	163	60	36.8%	19.5 days
Caffeine	86	43	50. %	22.3 days
Caffeine (in some combination)	271	154	56.8%	21.6 days
Antiserum	8	2	25. %	12.8 days
Pneumococcus antigen	12	3	25. %	11.1 days
None of the above drugs	636	112	17.6%	14 days
General average			27.1%	17.2 days

group in which digitalis was used in combination with caffeine. Although we did not compare the methods of treatment in 1916 with those of 1931, it is safe to say that digitalis was used routinely more often in 1916 than in recent years.

drug, the mortality was even higher, being 56.8 per cent. It should be stated, however, that this high death rate was not because of caffeine but in spite of it, since it was rarely given except when patients were desperately ill.

Quinine. Quinine was used in the third largest group. It was combined with some other drug in 163 cases, with a mortality of 36.8 per cent. Interestingly enough, the lowest mortality, 13.6 per cent, of any group was in the 44 cases in which quinine was used alone.

Symptomatic Treatment. The next most favorable group was the 636 cases treated symptomatically. In these the mortality was only 17.6 per cent. They were doubtless the mild cases, in contrast to the severe cases treated with caffeine and other stimulants.

Serum. The number who received pneumococcic serum and pneumococcic antigen was too small to warrant any conclusion.

According to popular opinion, pneumonia is a disease which ends by crisis, but in this series the numbers terminating by lysis and by crisis were almost equal (chart 11). The average age of those ending by crisis and lysis was 22 and 25 years, respectively. The ninth day was the average day of crisis in 616 cases in which the exact day could be determined. The average duration of the uncomplicated cases which ended by lysis was twenty-one days.

Considering the large proportion of negro patients at the Memphis General Hospital, an average mortality for pneumonia of 27.1 per cent over a period of sixteen years compares very favorably with statistics from large general hospitals in other sections. Dr. O. W. Bethea⁹ collected statistics from the Massachusetts General, Bellevue, St. Luke's, Garfield Memorial, Cook County, and the Charity Hospital and found that in 1915, of 2012 cases of

lobar pneumonia, the mortality was 32.3 per cent; in 1929, of 2489 cases, the average mortality was 40.4 per cent.

SUMMARY

1. An analysis has been made of 2039 cases of lobar pneumonia observed at the Memphis General Hospital from 1916 to 1931, inclusive.

2. A comparison has been made between the mortality rate for the hospital, the City, and the State.

3. The average mortality rate for the entire series was 27.1 per cent. In spite of the fact that the majority of these patients were negroes, the mortality rate compares favorably with published statistics from other municipal hospitals.

4. A comparison was made of the temperature, pulse rate, blood pressure, and blood count of those who died and those who recovered. No significant difference was found which would aid in the prognosis.

5. The mortality rate of those who gave a positive blood culture was 52.2 per cent, as compared with 24.2 per cent for those with a negative culture.

6. Digitalis was employed in 1231 cases, with a mortality rate of 31.1 per cent, as compared with an average of 27.1 per cent for the entire series and 17.6 per cent for those treated symptomatically.

7. Since lobar pneumonia is not a reportable disease in Tennessee, it is impossible to determine its true incidence or the mortality rate in private practice. There is reason to believe that the mortality rate for those cases treated in private homes is much less than these figures and other published statistics would indicate.

Twins as Biologic Controls in the Study of Human Constitution*

An Additional Approach to the Study of Clinical Medicine

By H. M. MARGOLIS, M.D., M.S., and V. W. EISENSTEIN, M.D.,
Pittsburgh, Pennsylvania

WE physicians who have seen a veritable flood of new discoveries in science have become impressed by the importance of the environment in relation to human disease. The achievements in the field of bacteriology pointed to the identification of many of the infectious diseases, and in many instances led to the complete solution of the problem of contagion and of prevention. The fruitful researches in the study of nutrition, the phenomenal discovery of the vitamins, for example, pointed out factors hitherto unknown in the production of disease. As the web of information concerning the function of the endocrine glands is being untangled, we become aware of still another group of factors—thyroxin, insulin, adrenal substance—which take their place as agents through which physical disease may be understood.

So startling and so important have been these discoveries that of late there has been a tendency at large to think of the mechanism of disease entirely in terms of infection, of metabolic derangement, of neoplastic activity, or of physiologic dysfunction in one direction or another. Many of the

unsolved problems of disease will, indeed, be conquered when attacked from this approach, through researches in bacteriology, biochemistry and biophysics. Still, there are certain questions which remain unanswered, despite most precise objective methods of study. What, for example, is the meaning of "resistance" or "susceptibility" to disease? What underlies natural or racial immunity? Why of two individuals in the same environment, is one chosen for a specific disease and the other left untouched? What are the relative values of the two factors, the environmental and the individual, in the complex known as disease?

To be sure, the medical concept of disease has always been cognizant, in a general way, of the individual himself as a large factor. The element of human constitution in disease has been noted many times in many ways. Hippocrates' humoral theory classified individuals into the traditional sanguinous, choleric, melancholic and bilious tempers. Through the centuries clinicians have repeatedly been impressed by something of the individual's "diathesis" in its relation to his disease. We have long become

*Received for publication August 29, 1932.

familiar with such terms as "phthisic habitus," and "fair, fat and forty," which bear the hint of the relationship of physical structure to disease.

More recently, observers, particularly on the continent, have concerned themselves intensively with attempts to define more precisely the meaning of human constitution. Müller¹, Bauer², Borchardt³, and others have made illuminating contributions, in which one finds an attempt to integrate those basic factors inherent in the individual with those other interplaying elements in man's environment which culminate in disease. In America, the pioneer efforts thoroughly to study man in relation to his disease came from Draper⁴, who, beginning with a study of man's morphologic attributes, proceeded to investigate certain physiologic and psychologic aspects of the individual in an attempt to make something concrete of the concept of human constitution. His studies have yielded data of considerable importance. They have pointed to possibilities of correlating individuals of particular constitutional make-up with their disease susceptibilities. His work is of particular interest to the clinician in that it demonstrates a tendency of certain pathologic entities to occur with striking frequency in some groups, and with relative rarity in individuals "constituted" differently. Here, indeed, is a suggestion that the development of certain disease states is facilitated under certain conditions of human constitution and apparently retarded by others.

Another recent attempt to appraise human constitution has been made by

Petersen and Levinson.⁵ In an extremely detailed and interesting investigation these writers sought to learn something of "the individual constitutional reactivity". This work is an attempt to define "human constitution" in terms of biologic reactions rather than in terms of morphologic attributes. In this respect this newer path should lead to a wealth of important data which, supplementing such studies as those carried out by Draper, should result in a more concrete conception of "human constitution."

The study of human constitution, because it concerns itself with the inherent susceptibilities underlying physical disease in man, does not lend itself to animal experimentation. We cannot add one iota to the knowledge of human constitution by investigations with guinea pigs or rabbits, no matter how carefully conducted and controlled. On the other hand, the study of human material has been hampered by a lack of suitable controls. "The weak link in the chain of evidence in human problems appears to be the biologic controls." And it is for this very reason that the study of human constitution, which is so vitally related to our understanding of disease and to effective preventive medicine, has never lent itself to exact scientific investigation.

This bar to a scientific approach is not entirely insurmountable. To a degree, adequate human controls are available. These are identical twins, one of whom serves as a "control animal" for the other. It occurred to us, therefore, that a study of monozygotic twins should afford a means of measuring the relative importance of

the constitutional susceptibility factor to disease and of the environmental influence. To evaluate the inherent constitutional predisposition to disease, we may observe the progress of certain conditions in one of two identical twins and then note whether a similar effect can be observed on the "control animal", the other of the twins.

This report concerns itself, therefore, with a study of identical twins reported in the medical literature, to determine an answer to the question, "If an individual is by constitution a candidate for a specific disease, would he in another trial at life be prone to develop the same disease?" For identical twins, being derived from the same ovum, are really one individual leading two physical existences. Would two such identical individuals, either in the same or different environments, develop identical pathologic processes? The material collected from the literature offers an impressive array of cases in twins in which the same disease attacked both of identical twins simultaneously, but under conditions which would indicate unmistakably the rôle of a latent *constitutional susceptibility*.

REVIEW OF THE DATA

A review of many different disease entities reported to occur in both of identical twins indicates that the simultaneous diseases of twins can be grouped roughly into two categories: first, conditions arising from obvious developmental defects, which are apparent practically from birth in both twins; second, diseases resulting from less obvious defects, which do not become revealed until a later age.

Identical anomalies of homologous twins have been the subject of numerous reports in the literature. Table 1 affords a résumé of obvious developmental defects observed in identical twins. K. Shirley Smith⁶, for example, reports three cases of congenital heart defect in twins. In each instance both twins exhibited a patent ductus arteriosus. Murray's⁷ review of this subject contains the cases of two sets of twins, in which congenital hypertrophic pyloric stenosis occurred doubly in each pair. His study included summaries of many cases of congenital abnormalities in twins including instances of cleft palate, spina bifida, polydactylism, absence of femora, albinism, and a multitude of other developmental defects. Twins, similarly born with multiple fractures of the extremities and ribs, constituting cases of osteogenesis imperfecta, have been reported by Welz and Lieberman.⁸

Some of the congenital abnormalities of twins do not become manifest until the infants are a few months old. Such are the cases of cretinism and infantile myxedema cited by Hanhart⁹ and by Petschacher.¹⁰ Mongolism has been so often observed in homologous twins that Mitchell and Downing¹¹ believe that in no case has it been demonstrated that mongolism can occur in only one of twins which are the result of a single ovum pregnancy.

Abt¹² calls attention to the fact that identical twins show a ready disposition to rickets, which may become apparent when the infants have reached a few months of development. In this connection, too, Atlee and Tyson¹³ have reported the unusually early de-

velopment of tetany, which rarely sets in before four months of age, but which came to his attention in twins eight weeks of age.

Cases of amyotonia congenita (Oppenheim's disease), not apparent at

not become apparent until later, when normal infantile movements are found lacking.

On the whole, this first series of cases demonstrates the fact that homologous twins often develop identical

TABLE I

Amyotonia congenita (Oppenheim's disease)	1	Forbus, W. D., and Wolf, F. S.: Bull. Johns Hopkins Hosp., 1930, xlvii, 309-322.

birth but manifest in both identical twins at the age of five months, have been described by Forbus and Wolf,¹⁴ who indicate that while the original germ defect is present from birth in the anterior horn cells of the spinal cord, the visible manifestations of the disease, such as muscular weakness, do

flaws in their embryonic building material, which become discernible in the growing infants as a dual anomaly or weakness.

The most interesting of the simultaneous abnormalities of identical twins are those which are presented late in life in a synchronous and often

dramatic manner. These may be grouped briefly into four categories, namely,

1. Neoplastic diseases.
2. Nervous and mental diseases,
3. Non-infectious systemic diseases,
4. Infectious diseases.

The simultaneous occurrence of neoplastic diseases in twins has been reported in a number of instances (table 2), and has in most cases been explained as a manifestation of a developmental defect common to both twins. Illustrative cases in this series are such as have been reported, notably by Croom,¹⁵ Benedict,¹⁶ Leavitt,¹⁷ Burkard,¹⁸ and Champlin.¹⁹ From the Mayo Clinic, Benedict has reported twin sisters who both developed retinoblastoma of the left eye, within seven months of each other. Burkard's report concerns twin sisters, both of whom at the age of 21 years developed fibroadenomas not only of the same breast, but of the same part of the breast. The twin brothers observed by Champlin had both developed small round cell sarcomas of the right testicle within a few years of each other. One of these patients died; the other was saved by timely operation because the diagnosis was early suspected.

Since normally the behavior of identical twins is remarkably alike, their similar mental aberrations are not surprising. By far the bulk of reports upon the diseases of monozygotic twins concerns their identical nervous and mental afflictions (table 3).

Soukhanoff²⁰ has reviewed 33 cases in which the form of mental disease was the same in each pair; and in which, frequently, periods of normality occurred in the psychotic twins at

the same time, even though the individual patients were in separate institutions. Likewise, Duncan and Campbell²¹ have written on 29 instances of mental disease in twins showing duplicate cases of dementia praecox, manic-depressive psychosis, paranoia, and so forth, which came on very often at the same time and in the same manner, and in several instances, even though the individual twins lived in different cities.

In the four sets of psychotic twins reported by Smith,²² the twins rather than the single children in a family became psychotic. This writer pointed out the significant fact that three of the four sets of twins had no hereditary psychopathic taint. Frantz²³ describes twin brothers, again without familial psychotic antecedents, who within two years of each other developed dementia praecox. Similar illustrations of homochronous dementia in twins have been furnished by Marie,²⁴ Worcester,²⁵ Wilson and Wolfsohn,²⁶ and others. Wilson and Wolfsohn cite the interesting observation that there is not a single instance in which dementia praecox occurred in only one of identical twins, and they conclude that when nervous disease thus occurs in duplicate, it is most probably the result of inherent defects present in both twins. Other examples of nervous or mental aberrations have been reported by Gill,²⁷ Clouston and Savage,²⁸ Toledo,²⁹ Hess,³⁰ Targowla,³¹ and others.

The systemic diseases, not of infectious origin, occurring simultaneously in homologous twins, comprise a variety of conditions, chief of which is diabetes mellitus (table 4). W. S.

TABLE II
TABLE SHOWING THE OCCURRENCE OF NEOPLASTIC DISEASES IN IDENTICAL TWINS

Condition	Number of Sets of Twins	Sex	Age of Twins at Onset of Symptoms	Remarks	Author and Reference
Adenocarcinoma with myoma of the uterus	1	F	53-53 yrs.	First menstruated on the same day and from 30 years of age suffered from menorrhagia until the menopause at 50.	Croom, quoted by Murray, G. R.: Lancet, 1925, i, 529.
Papilloma of larynx	1				Szontagh, V., quoted by Murray (<i>ibid.</i>)
Retinoblastoma	1	F		Homologous eye of each twin involved within 7 months of each other.	Benedict, W. L.: Arch. Ophth., 1929, ii, 545-548.
Glioma of cerebellum	1			Death at 6½ and 8½ years, respectively.	Leavitt, F. H.: Arch. Neurol. and Psychiat., 1928, xix, 617-622.
Fibroadenoma	1	F	21-21 yrs.	Surprisingly synchronous development of fibroadenomas of same part of left breast.	Burkard, H.: Deutsch. Ztschr. f. Chir., 1922, clxix, 166-174.
Sarcoma of testes	1	M	24-31 yrs.	Right testicle in both involved by small round cell sarcoma. One lived after early discovery and operation.	Champlin, H. W.: Jr. Am. Med. Assoc., 1930, xcvi, 96-97.

TABLE III
TABLE SHOWING CASES REPORTED OF THE SIMULTANEOUS OCCURRENCE OF NERVOUS AND MENTAL DISEASES IN IDENTICAL TWINS

Condition	Number of Sets of Twins	Sex	Age of Twins at Onset of Symptoms	Remarks	Author and Reference
"Insanity"	33 29			Mostly cases of dementia praecox, paranoia, and manic-depressive psychoses, coming on in twins at about the same time, and in the same manner. Often these lived in different cities.	Soukhanoff, S.: Arch. Med. Psychol., 1900, xii, 8th series, 214. Duncan, and Campbell, D.: Zwillingsirresein u. induziertes irressein, Inaug. Diss. Leipzig, 1902.
"Psychoses" (miscellaneous)	4	F	47-45 yrs. 22-23 yrs. 26 yrs. 43-43 yrs.	The simultaneous onset of psychoses in monozygotic twins is strikingly demonstrated in this series. In one sister no psychosis developed, only a marked religiosity.	Smith, P.: New York Med. Jr., 1912, xvi, 1268-1272.
Dementia praecox	1	M	18-20 yrs.	Developed within two years of each other.	Frantz, M. H.: Jr. Nerv. and Ment. Dis., 1919, I, 325-330.
Dementia	3	F	Menopause	Twins, living apart, developed psychosis same year at menopause. These twins exhibited similar behavior abnormalities although in different parts of institution.	Marie, A.: Encéphale, 1927, xxii, 370-372.
Mania	1	M	26-26 yrs.	Both developed tuberculosis within a month of each other, although one was in the institution two years prior to the other.	Worcester, W. L.: Am. Jr. Insanity, 1890-1891, xlvii, 535-537.

TABLE III—(Continued)

Condition	Number of Sets of Twins	Sex	Age of Onset of Symptoms	Remarks	Author and Reference
Feeble-mindedness with cerebral diplegia	1	M	Early childhood		Wilson, S. A. K., and Wolfsohn, J. M.: Arch. Neurol. and Psych., 1929, xxi, 477-490.
Congenital nuclear ophthalmoplegia	1	F	Early childhood		
Migraine	1	F		Attacks occurred at same time even if they were at different places. Both became insane at same time.	Gill, C.: Jr. Mental Sci., 1883, xxviii, 540.
Paresis	1	M	37-37 yrs.	Infected at same time; died at same time.	Clouston and Savage: Jr. Mental Sci., 1888, xxxiv, 65.
Epilepsy	1	F	8-8 yrs.	Onset of epilepsy within a few months of each other. Both became insane within two months of each other.	Toledo, R. M.: Jr. Mental Sci., 1919, lxxv, 262.
	1	F	9-13 yrs.		Wilson, S. A. K., and Wolfsohn, J. M.: Arch. Neurol. and Psychiat., 1929, xxi, 477-490.
Friedreich's ataxia	1	M	10-10 yrs.		Hess, J. H.: Med. Clin. of North Am., 1922, v, 1749-1755.
Disseminated sclerosis	1	F		Was present in one sister at early age; remained latent in the other until the fifteenth year.	Targowla, R., La Mache, A., and Daussy, H.: Encéphale, 1927, xxii, 487-489.

Curtis³² summarizes 13 cases of diabetes in twins. In the case reported by von Michaelis,³³ twin brothers, both obese, who followed different occupations, at the age of sixty years simultaneously developed diabetes, later leg paresthesias, perforating ulcers of the toes, and great psychic excitement. These brothers died within a few months of each other of uremia.

Another striking illustration in this series of the occurrence of diabetes in identical twins is that cited from Wolfsohn.³⁶ Twin sisters without familial antecedents of the disease, one of whom lived in San Francisco and the other in New York, simultaneously developed diabetes in their fifty-second year, and died within a short time of each other of cerebral hemorrhage. Other reported instances of the occurrence of diabetes in both of identical twins are those of Kückens,³⁴ von Müller,³⁵ Murray,⁷ Twinem,³⁶ Wilder (in a personal communication to Curtis³²) Bunce and Dougherty,³⁷ and Strouse.³⁸

The appearance almost simultaneously of chronic lymphatic leukemia in identical twin brothers has been described by Dameshek, Savitz, and Arbor.³⁹ The brothers, both cobblers, developed symptoms of chronic lymphatic leukemia in their fifty-sixth year and suffered a similar course, and died within sixty-eight days of each other.

Isaac Abt¹² has interestingly presented the fact that he and his twin brother were apparently both victims of cholelithiasis, his twin brother having died of "jaundice" previously.

Among the other medical conditions observed simultaneously in identical

twins have been nephritis,⁴⁰ bronchial asthma,⁴¹ bronchiectasis,⁴² psoriasis,⁴³ cataract,⁴⁴ pituitary anomalies,⁴⁵ Hodgkin's disease,⁴⁶ and Von Jaksch's anemia.^{47,48} In most of these cases the time of onset or the time of attacks was remarkably synchronous in any given set of twins. This tendency was well realized by the brothers reported by Trousseau, one of whom wrote his twin in a distant city: "I am now having my rheumatic ophthalmia, you must be having yours."

The simultaneous affliction of twins by any of the acute infectious diseases, especially the contagious diseases of childhood, are too numerous to mention. Galton¹⁰ and other observers, have noted, moreover, that such simultaneous attacks are most frequent in identical twins, less frequent in heterozygotic twins, and least common in ordinary siblings. Having observed this predisposition to simultaneous development of contagious diseases in no less than 9 out of 35 cases observed, Galton attributed this phenomenon to the like degree of susceptibility and defense mechanism inherited by both twins.

Remarkable instances of bacterial disease acting similarly and simultaneously in both of twin sisters have been described by Kretschmer⁴⁹ (table 5). The father of the twins had suffered with "white swelling of the knee". Within seven months of each other the sisters were admitted to the hospital, neither presenting any signs of active pulmonary tuberculosis, yet both having renal tuberculosis preponderantly in the right side. In both cases extensive calcification of the tuberculous process was found.

TABLE IV
TABLE SHOWING THE SIMULTANEOUS OCCURRENCE OF CERTAIN SYSTEMIC CONDITIONS (NON-INFECTIOUS) IN IDENTICAL TWINS

Condition	Number of Sets of Twins	Sex	Age of Twins at Onset of Symptoms	Remarks	Author and Reference
Diabetes mellitus	1	F	19-67 yrs.		Curtis, W. S.: Jr. Am. Med. Assoc., 1929, xcii, 952-956.
	1	F	3-13 yrs.	Ten years interval between onset of diabetes in one and the other.	
	1	M	10-12 yrs.	Not absolutely identical twins.	
	1	F	17-29 yrs.	No familial antecedents with diabetes. Onset of diabetes 12 years apart.	
	1	M	60-60 yrs.	Also developed simultaneously leg paresis, perforating ulcers, psychic excitement; both died of uremia.	von Michaelis: Arch. f. Rassen- u. Gesellschaftsch.- Biol., 1904, i, 198.
	1	M		Developed diabetes within two months of each other.	Kückens, H.: Klin. Wchnschr., 1925, iv, 2289-2291.
	1	M	advanced age	Both died of same cardiac complication within a few years of each other.	von Müller, Quoted from Siemens, H.: "Die Zwillingspathologie", Berlin, 1904.
	1	F		Diabetes developed the same year, rapid course in both.	Murray, G. R.: Lancet, 1925, i, 529-532.
	1	F	24-31 yrs.		Twinem, F. P.: N. Y. State Jr. Med., 1927, xxvii, 1192.
	1	F	11-11 yrs.	Diabetes developed in one ten weeks after its onset in the other.	Wilder, R. M.: (Personal communication to Curtis).
	1	F	52-52 yrs.	No antecedent family history of diabetes. One lived in New York, other in San Francisco. Both died of cerebral hemorrhage.	Wolfsohn, J. M.: (Personal communication to Curtis).

1	M	27-27 yrs.	No family history of diabetes. Developed the disease within four months of each other. Blood sugars 500-550.	Bunce, A. H., and Dougherty, M. S.: Jr. Am. Med. Assoc., 1929, xcii, 52.
1	F-M	11-11 yrs.	Not identical twins.	Strouse, S.: Med. Clin. N. Am., 1918, i, 1241-1243.
1	M	56-56 yrs.	Death within 68 days of each other.	Dameshek, W., Savitz, H. A., and Arbor, B.: Jr. Am. Med. Assoc., 1929, xcii, 1348.
1	M		Case of Dr. Abt and twin brother. One had cholelithiasis; brother died of jaundice previously.	Abt, I. A.: Jr. Iowa Med. Soc., 1924, xiv, 395-403.
1	M		Died of Bright's disease within seven months of each other.	Galton, Sir F.: Pop. Sci. Month., 1875, viii, 345-357.
1	M		Although in different places developed simultaneous attacks.	Trousseau, quoted by Cockayne, E. A.: Brit. Jr. Child. Dis., 1911, viii, 487-491.
1	F	18-18 yrs.	Similar roentgenographic findings in chest and skull.	von Losow, O.: Deutsch. Ztschr. f. Chir., 1928, ccxii, 71.
1	F	12-13 yrs.	No family history of psoriasis.	Lortat-Jacob, Michaux, L., and Sicard, R.: Médecine, 1927, ix, 122-124.
1	M		Simultaneous onset at advanced age.	Laycock: British and Foreign Med. Rev., 1844, 169.
1	M	16 yrs.	Radiographic evidence of abnormally small sella turcica.	Samaja, N.: Chir. degli organ. (Abstracted in Jr. Am. Med. Assoc., 1922, lxxviii, 765.)
1	M	4-5 yrs.	Developed within 18 months of each other.	Peacocke, G.: Lancet, 1904, ii, 1571.
1	F	12 mos.	One died, other recovered. (Presumably identical twins)	Jones, T. D.: Va. Med. Month., 1927, liv, 283-285.
1	M		Identical pseudoleukemias with similar blood picture, engorged abdominal veins, enlarged spleen and liver. Death about same time.	Dyson, J. E.: Jr. Iowa Med. Soc., 1927, xvii, 321-322.

TABLE V
TABLE SHOWING THE SIMULTANEOUS OCCURRENCE OF INFECTIOUS DISEASES IN IDENTICAL TWINS

Condition	Number of Sets of Twins	Sex	Age of Twins at Onset of Symptoms	Remarks	Author and Reference
Renal tuberculosis	1	F		No active pulmonary tuberculosis. Within 7 months of each other both twins showed signs of bilateral renal tuberculosis, most marked on the right side.	Kretschmer, H. L.: Ann. Surg., 1921, lxxiii, 65-71.
Pulmonary tuberculosis associated with mania	1	M	26-26 yrs.	Both developed tuberculosis within a month of each other; disease ran a rapid course in both.	Worcester, W. L.: Am. Jr. Insanity, 1890-1891, xlvii, 535-537.
Rheumatism	1	F	7 yrs.	Separated at 18 months of age. One lived in London; other in Ontario. Both suffered a good deal from tonsillitis, bronchitis, and rheumatism.	Newman, H. H.: Jr. of Heredity, 1929, xx, 57.
Primary chronic polyarthritis (infectious)	1	M	11-18 yrs.	No familial history of arthritis. Bilateral symmetrical involvement of joints with ankylosis.	Ley, J., and Snoeck, J. J.: Presse méd., 1931, xxxix, 264-268.

The twins reported by Worcester,²⁵ who developed mania simultaneously, likewise both developed pulmonary tuberculosis which ran an equally fulminating course in each.

Another noteworthy instance of simultaneous and similar bacterial activity has been observed by Newman.⁵⁰ Twin sisters were separated at 18 months of age, one residing in London, the other in Ontario. Both had attacks of measles at seven years of age, and subsequently suffered particularly from tonsillitis and bronchitis; both ultimately manifested frank evidence of rheumatic disease.

Primary chronic polyarthritis has been observed simultaneously in identical twin sisters by Ley and Snoeck.⁵¹ The children had no hereditary history of arthritis. However, both, within a few years of each other, developed bilateral, symmetrical involvement of the joints, with ankylosis.

DISCUSSION

The striking occurrence of identical diseases in identical twins, these conditions often developing at about the same time and running so often such a remarkably similar course, has a real bearing on the answer to the questions we have raised. Such occurrence is remarkable but not in the least mysterious. The mechanism behind the simultaneous appearance of disease in twins of advanced age is almost as definite as the mechanism behind the face of a clock, which causes the gong to strike when the hands arrive at the given hour. Let us examine this mechanism, the constitutional factor.

The development of identical disease, in each of two physically distinct

individuals derived from a single ovum, points unmistakably to some common denominator. This factor we choose to call the factor of susceptibility. It really represents a defect in the constitutional structure in each of the two individuals.

When this defect is patent at birth, it may be apparent as a duplicate error of gross morphologic nature. Such, for example, are the cases of congenital heart defects, spina bifida, or cleft palate.

In certain instances the inherent anatomic defect may be less obvious at the start, the abnormality not becoming apparent until a later age. Such, for example, is the case where each of twins is born with under-development of the anterior horn cells of the spinal cord. Since skeletal muscle development depends upon the trophic influence of these motor cells, this development fails, and as a result it becomes apparent at the third or fifth month that the child cannot raise its head well, cannot nurse satisfactorily, cannot move its limbs well, and in brief shows all the features of a case of amyotonia congenita or Oppenheim's disease. What we see is a muscular maldevelopment; what is hidden is the causal weakness in the motor cells of the spinal cord.

While the importance of a constitutional defect in the production of certain congenital anatomic abnormalities is obvious, it is still not often realized that the development of such conditions as diabetes, or nephritis, cholelithiasis, or renal tuberculosis, and probably all disease, is influenced by the constitutional predisposition or resistance to such disease. How can one escape

the conclusion that such an inexorable constitutional influence is at work in the production of identical types of neoplastic disease in identical twins? Such cellular activity must be the result of a ripening process in a hidden pathologic defect which had remained latent for a variable period of years. That such identical tumors may not come to fruition until the fifth decade indicates that a constitutional basis for disease which does not become apparent until late in life must still be sought. If it is assumed that some sort of inherent defect susceptible to neoplastic change is inborn, then it would appear that some adequate environmental stimulus is necessary to determine the ultimate development of the neoplasm.

Functional failures have likewise their counterpart in the category of disease. Under certain conditions of living, for example, a latent functional defect of the islands of Langerhans will become manifest at some later time as frank diabetes, as in the twins here reported. Likewise, an obscure defect of mental function will ultimately spell psychosis in individuals so constituted. The probabilities are, however, that the mental derangement will not occur until the individual either arrives at one of the critical developmental periods, such as puberty or the menopause, or experiences some unusual environmental stress.

Considering the many cases of mental disease, of diabetes, of blood dyscrasias, renal tuberculosis, cholelithiasis, bronchial asthma, arthritis, and so on, observed in identical twins and reviewed in our series, one cannot escape the conclusion that in such twins

the constitutional basis for the development of disease is a tangible factor. The frequent development of identical disease in identical twins at the same period of life, and particularly at different periods of life, indicates beyond the possibility of doubt that the latent predisposition to a given disease lay in wait for these individuals, and depended only upon an adequate environmental stress to become apparent. Clearly depicting such a possibility is the case of twins reported by Kretschmer,⁴⁹ both of whom, within seven months of each other, developed renal tuberculosis, preponderantly in the right kidney. The inherent weakness in this instance was evidently in the right kidney. Disease did not result, however, until this weakened structure in each of the two twins met with the invasive organism. The lungs, and other sites equally open to the attack of the organism were significantly capable of escape. Incidentally, to guess whether such susceptibility is specific for any particular noxa is far beyond present knowledge.

So far it is compellingly demonstrated that in individuals for whom a very specific biologic control exists, that is, in identical twins, the rôle of pathologic susceptibility is a large factor. Through a study of the history of these twins the disease process is seen to be the result of some element in the environment plus the necessary vulnerable spot in the individual. So regarded, disease is seen to be not a capricious event but a necessary sequence that must follow when an individual harboring a definite inborn error is placed in an environment containing many possible

noxious elements. To most of the disease dangers which beset us we are probably not susceptible, else we were all in a bad way, but we all have the equivalent of an Achilles' heel.

of the pathologic process with some inherent weakness. The difficulty lies, of course, in the fact that in any given case one has no control experiment such as nature provides in identical twins.

The question may be raised as to how often identical twins do not present during their lives identical disease processes. Whatever the entire answer may be, this much is certain: that only one of the two twins harboring identical disease potentialities may be subjected to environmental stress of a degree sufficient to bring the disease to fruition. In such cases only one of the two twins may develop outspoken disease; the other will remain outwardly free of its manifestations. Such a process is admirably illustrated in one case reported by Smith,²² where one sister became distinctly psychotic in her forty-third year; her twin showed only a marked religiosity, but no definite psychosis. This religiosity was obviously the expression of a trend to mental aberration. The inference is naturally that there existed here some variation either in the degree of susceptibility or in the degree of environmental stress. That susceptibility to some sort of mental disease existed in both of these twins is, however, clearly evident.

Even in one of diabetic twins, the constitutional factor would hardly be impressive, were it not forcibly demonstrated by the simultaneous appearance of the same disease in the other twin.

If we are justified in the inference that the same causative factors are operative in the production of disease in ordinary individuals as in identical twins, then we may conclude that constitutional predisposition to disease is equally paramount. This predisposition is only more strikingly revealed in twins, because in them it is more readily discernible through their biologic controls.

While recent developments in our knowledge of the causes of disease have focused our attention largely on the external factors, it would seem from our study that this focus has produced some distortion. Too great a rôle has been assigned to the purely external causes of disease, too little to the vital intrinsic mechanism. Had nature provided a biologic control, an identical twin, in every instance of human disease, we should long since have been impressed by the predominant rôle of human constitution.

The concept of human constitution has in the past lacked clarity because it lacked definition. The numerous exceptions to the expected disease potentialities associated with the so-called "phthisic habitus", for example, has detracted from the value of this con-

cept in its practical application to the study of disease. This is not surprising because "habitus" represents only the superficial pattern in the fabric. It is really the warp and woof of that fabric that is the basis of human constitution.

We are only now beginning to study these intimate components of the human fabric. The painstaking studies of Draper and of his associates have already revealed myriads of threads that can now be followed to the individual's disease potentialities. Thus, by detailed anthropometric and psychologic investigations on clinical material comprising a variety of disease entities, they are already able to correlate, to an extent, certain distinct constitutional potentialities with certain definite diseases. The work of Petersen and Levinson enlarged upon the possible indices of human potentiality, by "seeking to define constitution in terms of measurable biologic reactions, rather than in developmental attributes". Their approach is through a study of various physiologic responses of the individual, such as to heat, epinephrine, thyroxin, the effects of manual labor, and other stimuli too numerous even to mention. Just as Draper's data through one mode of approach, so the correlation of these physiologic responses, too, affords a means of appraising various types of

human constitution. We have only begun to unearth the various indices of human constitution. It is to be hoped that the impetus gained from such investigations will in time result in studies that will corral all of the factors comprising the various types of individual make-up. When this has been achieved it is likely that the adequate clinical investigation of a patient's disease will be preceded by the analysis of the individual himself.

SUMMARY AND CONCLUSION

The study of pathologic conditions in identical twins affords an excellent means of discovering disease potentialities.

The element of constitutional predisposition is most clearly evident in identical twins, since one of these individuals serves as a control for the other.

It is suggested that by such controlled investigation and by other related biologic means, including explorations into the chemical and serologic reactions of the individual, the isolation of the specific components of disease susceptibility is made possible. When the clinician is in possession of these objective indices of various types of human constitutions, he will then be in a position to study thoroughly the patient as well as his disease.

SPONTANEOUS HYPOGLYCEMIA VERSUS HYPERINSULINISM

The symptoms associated with an abnormally low blood sugar have become relatively well known to the medical profession in recent years. The advent of insulin brought into prominence the clinical manifestations of insulin overdosage, the so-called insulin shock, and but a few years elapsed before Harris in 1924 drew attention to the spontaneous occurrence of similar attacks which he showed to be accompanied by low blood sugar levels. Such instances of spontaneous hypoglycemia, that is hypoglycemia unassociated with the administration of insulin, have been reported with increasing frequency in the medical literature.

In the milder types of reaction the symptoms consist of weakness, tremor, sweating and sensations of coldness and numbness of the extremities. There may be a feeling of intense hunger, though this is by no means constant. In more severe attacks diplopia and tinnitus may be complained of, and emotionalism, mental confusion and even mania may be observed. Finally, stupor, or deep unconsciousness may develop with or without epileptiform convulsions. The blood sugar in milder cases may not be much below 70 milligrams in 100 cubic centimeters of blood, but in the more severe type of hypoglycemic reaction it is usually less

than 50 milligrams and sometimes less than 30.

It seems well established that the development of these striking symptoms is dependent in some way upon the low blood sugar level since in the majority of cases prompt relief is obtained by the oral or intravenous administration of glucose. In symptomatology, in the presence of a low blood sugar level, and in the relief afforded by the giving of glucose, these cases of spontaneous hypoglycemia parallel the cases of insulin shock. It is natural, therefore, that the condition is frequently called hyperinsulinism.

The use of this term is certainly justified in any case like that described by Wilder, Allan, Power, and Robertson.¹ Their patient at times required 1000 grams a day of glucose to keep the blood sugar above hypoglycemic levels. Operation and later autopsy showed the presence of a carcinoma of the pancreas, originating from islet cells, with metastatic growth in the liver. From these metastases, a large yield of insulin was obtained. This case, however, still stands alone in the completeness of proof of the existence of hyperinsulinism. Almost as convincing are the cases reported by How-

¹WILDER, R. M., ALLAN, F. N., POWER, M. H., and ROBERTSON, H. E.: Carcinoma of the islands of the pancreas; hyperinsulinism and hypoglycemia, Jr. Am. Med. Assoc., 1927, Lxxxix, 348-355.

land, Campbell, Maltby and Robinson,² by Carr, Parker, Grove, and Fisher,³ and by Womack, Gnagi, and Graham.⁴ In these cases relatively small adenomas of the pancreas made up of islet cells were removed surgically with resultant cure of severe forms of hypoglycemic attacks. The demonstration of the insulin content of these tumors is lacking, however, and Bensley, who carefully studied the histology of these tumors, found certain cytological features which were not typical of normal islet cells. But even conceding their insulin content as highly probable, the small size of one tumor (0.5 cm. in diameter), in comparison with the normal islet content of the pancreas, seems to necessitate the conception that such tumors can produce hypoglycemia only through an unregulated secretion of insulin at a time when the blood sugar level is low. So that perhaps the symptoms in these patients were due, not so much to hyperinsulinism in a quantitative sense, as to insulin delivered in an unphysiological manner. The terms *dysinsulinism* and *dysinsulinosis* have been proposed to designate such defects in insulin secretion.

But if there is reason for qualifying the use of the term *hyperinsulinism* in

connection with these cases which possess a definite pathological lesion suggestive of its presence, how much more is caution desirable in the far larger group of cases of idiopathic hypoglycemia to which some authors would apply this term.

The chief factors influencing the blood sugar level are summarized by Cori⁵ as follows:

"The blood sugar level depends on the relative rate at which sugar enters and leaves the blood stream. Maintenance of a constant blood sugar concentration requires an in- and out-flow of sugar of equal magnitude. When this equilibrium is disturbed, the blood sugar may either rise or fall, depending on the preponderance of the processes which contribute or which cause a withdrawal of sugar from the blood. Since the blood sugar of mammals remains normally in the neighborhood of 0.1 per cent, there must exist a regulatory mechanism which is set in motion whenever the blood sugar ranges much below or above this figure. It is now generally accepted that a rise in blood sugar elicits a secretion of insulin and that a fall in blood sugar below a certain level is followed by a discharge of epinephrine. The mechanism of blood sugar regulation is therefore intimately connected with the action of these two hormones on blood sugar production and utilization. Two processes contribute sugar to the blood, namely, absorption of carbohydrate from the alimentary canal and sugar formation in the liver (from glycogen and other sources). The disappearance of blood sugar depends on its oxidation in the

²HOWLAND, G., CAMPBELL, W. R., MALTBY, E. J., and ROBINSON, W. L.: Dysinsulinism: convulsions and coma due to islet cell tumor of the pancreas with operation and cure, Jr. Am. Med. Assoc., 1929, xciii, 674-679.

³CARR, A. D., PARKER, R., GROVE, E., and FISHER, A. O.: Hyperinsulinism from B-cell adenoma of the pancreas. Jr. Am. Med. Assoc., 1931, xcvi, 1363-1367.

⁴WOMACK, N. A., GNAGI, W. B., JR., and GRAHAM, E. A.: Adenoma of the islands of Langerhans with hypoglycemia, Jr. Am. Med. Assoc., 1931, xcvi, 831-836.

⁵CORI, C. F.: Mammalian carbohydrate metabolism. Physiol. Rev. 1931, xi, 150

tissues and on its conversion into glycogen and fat; under certain conditions sugar is lost from the blood on account of excretion in the urine."

It is obvious that the possible causes of hypoglycemia are very numerous, and that hyperinsulinism is only one of these. Aside from a quantitative increase in the amount of insulin formed, there may occur a state in which insulin is secreted continuously or at moments of low instead of high blood sugar. Some have supposed that the secretion of an abnormal type of insulin may explain spontaneous hypoglycemia. It is possible that at times normal amounts of insulin may exert an abnormally great effect because of the absence of some opposing substance. Sugar is known to diffuse from the blood at varying rates. The rate of diffusion of sugar through membranes is affected by the presence of very minute amounts of insulin in the solution. It is possible that factors abnormally accelerating diffusion into the tissues may be at fault in some instances of hypoglycemia. Hepatectomy in animals and extensive liver damage in humans are accompanied by hypoglycemia presumably due to an absence of liver glycogen as a source of blood sugar. Defective liver glycogenesis or defective glycogenolysis may equally then be causes of hypoglycemia. Adrenalin normally causes glycogenolysis, and it is understandable, therefore, that disturbances in adrenalin formation or in its timely secretion may allow the blood sugar to fall to hypoglycemic levels. The relationship of the pituitary to the normal blood sugar is far from clear, but since pituitrin will raise the blood sugar in hypoglycemic patients

one must envisage the possibility that there may occur a type of hypoglycemia due to pituitary disease.

It would be needlessly tiresome to discuss theoretical possibilities if in fact all human cases of hypoglycemia exhibited identical clinical physiognomies and if all whose pancreases had been explored surgically had yielded evidence of lesions capable of producing insulin. Such, however, is far from being the case. The hypoglycemic symptoms in the reported cases of hypoglycemia, while on the whole qualitatively similar, have shown the widest variability in their relationship to such factors as exercise, nervous strain, the intake of food, infections, etc. They vary likewise in severity of symptoms, and in tendency to progress or regress. They differ in the type of response they give to the glucose tolerance test and in the benefit they obtain from the use of high carbohydrate diets or of ketogenic diets. They do not exhibit the same effects from the therapeutic administration of glucose or adrenalin or pituitrin. Moreover the great variety of clinical conditions in which an associated hypoglycemia has been observed is evidence in favor of its production by varied mechanisms. Without mentioning all of these clinical associations it may be stated that hypoglycemia has been reported in connection with hypothyroidism. Addison's disease, adenoma of the adrenal, diabetes, acromegaly, pluriglandular syndromes, scleroderma, fatty livers, eclampsia, after serious burns, and in 36 per cent of a group of 33 moribund patients.

It may well be that closer clinical study of patients who exhibit hypoglycemia and the symptoms that accom-

pany it will enable us to determine more definitely which cases are due to pancreatic tumors of islet tissue. The present evidence would seem to indicate that true hyperinsulinism due to such a tumor is among the rarest causes of hypoglycemia. Exploratory operation may well be reserved for those cases in which the severity of the attacks leads to serious disability or is threatening to life. In the absence of a tumor it would seem on theoretical grounds a dubious procedure to resect a large portion of the pancreas as has been proposed, since in such cases there is at present no way of knowing whether the pancreas has been the cause of the symptoms. It is true that the loss of the major portion of the islets could at the worst be compensated for by insulin injections, but the loss of a great deal of the external secretion of the pancreas may prove to have serious consequences. Reported operations of this type have not yielded satisfactory results. For the present it would seem more in accordance with our actual lack of knowledge to designate all cases of hypoglycemia in which no definite proof of cause exists as spontaneous or idiopathic hypoglycemia rather than as cases of hyperinsulinism.

BEDSIDE TEACHING

There is nothing new under the sun. Hippocrates taught at the bedside; and from the later school at Salerno, there has survived the plaint of a patient at what he had to endure from the cold hands of examining students. Today, bedside teaching is no longer the novelty in this country that it was thirty

years ago, when its inclusion in the curriculum was mentioned with conscious pride in the school catalogue. Yet, it is questionable whether in all these centuries the technic of bedside teaching has been improved or has deteriorated.

Too often today bedside teaching consists of the presentation of the history of a patient by the Clinical Clerk and of a fifty minute lecture at the bedside by the Instructor, who may or may not devote a few minutes of this time to the examination of the patient. The lecture is apt to deal with the metabolic abnormalities, the defective hematopoiesis, or the renal functional pathology of the patient, as with anything that can be seen, felt, heard, or smelled, about his body. It is not that this kind of instruction is not of value, but that to give it at the bedside seems unnecessarily hard on the students' feet.

The *raison d'être* for bedside teaching, is demonstration of the patient. There are many ways, of course, of demonstrating. Physical signs may be taught as a part of the elementary course in physical diagnosis and a comparative study of such signs made on different patients in the ward. For example, an interesting period may be spent in analyzing the various types of respiratory difficulties when there is occasion to observe them in a number of different patients; or students may be shown how to differentiate the commoner small red spots on the patient's skin. Such bedside teaching is usually only possible for the physician who is responsible for the ward and hence knows all of its patients intimately.

Quite another type of demonstration

Dr. D. E. Markson (Fellow), Chicago, Ill.—1 reprint;

Dr. James R. Nakada (Associate), St. Louis, Mo.—4 reprints.

Dr. Emil Weiss (Associate), Chicago, Ill., recently resigned, due to ill health, as Professor of Bacteriology at Loyola University School of Medicine.

Dr. Llewellyn Sale (Associate), St. Louis, Mo., was elected President of the Missouri Social Hygiene Association on January 9.

Dr. Leon T. LeWald (Fellow), New York City, has been elected President of the Medical Association of the Greater City of New York.

Dr. George Morris Piersol (Fellow and President), Philadelphia, Pa., was elected President of the Medical Club of Philadelphia at its annual meeting during January.

The Department of Postgraduate Medicine of the University of Michigan and the Michigan State Medical Society offered a postgraduate course in Pulmonary Tuberculosis, March 20-24, 1933, at the University Hospital, Ann Arbor. Dr. Carl V. Weller (Fellow) gave a paper and demonstration on "Pathology of Tuberculosis"; Dr. Arthur C. Curtis (Fellow) gave a lecture on "Value of the Physical Examination in Various Types of Pulmonary Tuberculosis"; and Dr. Salvatore Lojacano (Fellow) gave a lecture on "Treatment—Fundamentals."

Dr. Francis B. Johnson (Fellow), Charleston, S.C., was elected President of the Tri-State Medical Association of the Carolinas and Virginia at its Annual Session at Greenville, S.C., during February.

Dr. Peter Whitman Rowland (Fellow), University, Miss., was elected President-Elect of the Mid-South Postgraduate Medical Assembly at its Annual Meeting in Memphis, February 16. Dr. Arthur F. Cooper (Fellow), Memphis, Tenn., was re-elected Secretary.

Dr. Frederick L. Fenno (Fellow), New Orleans, La., was recently appointed Consulting Neurologist to the Eye, Ear, Nose and Throat Hospital of that City.

Dr. Aldo Castellani (Fellow), New Orleans, La., was recently appointed Director-in-Chief of the Ross Institute and Hospital, London, to succeed the late Sir Ronald Ross.

Dr. J. O. Elrod (Fellow), Forsyth, Ga., has been elected Vice-President of the Monroe County Medical Society for 1933.

Dr. E. C. Swift (Fellow), Jacksonville, Fla., was recently elected Treasurer of the Duval County (Florida) Medical Society.

OBITUARIES

DR. HENRY G. MEHRTENS

Dr. Henry Mehrtens' death came as a sudden shock to his friends and associates. Stricken on February 13 with coronary occlusion, he did well for a few days, but after a second attack he failed rapidly and died on February 28.

Dr. Mehrtens was born and reared in San Francisco and in 1911 he graduated from the University of California. It was to Stanford, however, that he went for his medical work. Somewhat more mature than the average student, he soon displayed unusual ability not only in his specialty of Neuro-Psychiatry but in administrative medicine; it fell to his lot in various times of emergency to serve as Superintendent of Stanford Hospital, and since Dr. William Ophüls' resignation

uated from the University of California. It was to Stanford, however, that he went for his medical work. Somewhat more mature than the average student, he soon displayed unusual ability not only in his specialty of Neuro-Psychiatry but in administrative medicine; it fell to his lot in various times of emergency to serve as Superintendent of Stanford Hospital, and since Dr. William Ophüls' resignation

last fall he acted as Dean of the Stanford Medical School.

Always a student and bibliophile, and a voracious reader of good literature both medical and non-medical, he had a happy faculty of clear speech and sound exposition which at the bedside or in colloquium sustained the interest of his students. Irrepressible scientific curiosity impelled him and his associates to carry out numerous scientific investigations which have made his name familiar to all neuro-psychiatrists. With his patients he had a unique approach: he rode no psychiatric hobby, adhered to no cult and sustained no exclusive thesis. But with a broad technical training and sound psychological background, tempered with unfailing patience and good humor, he led his patients out of the labyrinth of their difficulties and retained them as lifelong friends. Finally, there should be set down as his major contribution the organization along modern lines of the Psychiatric Wards at Stanford Hospital. Dr. Mehrtens had been a Fellow of the American College of Physicians since 1931.

(Furnished by ARTHUR L. BLOOMFIELD, M.D., F.A.C.P., San Francisco, Calif.)

DR. CHARLES HOWARD
MILLER

Dr. Charles Howard Miller, a Fellow of the American College of Physicians

since 1925, died suddenly from coronary occlusion on February 2, 1933, at the Southern Pacific Hospital in San Francisco.

Dr. Miller was sixty-one years of age, a native of Pennsylvania and resident in California since 1880. He was a graduate of Cooper Medical College, now Stanford University Medical School, in 1896. Except for a period of two years in San Juan, Dr. Miller's entire professional life was spent in San Leandro, where he succeeded to the practice of his father on the death of the latter. Beginning thus as a country doctor in what was then a village some miles from Oakland, but now essentially a contiguous part of the larger city, Dr. Miller became one of the most prominent and probably the best beloved of the citizens of his community, which he served in many civic capacities in addition to his busy professional activities.

As a physician, Dr. Miller always exemplified in highest degree the finest traits which, we like to believe, characterize our profession. He was a member of the Alameda County Medical Association and of the American Medical Association and on the staff of the East Oakland Hospital and of the Highland Hospital.

ANNALS OF INTERNAL MEDICINE

VOLUME VI

JUNE, 1933

NUMBER 12

President's Address*

By F. M. POTTENGER, M.D., F.A.C.P., *Monrovia, California*

ONE of the greatest honors which can come to an internist in America is to have his colleagues entrust to his care and guidance the destinies of The American College of Physicians, for this organization stands for the highest ideals and the noblest sentiments which actuate medical men in the pursuit of knowledge and in the application of medical facts to the prevention and cure of disease, and to the alleviation of suffering. A year ago, on assuming the duties of President, I thanked you warmly for the confidence which you reposed in me, and tonight, I again wish to express my grateful appreciation for this high honor.

In accepting the honor, the President also assumes the responsibility of furthering the interests of the organization by keeping in touch with the members and studying their problems. In his Presidential Address he is expected to comment on the subjects which he considers of special importance to the College, either in conducting its inter-

nal affairs, or in advancing and upholding its standards in laboratory and clinical practice; or upon special problems which may confront the College at the time, or press for solution in the near future.

The internal affairs of the College seem to be in good order. Its position in American Medicine is unquestioned. It numbers among its members men who are representative of the best in research, teaching and practice. By the intimate association of its members medical knowledge is furthered, the enthusiasm of the members is increased, and friendships are cemented. While there are many fields in which our organization may direct its energies in the service of Medicine, it has seemed wise thus far to confine our efforts to strengthening our own organization. Heretofore our members have preferred to have the College stand for leadership in medical thought rather than in organization, yet questions of a vital economic nature are arising today both in Medicine and in the body politic which are forcing themselves upon us and calling for leadership in their solution. Would it

*Read at the Seventeenth Annual Clinical Session of the American College of Physicians, Montreal, Canada, February 6-10, 1933.

not be well for the members of the College to answer this call and give to the solution of these problems the aid of their well trained minds?

THE OPEN MIND

From the time of Hippocrates, interest in the study of Medicine has been stimulated by the fact that it has been a continuous excursion into the unknown. New fields to be investigated have required new methods of procedure and taxed the ingenuity of the curious. New facts obtained have called for imagination and patient observation to determine the manner in which they were to be utilized to improve conceptions already held.

One of the difficulties met in the development of Medicine is that which attends advancement in any unfolding science, that of putting a true value both on the ideas already held, and on the new ones which are advanced from time to time.

The medical mind can never become static. It is necessary only to look back a few decades, to see that ideas which were accepted as guiding principles, now, as a result of further investigation, are either greatly modified or wholly displaced. We have many facts which are safely grounded; and many more which, though accepted, are not fully proved.

The open mind in science is the only safe mind, the only mind that can be expected to progress and utilize knowledge as it is acquired. It is the mind which, knowing its limitations, receives new things sympathetically, critically, but with a readiness to displace prevailing belief, no matter how well it seems to be founded, by any new knowledge that may be definitely

proved. Thus, Medicine calls for an openness of mind and a criticalness of judgment such as it is almost impossible to attain. It demands a conservatism born of knowledge and experience, combined with the liberality of the adventurer who considers the known as never final, but always subject to change with increased experience.

Edison is credited with having approached new theories with a rare open-mindedness and to have classified them into two categories: one, that which agreed with what he believed to be true; the other, that which did not agree and so was to be investigated. It requires a well organized and controlled mind to classify data as agreeing or disagreeing with "what one *holds to be true or false*" rather than with "what one *knows to be true or false*." Such a man might never be able to speak with the dogmatism of authority, yet he would be a safe leader to follow, for knowledge to him would be an open book with every page unfinished.

Medical progress has come through continuous questioning. A leader who progresses along accepted lines and pushes the outposts of knowledge a little further than those previously established, but does not depart too much from the known, is readily followed by his confreres; but the leader who climbs over the sides of the groove which confines prevailing thought and constructs a bridge into the unknown, is followed by few. He at once meets opposition from those who are satisfied with their own beliefs and whose minds can not or will not follow.

There is a general belief that the human mind hungers for knowledge,

but it also must be apparent that it often shows a strong tendency to resist the knowledge which would satisfy the hunger; for, as has been so aptly said, "As a means of retarding the entry of unusual notions the human cranium is a well-nigh perfect mechanism." This was well illustrated in the slowness with which the works of Harvey, Jenner, Pasteur and Lister were accepted by the leaders of Medicine of their day, and in the hostility with which new ideas in the economic field have always been met by the followers of *laissez faire*. Original investigators who conquer the unknown generally receive their greatest recognition after they have passed on, but continue to receive it until the horizon becomes dimmed by time.

In this generation, progress has been made so rapidly in all fields of endeavor that even those who have added greatly to the sum total of our knowledge are apt to go unrecognized. We have many such who sit at the meetings of this Association. They walk among us so freely that we forget the contributions which they have made. We accept their gifts of knowledge with less ado than we accept gifts from friends; yet if a few score of these creative minds, with their contributions to science, were removed from the Medicine of the present generation, our profession would be comparatively barren of interest.

The members of the College have certain obligations to fulfill, not alone in Medicine but as leaders in this period of reconstruction which is upon us. A prime essential of leadership is an open mind, an ability to recognize the fact of an ever-changing present and envisage a future which will probably

be characterized by still greater change. One must be able to look forward for the solution to unsolved problems, not backward. The fundamentalist can not satisfy the inquiring mind of the present generation nor successfully solve the problems which confront it and future generations by looking back to the interpretation of moral and religious problems as given centuries ago.

TRENDS IN DEVELOPMENT OF PRESENT-DAY MEDICINE

The greatest advance which Medicine is making today is in the prevention of disease. The greatest advance in the domain of clinical practice is being brought about through a better understanding of its physiologic side. Until the immediate past, structural anatomy and structural pathology dominated the entire field. Symptoms which were unattended by recognized anatomical change were considered to be of no importance no matter how much they distressed the individual, and were ignored by able clinicians. Physicians regarded such symptoms with unconcern until sufferers began to seek aid from various irregular practitioners. This failure to grasp the importance of disturbed function is almost incomprehensible today, because the practice of Medicine is centered about a desire to understand the cause of symptoms, and to apply remedies which will relieve them.

Just when Medicine appeared to be definitely established on a structural basis, and organic lesions seemed to be secure in their occupancy of the entire stage of interest, a disturbing element entered in the form of new developments in the field of physiology. Advances in biophysics, biochemistry,

neural physiology and endocrinology came swiftly to the fore, and the importance of psychic reactions became appreciated as never before. We then learned that many of the symptoms which physicians are called upon to treat are changes in function without structural change in the organ showing the physiologic disturbance. We were then able to appreciate the ridiculousness of such statements as were current but a short time before to the effect that 90 per cent of the patients who visit doctors' offices have nothing the matter with them.

Physiologic studies emphasize the fact that the human organism is a united whole, in which the action of any one part may be influenced by every other part; and physiologic balance and imbalance now begin to assume great importance in the definition of conditions of health and disease. The cause, whether constitutional, environmental, structural, physiologic or psychologic, matters less than the fact that the patient is ill.

Approached from this angle, Medicine becomes a more rational study. It becomes both a physiologic and anatomic study. The fact that constitutional factors determine to a large degree the manner in which a given individual will react to environmental stimulus now becomes evident.

The nervous system, both somatic and vegetative components, each in its integrative action in its own separate field and in the interplay between skeletal and visceral structures now assumes an unexpected importance, not only because of its central reactivity to chemical and physical stimuli, but also because of its function in producing physiologic and pathologic reflexes.

Only by developing a more accurate knowledge of the vegetative nervous system can we understand the efficient correlating mechanism by means of which unity of action is brought about and maintained in distantly separated organs through centers in the brain and cord both during conditions of health and in states of disease.

Hormones, vitamins and salts, in normal proportions, as circulating regulators of cellular activity during health, and, in abnormal proportions, as disturbers of cellular activity during illness, become important determining factors in many aspects of physiologic and pathologic function. The electrical reactivity of cells seems to hold much in store for explaining body reactions, although as yet it is vague in the minds of most investigators. The pH of the tissues also bulks large in importance.

In physiologic Medicine, psychic reactions assume a prominence in the health of individuals which approaches in importance that of structural change, and which often proves to be of greater importance to their happiness. No matter what the disease, it has its psychic component which will either help or hinder recovery.

Physiologic Medicine is more difficult to comprehend and develop than anatomic Medicine, but medical science and practice can not be rounded out until this subject has been thoroughly investigated. It is more elusive and more erratic than anatomical studies. There are more variables in each problem. The field of study can not be embedded in a fixing solution and prepared for microscopic investigation. Physiologic reactions are subject to all changes which depend on inherited and acquired constitution, and on the adap-

tation of the living processes to environment in its broadest sense—both internal and external, both physical and psychical.

The rapid decrease in mortality in early life has permitted many with weak constitutions, who formerly would have succumbed to disease in infancy and childhood, to live and attain the age in which the human machine shows more plainly the effects of wear and tear, the age in which the degenerative diseases hold sway. This has forced Medicine to become increasingly interested in the patient as well as in the cause of the disease and the cellular changes produced by it.

Inherited qualities; physical and chemical constitution, as determined at birth and modified by environment; correlation and integration of activity through the hormones and nervous systems; and lastly the psychical structure of the patient now call for as full consideration as cellular pathology and the cause of infectious disease did but a short while ago. This shift adds a new, and in the minds of many men a greater, interest to Medicine.

Heredity, although its meaning was poorly defined, had been considered to play an important part in certain diseases prior to the time that their etiology was discovered; but, as specific causes, one by one, were discovered, heredity was forced for the time being to occupy an insecure position. With greater fundamental knowledge, however, we are learning that heredity plays some part in all diseases, and a very important one in many.

We assume that to attain old age one must be endowed with an anatomic and physiologic mechanism which adapts itself well to the work that it must do,

and meets the changing requirements of environment in a satisfactory manner; and further, that it does not become incapacitated by misuse, abuse or illness.

If the individual passes through early childhood, the chances are greatly in favor of his reaching adult life. Among those who attain adult life are many who are fit to live only because conditions have been made especially favorable for them. On the other hand, we must look upon the attainment of advanced age by most people as being due to a better, more virile stock. Captain MacMillan, the arctic explorer, once told the writer that the survivors of lost expeditions in the arctic were not saved by accident, as is commonly believed, but that their survival was evidence of a better heredity, a more rugged stock. He further said that nearly all such survivors, instead of having their bodies weakened by the exposures and hardships, endured them without apparent injury and lived to a "ripe old age".

SPECIALIZATION

One of the very interesting and important phases in present-day Medicine is the development of the specialist. While specialization is not new it has become a dominating characteristic of the Medicine of the last quarter of a century. It is the natural sequence of fruitful, systematic investigation.

With the rapid advance in knowledge at the turn of the century so many new facts were being brought forth that specialists became necessary in order properly to apply them to research and practice. When we behold the present highly specialized status of Medicine it is difficult to realize that

we are only one generation away from the general practitioner who applied, in treating the patient, all of the facts that were then known to all of the diseases that were recognized.

During the past quarter of a century keen observers have interested themselves in nearly every individual phase of Medicine; individual diseases, diseases of individual organs and systems, even symptoms caused by certain body reactions. They have set these subjects apart for special study, picking out the data which bear particularly upon the subject under investigation.

Individual men have chosen for special study those phases of Medicine which have appealed to them most, and so have added a sympathetic interest, which accounts for much of the rapid progress. Once started, the idea of specialization grew rapidly. It seemed impossible for single minds to comprehend and accurately weigh the new facts which were being added to the sum of medical knowledge and to apply them to medical subjects as a whole. Only through the study of limited fields was great success possible. By intensive specialization, in the short space of two or three decades, our knowledge of many subjects has been well systematized and our opinions and impressions have been replaced by facts.

We are today so accustomed to being directed and protected by the laws of public health, for example, that it seems as though this important phase of Medicine, calling as it does for highly trained specialists, must always have existed; yet the public health official had little scientific background and small reason for existence until the latter part of the nineteenth century,

when bacteriology developed and the theories that disease was due to supernatural powers and miasmas were displaced by actual proof of the cause of contagion.

Specialization during this developmental period threatened General Medicine with disaster. Its influence was largely disintegrative. It tore Medicine asunder, divided it up into many parts and attempted to create many separate entities. But strange to say this disintegration finally checked itself and resulted in a demand for a new assessment of values; for, as each specialty developed further it became more and more apparent that it was not a separate medical entity but only a part of Medicine as a whole, and a much more intimate part than some of the earlier specialists realized.

We now find that each specialty has resulted in enriching Medicine as a whole to the extent of its individual development; and Medicine, divided by the multitude of specialties during the period of their development, is now being reunited into a completed whole in which the internist is able to render a greater service than the specialist could give but a few years ago. That this process of unification and coördination is well under way is evidenced by the high character of service which is now being rendered by internists in fields which were limited to specialists but a short time ago.

Specialists will probably always be necessary, but their position will doubtless change. In the future the specialist, in the more restricted sense of the term, will probably assume the rôle of consultant in his particular line, and internists will specialize in those subjects which interest them predominant-

ly, but not to the exclusion of other phases of Medicine. In this way the narrowing tendency of specialization will be checked.

THE INTERRELATION BETWEEN MEDICINE AND GENERAL ECONOMICS

Much of the recent discussion of medical economics has not taken sufficiently into account the relationship of medical problems to the general economic condition.

The relationship which Medicine bears to the public was established before the birth of public health with its life-saving campaign and before the advances in science and technology were allowed to destroy the stability of industry. The logical solution of the problems of medical economics depends on the solution of the problems of general economics. If the state is to control industry, it will and probably should control Medicine. If, on the other hand, we are able to maintain the principle of individual effort in industry, it is but justice that the same principle should be applied to Medicine. Just at present, however, it appears as though Medicine were being forced to make an adjustment to an unadjusted and an admittedly unsatisfactory general economic system. If an open mind were ever needed in the solution of problems in Medicine, it is today.

The rapid development of modern Medicine has been made possible through advances in the cognate sciences. This in turn has called upon those desiring to practice Medicine or to engage in research to spend much time and money in preparation. It requires of the student who would fit

himself for the practice of Medicine an expenditure of from ten to fifteen thousand dollars, and the loss of earning power for the seven to ten years spent in study, a total of some \$15,000 to \$25,000.

While the cost of medical education has been increasing in recent years, changes have been going on within Medicine itself, as well as in our economic system, which tend greatly to alter the status of the profession; and, with present trends, to make its position in the body politic insecure. This situation is growing more and more serious, and must be carefully considered by present practitioners and prospective students.

Physicians are attempting to carry out principles of altruism, living ethical lives and following high traditions, in a competitive age which is characterized by uncontrolled ambition for profits. Laymen do not understand the motives which underlie the ethical acts of medical men. The aims and methods in Medicine are so foreign to those prevailing in business that it is impossible to furnish the laity with an intelligible explanation of our course of action. Were a business concern to foster methods which would limit its chances of economic success, the act would be looked upon as being not only foolish but one of insanity; were a business firm to refuse to take on a new purchaser because he was a regular customer of another firm, the act would be considered as contravening all business principles. On the other hand, were business concerns to adopt the altruistic spirit of physicians and take less profits, or no profits at all, from those who are unable to pay for their goods, it would soon change the

ruthless psychology which dominates modern economic life. Medical men do all of these things regularly as a part of their ethical standards.

Sentiment causes physicians to give their services to the sick poor without compensation. This they do gladly because they realize that they are not dealing with inanimate substances such as merchandise, but with human beings. Unfortunately, however, this very altruism exaggerates an already firmly established belief in the minds of laymen to the effect that medical service costs the doctor nothing, and that it is the province of Medicine to care for those for whom our present economic system fails to provide. Those ideas should be corrected, for they prevent the physician from being adequately compensated. Laymen should be made to appreciate that lengthened life, decreased morbidity and increased efficiency through relief from illness have a monetary value.

We shudder at the idea of State Medicine, yet under recent economic conditions during normal times the state furnishes medical care for a large percentage of the population, some justly, some unjustly, or at least questionably; as for example, veterans of the World War whose illness has no connection with service. Medical men vie with each other for positions on the staffs of charity hospitals where they give their services without remuneration. Many students of the subject put forth the argument that it is not fair that, of all services to the

poor, medical care alone should be furnished without cost. State Medicine, sick and accident insurance, unemployment insurance, old age pensions and group care are some of the many plans that have been suggested to insure adequate medical care to those who can not readily pay for it out of their earnings. Whether medical men are favorable to the idea or not, unless adequate changes are quickly made in general economics, some of these plans will be adopted. To the extent that they contravene the individual relationship between physician and patient they will be unsatisfactory; to the extent that they guarantee a better medical service to the people and give more adequate remuneration to the physician for services rendered they will be acceptable.

Perhaps there is no better way to obtain an idea of the problem of medical economics and no way better to judge the ability of people to pay for medical services than to study the incomes of groups of the population. Numerous surveys have been made, but I shall use the data obtained by the Commonwealth Club of San Francisco in 1931, and that acquired by the Committee on the Cost of Medical Care. Let me say, in passing, that conditions in San Francisco are much more favorable to the working classes than in many other cities of the country, for labor has had a large share in the government of this city.

The following is the grouping of incomes as brought out as a result of the San Francisco survey:

14 per cent of incomes were less than	\$1,000
30 per cent of incomes were from	\$1,000 to 1,500
35 per cent of incomes were from	1,500 to 2,000
14 per cent of incomes were from	2,000 to 3,000
5 per cent of incomes were from	3,000 to 5,000
2 per cent of incomes were over	5,000

If these statistics are analyzed from the standpoint of the population's ability to pay for medical care, it gives little comfort to physicians.

There is no fixed standard by which we may determine who can pay for medical services, and what the fee should be. It is supposed to be based upon the financial status of the patient, but this is determined not alone by the amount of a given income but by the demands made upon it. An unmarried individual without dependents naturally can pay a much larger fee than the head of a family with the same salary.

That portion of the population with dependents to care for, who receive salaries below \$1,500 a year, are not in a position to pay very much for medical care, for it is estimated that bare necessities cost about \$1,500 per year for a family of four persons in the larger coast cities. Unless more than one member of the family is working, those belonging to this group are forced to obtain most of their treatment in free clinics and public hospitals.

The 35 per cent of people with incomes from \$1,500 to \$2,000 with dependents to care for, should be able to finance ordinary illness requiring only a few visits of the physician, but long illness, or illness requiring the services of medical or surgical specialists, could not be financed except by markedly reducing the family's living standard.

Thus we have 79 per cent of the population of San Francisco, according to these statistics, who are unable when ill freely to consult physicians. This leaves 21 per cent of the people who might be considered as able to pay for medical care.

Now, turning to the findings of the

Committee on the Cost of Medical Care, we find that, based on a twelve months' survey made during 1928-1931, the combined earnings of the members of 50 per cent of the families in the United States amounted to less than \$2,000 a year, and of 40 per cent, amounted to from \$2,000 to \$5,000. Their report also shows that 80 per cent of individuals had incomes less than \$2,000; and 95 per cent, less than \$3,000. One fact which was brought out by the report is that 4 per cent of the families with incomes under \$1,200 per year, collectively, spent as much money for medical care as 80 per cent of the same families, collectively. This is discussed along with other findings and interpreted as showing that the uncertain cost of medical care and the inability of the people to meet such cost readily is deterring people with small incomes from freely consulting physicians. If medical care is a necessity, however, as we certainly believe it to be, this should be interpreted as showing that people do not have sufficient income to pay for the necessities of life, and should call for adjustments in general economics rather than sacrifice on the part of physicians, for the same people are unable to supply themselves adequately with other necessities such as food, clothing and shelter.

Public health and sanitary science, by creating a better environment to live in, have protected and strengthened the race, lowered the incidence of disease, and markedly reduced mortality. Based on these facts optimists have dared to express the hope that infectious disease may be eliminated from the face of the earth. Whether such a desideratum may or may not be accomplished, at least every increase in bac-

terologic and epidemiologic knowledge, and every advance in sanitary practice brings such an accomplishment nearer of attainment; and, simultaneously, restricts further the field of medical practice.

General mortality has been reduced 50 per cent during the past 50 years. infant mortality 60 per cent in 20 years, and life expectancy has been increased from 40 to nearly 58 years in the past 40 years. Where only one-half of the population could expect to survive the eighteenth year one hundred years ago, one-half of those born today may expect to live to be 66 years of age; and one-fourth, 76.

While the population, as a whole, has greatly profited by these accomplishments, medical practice and economics have undergone changes which demand readjustment. Physicians have been deprived of a large source of practice among children whose medical care is paid for by parents during the most prosperous period of their lives. They find themselves instead treating an ever-increasing number of older people during the period of declining efficiency, when their earning power is decreasing and when, too often, they have already reached a state of dependency. Also they find themselves treating an increasing number of people with small incomes and an increasing number of the unemployed.

The reduction in illness and mortality in early years, and the rapid increase in life expectancy, have not only brought about important changes in the trends of study, practice and economics of Medicine, but at the same time have exerted a definitely disquieting influence upon the general economic

condition of the country. These influences are so subtle that they have scarcely been appreciated, and therefore have not received the attention which their importance demands.

At first glance it would seem that the effect of an increasing number of people reaching adult life should be favorable to medical practice, and this would be the case if continuous employment at adequate wages were obtainable for all, so that physicians might be freely consulted when sickness arises; but, unfortunately, the number of people who are competing for employment is increasing at a time when, on account of the changes in our industrial system, fewer workers are required. Chase says that every census for an hundred years showed an increased number of men in the factories until the late war, after which production has gone steadily up, increasing 70 per cent between 1914 and 1927 with the number of employees as steadily decreasing. While 1929 was the peak year of production in industry in the United States for all time, yet there were one million and a quarter more workers idle than in 1923. We are saving lives and enabling men to live to old age, but are not making provision for them in our economic system. Therefore, increased longevity may prove to be a curse to those who attain old age, and it may throw an added burden on the physician in the way of more illness to care for without increase of his compensation.

As has been seen, workers who receive \$1,500 and less per year represent a very large proportion of our population. As an example we cite the shoe industry, which in 1925 paid an

average annual wage of \$1.090 per worker. Workers reach their highest earning capacity at the age period of 43 to 55, after which their earnings decrease; and since the earnings for most of this class have been barely sufficient for necessities during their most productive period, savings for sickness and old age have been scant or have amounted to nothing at all.

We may appreciate the effect which a shift of a large portion of the population to the higher age periods may have upon the medical profession, and also on the general economic condition of the country by determining the proportionate changes which the percentage of the people in the various age brackets has undergone in recent years. Fortunately we have for comparison the statistics of 1870 and 1920.

In 1870, when mortality in childhood and adolescence was high, the death rate was so great that 49.5 per cent of the population was in the age period from birth to 19 years. By 1920, largely through the application of preventive health measures, so many more people had already lived through childhood and adolescence and passed on to adult life that only 40.3 per cent of the total population were found between the ages of birth and 19 years. In the same 50 years the percentage of those between 20 and 44 years had increased from 12.6 to 16.9 per cent, and those above 65 from 2.9 to 4.5 per cent of the population.

The significance of this shift may be clearly seen by reducing the changes to percentages of the 1870 population.

During the 50 year term, the percentage of the total population included in the age-group from birth to 19

years decreased 19 per cent. The percentage of the population from 20 to 44 years, during these same 50 years, increased 9.4 per cent; giving 9.4 per cent more workers for whom employment must be provided during this most productive period of life. Those from 45 to 64 years increased 34 per cent, furnishing another very large group for whom work must be found; and those above 65 years increased 55 per cent, more than doubling the number of people in this period in which dependency and illness are most frequent. During this same period immigration also brought many workers into the country to compete for employment.

The shifting in age groups will become still more serious when, as we are told by statisticians, in a few more years our population becomes stationary and the younger group will constitute only about 30 per cent of the population, while 10.7 per cent, an increase of 138 per cent over the figures for 1929, will be over 65. The stationary period in the growth of our population will be hastened by the stop which has recently been put to immigration. Industry must take this reduction in purchasing power of future domestic consumers into consideration.

In order more fully to appreciate the interrelation between medical and general economics, we must examine the changes which have been wrought in our general economic system and the factors which have been responsible for them.

For four thousand years prior to the discovery of steam power there had been practically no change in man's productivity. Handicraft ruled the

world. There was no machine problem. There were no labor crises. There was no game of industrial warfare.

Steam ushered in a new era, and caused machines driven by the new power to compete with handicraft. In these early years the machines were thought to be inventions of the devil and were feared by the workers; but none realized the extent of the economic changes which were to be brought about by them in a fully mechanized age.

In the middle of the nineteenth century the effect of steam on industry was well established. At first machines were confined to a few industries and to industrial centers, and invention was directed toward increasing the production of those things which were necessary for man's welfare. The result was a ready consumption at home and available markets nearby for the surplus. This was the dawning of a new era in which human comforts were increased, and a new plane of living was ushered in.

Modern science, however, has made invention a plaything, and the world the market for its produce. Machine after machine has been invented, the sole aim of which has been to make more goods, not necessarily because they were needed, but because they offered profit to the inventor and those who were associated with him in their manufacture. Production is no longer wholly directed toward supplying man's needs, but toward supplying luxuries and satisfying man's whims. With special high-pressure salesmanship adapted to each article, accompanied by installment buying, almost anything has become salable, and people of mod-

est incomes have enjoyed comforts and luxuries as well as necessities.

Man power up to the time of the introduction of steam was considered to be equal to one-tenth horse power. On that basis the energy value of the adult male population of the United States today would be 3,600,000 horse power, but it actually is 1,000,000,000 horse power.

Many statistics of machine efficiency have been cited in current literature to show the extreme to which man power displacement has gone. These are passed over as fantastic by the more conservative; they are accepted at face value by the radicals; and are being considered as worthy of impartial investigation by a large mass of our people. While these statistics have been criticized by some investigators as being incorrect in certain details, that they are correct in principle is not questioned, and that our social and economic systems have not taken sufficiently into account the unemployment caused by the machine, nor made adequate adjustment to the various changes which the revolution in industry has brought about, is also unchallenged.

The following examples will illustrate the point:

For centuries one man could make about 450 bricks in a day; today a modern brick plant will make 400,000 bricks per man per day. For centuries a man could make one and a half barrels of flour per day; a modern flour mill will make 30,000 barrels of flour per man per day. The flour industry in 1899 was represented by 9,000 plants, employing 32,000 workers and utilizing 471,000,000 bushels of wheat. The number of plants increased to

11,700 in 1909; but in 1929, the number had been reduced to 2,900, employing only 26,400 men but utilizing 546,000,000 bushels of wheat. In 1900 the steel industry in the United States produced 11,000,000 metric tons of steel, requiring an energy of 600,000,000 man hours, which was equal to 70 man hours per ton, in 1929 the industry produced 58,000,000 tons, using 770,000,000 man hours, or at the rate of 13 man hours per ton.

So it goes on down through the whole field of industry; one man and a machine doing the work of many, and casting off those who are displaced to find new jobs or to join the unemployed. Each advance in science, and each new invention, makes adjustment in the established order necessary and opens up new possibilities for further scientific advance and invention. This calls not only for readjustment in industry, but in the social and economic spheres as well. It is not rational that science and invention should work harm to civilization, but by the failure to make proper adjustments the very foundations of our social and economic systems are being threatened. Did the late President Roosevelt have an inkling of what was going on when in 1918, to the query as to how long the present government of the United States would last, he replied: "Not to exceed fifty years".

The above striking illustrations of modern mechanization by no means reveal the end of technical possibilities. They show the inevitable trend of invention and mass production toward the displacement of men, but so long as existent industries, or industries newly established, were able to absorb

the displaced workers readjustments were effected. During the past decade, however, regardless of the establishment of new industries, unemployment has increased. Unfortunately, invention is displacing the skilled artisans and putting industry in the hands of machines and unskilled workers. While the products may be better, the machine has become the producer and the skilled worker has been degraded.

The present-day program of industry aiming at mass production also calls for large combinations of capital to insure distribution. It drives owners of smaller, independent businesses to the wall because of their inability to compete with larger companies, a policy which is rapidly eliminating the great middle class, the class which has shown the greatest appreciation of medical service and has given physicians their surest and most satisfactory return, the class which has always been recognized as the backbone of democratic nations. The independent merchant, the small manufacturer, and the farmer who owns his farm are being displaced one by one, for they have no place in the new order. They have been ruthlessly crowded out of the picture with nothing to compensate them or the nation for their loss. If the middle class is to have no place in a thoroughly mechanized society, then something must be devised to take its place. No people can be happy, nor can a nation long endure, if only a small percentage of the population who control industry are independent, while the rest are dependent upon them.

The rapidity with which production is shifting to large corporations is amazing. The small unincorporated

manufacturer does only 5 per cent of the manufacturing of the country today. In Illinois, in 1909, the individual owner employed 10 per cent of wage workers; and in 1919, 5.5 per cent, a decrease of nearly 50 per cent in 10 years. In the same state, in 1928, the net profits of all incorporated manufacturers was \$5,280,000,000; that of individual manufacturers was \$210,567,000, only 4 per cent of the total. This tells the story of the small independent manufacturer. Add to this the story of the independent farmer. We have boasted that American farmers alone in all the world have never been of the peasant class; but during the twenties, when all industries exclusive of agriculture were having the most prosperous years ever known, the farmers were in dire distress, were rapidly losing their farms and independence, and were sinking into a state of despair. The average net income of the 6,668,681 farms in 1929, for use in meeting the expenses of "capital, management and family living," was only \$847 per farm; and this had dwindled to \$342 per farm in 1931, and was probably about 25 per cent less in 1932.

Mass production, governed by competitive regulation, affects the employer as well as the worker, the difference being one of degree. It forces costly changes in productive plants, that each may be kept at the highest production efficiency, and is responsible for recurrent periods of saturated markets followed by inevitable unemployment, and shrinking in capital values. In 1929 there were 2,250,000 workers idle and 513 persons with incomes of over \$1,000,000 reported in the United

States; in 1931 there were 11,000,000 workers idle and 75 persons with incomes over \$1,000,000; while at the present time it is estimated that there are 14,000,000 workers idle and an equal number working only one-half time, with only a few individuals having incomes of \$1,000,000 a year.

Inventive genius and the genius to establish large combinations of capital in production and distribution, if uncontrolled, can produce only industrial instability and social unrest; if properly guided, on the other hand, they could be made into forces for a greater civilization.

The fact that the number of people above 65 years of age has increased so markedly in recent years requires that our economic system make adequate provision for workers both during their productive period and in their declining years; otherwise, public health measures become a mockery, and work an injury rather than a blessing.

The following statistics show with what rapidity unemployment is increasing in workers beyond 65 years of age. In 1890, 26.2 per cent of the male population over 65 years of age was idle; in 1920 the percentage was 39.9 per cent, an increase of 52.23 per cent in 30 years. We have no statistics at hand which give the amount of forced unemployment among the older workers which took place preceding 1929. We do know, however, that in 1929 there were 2,250,000 wage earners idle in the United States, an increase of more than 1,000,000 over the number idle in 1919; and we further know that the age group above 40 contributed more than its natural proportion to this

number, and that the proportion of those above 65 was likewise very exaggerated.

The increased amount of illness which affects those of the higher age groups makes it much more difficult for them, when once they lose their positions, to secure employment again. For those beyond 65 it becomes almost impossible. Even the insurance against illness which is supposed to work in favor of the employee works against the older man, for he is too apt to become a beneficiary to make him profitable to the employer, or to the insurance company.

Businesses of all kinds recognize that young, alert workers are able to accomplish more than those in declining years. While age may bring with it an improved judgment, modern technology leaves little place for judgment on the part of the worker. In vast commercial combinations judgment is furnished by overseers with exceptional technical training; very often by men who have no interest in the organization for which they work, except that of salary. The particular ability which calls for special monetary reward in the present economic system is that of supplying capital, organizing the business and choosing trained experts to do the technical work.

Since the economic prosperity of the nation depends upon maintaining the proper balance between production and consumption, we can turn back and hear the death knell of prosperity sounding a decade before the crash of 1929 came; but it fell on deaf ears. Productivity was fast outstripping wages. It had increased 54 per cent but wages only 30 per cent between

1900 and 1925, and by 1929 productivity in manufacturing had increased 90 per cent and wages only 40 per cent. Even with this enormous productivity manufacturing plants were running at only 60 per cent of their capacity. Such a divergence between productivity and wages caused a corresponding lag in consumption of goods which could only be remedied if those who received the difference in remuneration should consume the excess in goods, or failing this, if the commodities should be absorbed in foreign markets; neither of which was possible.

Since mass production calls for mass consumption, every idle man causes the loss of the consuming power of himself and those dependent upon him. If the 40,000,000 or more idle men in Europe and America, of whom at least 14,000,000 are in the United States, could be put to work at reasonable wages today, their consuming power would start all essential industries going. Indeed, what can start industry going other than an increased demand for goods? A prominent industrialist, keenly interested in the unemployment situation, recently stated that on account of the increased productivity which has been brought on by our modern industrial methods, we shall not have full time employment for our 48,000,000 workers in the United States for some years to come, probably never. Such a statement, if true, calls for complete industrial readjustment.

A machine driven by one man may do the work of ten or twenty men, and many will do that of a hundred; yet even so, there may be an enormous loss to the employer as well as to the workers who are thrown into the un-

employed ranks, unless, at the same time, provision is made for the consumption of the goods which the displaced 9, 19, or 99 men, with their families, would have consumed.

The most dependable market is made by employed workmen. They are far more important as consumers than the 2,000 directors of the 200 corporations in the United States which are said to control from 35 to 45 per cent of the business wealth, for the latter can not consume from 35 to 45 per cent of the goods produced.

Crises have recurred periodically since machine power became prominent in industry, but have become more frequent and more severe as efficiency in production has increased, and as world problems have become more complex. The aftermath of the World War has been partially responsible for the severity of our present economic crisis, but not the cause of it. Nevertheless international adjustments would greatly facilitate economic recovery. Many believe, with Lloyd George, that the present is not just one more recurrent depression but an indication of the total breakdown of our social and economic systems.

The United States has about 6.2 per cent of the population of the world, but it has 50 per cent of the world's energy. It has been calling upon its natural resources; its forests, coal, oil, natural gas and iron with unpardonable prodigality. It has ignored its agricultural class until it has driven the farmers to ruin. It has been the most active nation in applying science and invention to industry, hence has shifted the major portion of its population from the country to the city. It has

equipped its manufacturing industries so as to be able to produce enough goods for a great proportion of the world's population. In its mad onward rush it has neglected to make necessary adjustments in the social and economic life at home, and has also failed to take sufficiently into account the fact that other nations were also taking advantage of science and invention and equipping their industries for satisfying most of their own wants, and were also bidding more and more for foreign markets. So, just when equipped for an unwarranted production of goods, markets were found wanting, and industrial stagnation supervened.

During crises workers suffer a reduction in wages and lose their positions, capital becomes unremunerative, industrial plants remain idle and deteriorate, and distributing systems cease to function. Depressions are spoken of as inevitable. They are no more inevitable than the plagues of old. They call for scientific investigation and purposeful action; not mute acquiescence. They may be prevented if an altruism which recognizes human rights as being supreme, and the opportunity to supply the necessities of life by work as being an inalienable God-given right is made to pervade the industrial and economic world. Every man who wants to work should have employment. We must get away from the idea that every man in industry who can not do the maximum amount of work is waste. Every man is a potential consumer of goods, and all else being equal the larger the salary of the working man, and the more workers employed, the greater the consumption of goods, for their weekly incomes

represent their weekly expenditures. Every idle man, on the other hand, is a burden on some one, either temporarily or permanently.

The requirements of greater combinations of capital which characterize the "machine age" have put into the hands of the bolder and keener business men an undreamed of opportunity for the accumulation of profits and hoarding of wealth. These men by nature are neither worse nor better than the small manufacturers, merchants, and workers whom they have displaced. It is not against men that remedial measures are to be directed, but against the system which fails to recognize the rights of all men. Stripped of its glamour, the accumulation of great wealth is neither necessary nor desirable. It gives an unnecessary advantage to its possessor which few, if any, are able to use wisely, and worst of all creates an aristocracy based on power to command rather than on ability to do.

Many remedies for our present economic maladjustment have been proposed, each attempting to satisfy certain principles held most important by the one who makes the suggestion. Is it to a new order that we must look, such as socialism, communism, or fascism; or may a satisfactory solution be brought about, as many of us hope, through a modification of our present capitalistic system which will make it meet the requirements of the population as a whole, giving collective protection while preserving individual effort?

It is evidently impossible to make the same economic ideas that we held a century ago fit into the new order which has been ushered in by modern

science and invention. We must not try to cure a body politic suffering from systemic infection by directing our attention to a single organ. We must have the body economic examined by the most competent specialists to be found, and when they have catalogued and analyzed the symptoms and arrived at a comprehensive diagnosis, have our statesmen devise effective remedies, which will permit each social and economic group to develop to a maximum degree and render the best possible service to the people. It is useless for Medicine or any other single group to attempt to adjust its affairs to the present unsatisfactory general economic state; on the other hand, it is the duty of Medicine to join with other social and economic groups in bringing about a complete reappraisal of our entire social and economic system.

The experience of Medicine by which it was removed from the chaos caused by belief in spontaneous generation and miasmas, and in a brief space of time put upon a scientific basis by a few great leaders, such as Virchow, Villeman, Pasteur, and Koch, should suggest the way out of our economic distress. Leaders alone, however, can not produce the results. It requires followers possessed of open minds in whom the spirit of progress is held in greater esteem than are established opinions. General economics is still in the age of plagues and miasmas. It is waiting for a scientific awakening. It is calling for statesmen with the same originality as that shown by our great leaders in Medicine. Such leaders must be imbued with the same belief in human rights which has actuated those who

have met other great crises in history. The rights of all people must be paramount, and more "golden rule" and less "gold rule" must enter into the solution.

The scientific methods which have been applied to modern industry should guarantee to all of the people of the world a greater degree of economic security and the continuous enjoyment of a better health, a greater happiness, and a higher type of physical and cultural attainment than has ever before been possible. Unfortunately, however, we have been rushed from one

achievement to another with such precipitous haste that we have failed to adjust our progress to man's requirements. We are idle in the midst of the greatest producing devices in the history of the world; we are hungry and cold in the midst of abundance of food and clothing; and the wheels of industry are blocked although backed by the greatest concentration of wealth known to man. How to harness science for the good of mankind and not allow it to run on to his debasement and destruction is the burning question which this generation must settle.

Observations on Addisin in Diseases of the Blood*†

By ROGER S. MORRIS, F.A.C.P., MURRAY L. RICH, LEON SCHIFF,
JOHN H. FOULGER, and HENRY FELSON, Cincinnati, Ohio

It has been demonstrated^{1,2} that the normal stomach in man, swine, dogs and cattle secretes an hemopoietic substance which, when properly concentrated and purified, may be injected intramuscularly into man. This substance is thermolabile, dialyzable through celloidion, and exhaustible, and may be converted to an ethyl ester and extracted with non-aqueous solvents (ether, acetone, chloroform) without impairing its hemopoietic activity. These properties, which characterize both the material obtained from human gastric juice and that from the gastric contents of swine, practically exclude the possibility of its being an enzyme. It is probable that it is a physiological hemopoietic hormone, for which we have proposed the name *addisin*. Without sufficient evidence to enable one to arrive at definite conclusions, it seems likely that *addisin* is identical with the "intrinsic factor" of Castle³ and with "hemopoietin" of Wilkinson,⁴ a substance expressed under high pressure from the stomachs of swine.

Practically pure gastric juice has

been obtained from man through a stomach tube and from dogs through a gastric fistula. Such gastric juice, without an "extrinsic factor" such as beef or vitamin B₁₂, when properly concentrated, gives a prompt hemopoietic response following intramuscular injection in a patient with pernicious anemia. There is no noteworthy histologic change at the site of injection in man and in rabbits (figure 1 (B)), and we believe, therefore, that an "extrinsic factor" is not essential in parenteral administration.

METHODS OF PREPARATION

Various methods of preparing gastric juice and gastric contents for intramuscular injection have been tried. Concentration by evaporation is unsatisfactory, but (a) concentration *in vacuo* yields an active product. *Addisin* in active form has also been obtained (b) by preliminary concentration *in vacuo*, dialysis, and further concentration *in vacuo* of the dialysate; and (c) by esterification of the concentrate obtained in either of the two preceding methods. A paper giving the details of these procedures is in preparation.⁹ As yet, we do not know which method yields the most active product. In each of the methods hy-

drochloric acid has been neutralized *after* concentration. Sodium hydroxide, sodium bicarbonate or a saturated solution of disodium hydrogen phosphate has been used for neutralization of the acid. Enough is added to render the mixture faintly alkaline to litmus. With

temperature of the gastric contents be kept below 37°C. in any of the procedures mentioned above.

DOSAGE

To establish a rough measure of dosage, we have designated as *one unit*

FIG. 1. A. Percentage of reticulocytes and red cell count following 9 units of human gastric juice in *divided* doses. B. The same following 9 units in a *single* dose.

aseptic precautions, the final product is usually sterile. When contaminated, however, the neutralized concentrate is diluted with four volumes of ethyl alcohol. The mixture is then passed through a Berkefeld filter, and the filtrate is collected in a sterile flask. The alcohol is readily removed by distillation *in vacuo*. It is important that the

of addisin the material recovered from 100 c.c. of original gastric juice or gastric contents. It has been found that repeated small injections are less effective than a single large dose (figure 1). Thus, the administration in divided doses of 9 units of addisin (human) has failed to produce the hematologic response in pernicious

anemia which later followed a single injection of 9 units in the same patient. Analogous results have been obtained with addisin from swine.

The hematologic response to addisin prepared by each of the three methods

shown definite evidence of hemopoietic activity.

Large quantities of gastric contents may be secured at slaughter houses from swine and cattle. Unlike the pure gastric juice obtainable from man or

FIG. 2. Percentage of reticulocytes and red cell count following the injection of 10 units of ethyl ester of human gastric juice.

referred to previously is prompt in pernicious anemia. The product obtained by concentration *in vacuo* of human gastric juice and its ethyl ester each cause reticulocytosis and maturation of the red cells (figures 1 (B) and 2). Studies with the dialysate of concentrated human gastric juice have also

from dogs with a gastric fistula, the gastric contents of swine and cattle contain food in various stages of digestion. This material is analogous to the gastric juice plus beef or vitamin B₂, as employed in Castle's experiments, but the material obtained from its concentration gives a response in

every way similar to that obtained from concentrated human gastric juice without an extrinsic factor.

PERNICIOUS ANEMIA

Remarkable hemopoietic responses in pernicious anemia have followed the

globin from 47 per cent to 93 per cent (figure 3). A second patient with pernicious anemia received 57 units of concentrated swine gastric contents. The immediate effect was a blood crisis lasting 24 days and a reticulocytosis of 44 days' duration. Without other

FIG. 3. The hematologic response following a single dose of 30 units of the ethyl ester of swine gastric contents.

use of single large doses of addisin obtained from swine. The injection of 30 units of esterified concentrate resulted in a prompt reticulocytosis of 24 days' duration, accompanied by a blood crisis during the first 12 days. In the course of 115 days, without further treatment, the red count rose from 1.4 million to 4.5 million and the hemo-

treatment, there was a rise in the red count from 1.5 million to 4.2 million and in hemoglobin from 44 per cent to 80 per cent in the course of 64 days (figure 4). From patients now under observation, it is probable that similar results may be expected with addisin obtained by dialysis and also from the esterified dialysate. Following intra-

muscular injection of a large dose, the greater part of the addisin may be transported to the liver for storage, though proof of this is lacking.

Studies on addisin in the gastric contents of cattle are not advanced to

the filtered gastric contents of cattle ten minutes after slaughtering. Their results are analogous to those reported by Castle³ and his co-workers with oral administration of human gastric juice incubated with beef or with vitamin

FIG. 4. The hematologic response following a single dose of 57 units of concentrated swine gastric contents.

the point we have reached with material from man and swine. There is, however, definite evidence of hemopoietic activity following intramuscular injection of the concentrate of the gastric contents of cattle. Williams and 'Vander Veer' have obtained a remission in pernicious anemia in four patients by the oral administration of

B₁₂. In the light of these positive findings, it is surprising that Wilkinson⁶ was able to obtain no response from administering preparations of the stomach tissue of cattle.

To date, five patients with pernicious anemia in relapse have received injections of concentrated human gastric juice and eleven have been given con-

centrated swine gastric contents. In each, a reticulocytosis was produced. The earliest response was within 10 hours, the latest within 5 days. In Conner's⁷ patient, treated with human gastric juice, the reticulocytosis appeared on the tenth day. The best results, as judged by height and duration of reticulocytosis and blood crisis and by maturation of the erythrocytes, have followed the single injection of 30 to 60 units of potent material obtained by concentration *in vacuo* of swine gastric contents and by the esterified concentrate. An inadequate supply of material secured by dialysis has thus far prevented a comparison of potency with the other preparations.

Symptoms of shock, possibly due to histamine, have developed promptly on attempts to administer, intravenously, concentrated gastric contents (both from man and from swine). With our present preparations, intravenous use is dangerous and is not employed. With most of the preparations we have used, intramuscular injection has caused only a minor local reaction and little or no general reaction. Before injecting, it is important to be sure that the needle has not entered a vein. No anaphylactic phenomena have occurred.

ERYTHREMIA

Erythremia (polycythemia vera) is in many respects the antithesis of pernicious anemia. The etiology is unknown. In this disease there is a normoblastic marrow in contrast to the megaloblastic marrow of pernicious anemia. Theoretically, most of the changes observed in this disease might result from a hypersecretion of addi-

sin or from a hypersusceptibility of the bone marrow to stimulation.⁸ A patient* with 8.9 million erythrocytes was given 12.5 units of addisin (swine). The immediate response was a reticulocytosis of 2.5 per cent and 14,700 red cells per cu. mm. containing minute nuclear particles. The latter is a reaction to addisin which we have observed repeatedly in pernicious anemia at the onset of the reticulocytosis or just preceding it. In the patient's blood, none of these cells was found prior to the injection of addisin. A week later they had disappeared. A patient with pernicious anemia, refractory to liver extract intramuscularly, whose red count was 4.1 million, received 3 units of addisin (human). A reticulocytosis of 2.7 per cent and increase in red cells containing nuclear particles to 6,500 per cu. mm. appeared promptly, followed by a rise of the red count and hemoglobin to normal. The numerical response of reticulocytes of the patient with erythremia was twice that of the patient with pernicious anemia (table 1). However, differences in dosage and in preparations may account for this. The bone marrow of a second patient with erythremia showed a similar response to addisin.

It is a matter of interest that the first patient with erythremia has also had a duodenal ulcer. He has kept careful records of his blood counts over a period of years. In June 1930, when the red count was 10.0 million, he began gastric aspiration at 9:30 p. m. and lavage three to four times

*We are indebted to Dr. D. P. Abbott of Chicago for the opportunity to study this patient.

each week and continued this until the following December. Without other treatment, there was a steady decrease in the red count to 5.3 million. The lavage was discontinued in December, and in the course of the next few months the count rose again to 10.2 million. The lavage three to four times weekly for a period

cytosis, which is permanent in acholuric jaundice, is seen temporarily in pernicious anemia in response to liver and its derivatives, to ventriculin and to addisin, and in spontaneous remissions. In pernicious anemia, the low red count is due chiefly to failure of both production and maturation of the erythrocytes. In acholuric jaundice, on

TABLE I
MAXIMAL RETICULOCYTE RESPONSE TO ADDISIN IN REMISSION
OF PERNICIOUS ANEMIA AND IN ERYTHREMIA

Disease	No. of red blood cells	Percentage of reticulocytes	No. of reticulocytes
Pernicious anemia	4.1 million	2.7	110,700
Erythremia	8.9 million	2.5	212,500

of six months must have removed an appreciable quantity of addisin from the stomach, a fact which we believe supports our theory and may explain the return of the blood count to a normal level. Through the action of drugs and roentgen-ray exposures over the stomach, as well as by repeated injections of histamine, we have attempted to lessen the secretion of addisin and so to improve the condition of the blood. As yet, we have not met with success.

ACHOLURIC JAUNDICE

Acholuric jaundice is a disease with characteristic hematologic findings. In certain respects, the qualitative blood changes are similar to those seen in pernicious anemia. The increase in the bilirubin of the serum and of urobilin in the urine in each of these diseases is generally attributed to increased destruction of the red cells. The reticulo-

the other hand, lack of normal maturation of the red cells may be an important factor in causing the anemia. Theoretically, it would seem possible that addisin might promote maturation in this disease. If so, one would expect a *decrease* in reticulocytes following its administration in acholuric jaundice, — a reaction the reverse of that seen in pernicious anemia.

There has been opportunity to study the effect of addisin in only one patient with acholuric jaundice. Daily reticulocyte counts for a period of two months showed a variation between 11.6 per cent and 23.1 per cent. The mean percentage for this period was 15.8. On December 19th, 30 units of addisin were given. Three days later the reticulocytes had decreased to 8.9 per cent and at the end of five days the minimum of 6.7 per cent was reached. The percentage was relatively low for the next six days (figure

5) and then rose. This lot of addisin, when given to a patient with pernicious anemia, was found to be of low potency. It caused a reticulocytosis which was maximal on the fifth day. In the patient with acholuric jaundice it may be significant that the *minimal* percentage of reticulocytes occurred also on the fifth day after the injection.

A second intragluteal injection of 55 units of this lot of addisin was given on January 20th, when the reticulocyte percentage was 11.5. On January 23rd, the percentage had decreased to 5.8 and on January 25th it was 6.6 per cent.

The decrease in reticulocytes soon after each of two doses of addisin is significant of an effect on the bone marrow and indicates the possibility of establishing better, perhaps normal, maturation in acholuric jaundice through the use of more potent preparations. Studies on the fragility of the erythrocytes and bilirubin content of the serum before and after addisin are also being made, both in pernicious anemia and acholuric jaundice.

AGRANULOCYTIC ANGINA

In agranulocytic angina there has also been opportunity to study the effect of addisin in one patient.* A white male, aged 21, was admitted to the hospital January 15, 1933. There was a history of sore throat, beginning four days before admission. Two days later the temperature was 102. The throat became worse. He had one chill the night before admission, and was ex-

tremely prostrated. His temperature was 103, pulse 118, respirations 26. There were herpes on the lips and nose. Numerous superficial ulcers were seen on the gums and anterior pillars, and there was a larger ulcer on the lower half of the left tonsil. The glands at the angle of the jaw were enlarged and tender. The remainder of the physical examination was negative. Examination of the blood showed 6.7 million red cells, 115 per cent hemoglobin (Sahli), 1,400 leukocytes. A differential count showed only 7 per cent polymorphonuclear neutrophils and no other granulocytes. A diagnosis of agranulocytic angina was made.

On the evening of January 16th, the patient was given 30 units of addisin, and a remarkable leukocytic response followed, as shown in table 2. The counts were controlled with the supravital technic. In less than 24 hours there was an increase in the granulocytes, and soon myelocytes in appreciable quantity were found. Evidence of marked stimulation of the bone marrow is reflected in the differential counts and in the increase in the number of leukocytes. Rapid clinical improvement also accompanied this change in the blood. The temperature was normal at the end of two and one-half days following injection and has remained so.

Here again the result in a single case is so encouraging that an extensive trial of this form of treatment is indicated as soon as material, both clinical and therapeutic, is available.

The lack of an adequate supply of addisin of proved activity has prevented its trial in other blood diseases, such

*This case is being reported elsewhere in greater detail.

as secondary anemia, idiopathic hypochromic anemia, sickle cell anemia, the thrombopenic purpuras, the leukemias, et cetera.

2. Addisin may be recovered in a form suitable for intramuscular injection by concentration *in vacuo*, by dialysis and by conversion to an ethyl

FIG. 5. The decrease in the percentage of reticulocytes following the injection of the concentrate of swine gastric contents.

CONCLUSIONS

1. An hemopoietic hormone (addisin) is a normal constituent of the gastric secretion of man, dogs, swine and cattle. It is probably widely distributed in the animal kingdom.

ester. A preparation for intravenous use has not yet been obtained.

3. A single large dose of addisin may be sufficient to induce a remission in pernicious anemia, and is more effective than repeated small doses.

4. There is evidence to suggest that

*The differential counts were controlled with supravital technic. The figures represent percentages. Blood for counts was taken daily in the forenoon.

the cause of erythremia may be a hypersecretion of addisin or a hypersusceptibility to stimulation by it on the part of the bone marrow.

5. The results of treatment of acholuric jaundice with addisin are sufficiently encouraging to warrant further trial. The possibility of establishing normal maturation of the red cells is suggested.

6. In a patient with agranulocytic angina, the leukocytic reaction and clinical improvement have been remarkably prompt. In this disease, it is possible that addisin may be curative.

7. Theoretical considerations indicate the possibility that addisin may play a significant rôle in other blood dyscrasias.

Amebic Invasion of Lymphoid Tissue and Its Probable Clinical Significance*

By WILLIAM C. BOECK, M.D., F.A.C.P., Los Angeles, California

IN 1922, Ely, Reed and Wyckoff,¹ and Kofoid and Swezy² announced the finding of *Endameba histolytica* in the lesions of arthritis deformans. In this same year Kofoid, Boyers and Swezy³ described the presence of the amebae in the lymph nodes in cases of Hodgkin's disease. A new conception of the clinical picture of chronic amebiasis was developed as a result of these findings, and is described in the papers of Boyers, Kofoid and Swezy⁴ in 1925, and of Craig⁵ in 1927. The former authors, especially, stressed the multiplicity of symptoms due to chronic amebiasis and felt that the patients suffer from a true systemic infection with amebae, which they believed to be present in many sites in the body not previously considered as likely to be involved. Fatiguability, defective memory, loss of energy, nervousness and headache, are ascribed to the effects of chronic amebiasis on the nervous system. Digestive symptoms which suggest disordered function or even organic disease of the stomach or liver; constipation alternating with brief periods of diarrhea; cough, with or without bloody sputum; rapid pulse; defective vision, with or without iritis,

were also included as a part of the clinical picture. According to these authors, patients with chronic amebiasis might or might not show such gross lesions as abscess of the liver, lung, brain, skin ulcers, etc., as a cause for these widespread symptoms.

To explain the presence of amebae in places outside the colon, as, for instance, the liver, lungs, brain, spleen, bone marrow and lymph nodes, the conception of "systemic infection" had been previously offered by Kofoid, Boyers and Swezy,⁶ who asserted that: "From its portal of entry through the epithelium of the colon into the submucosa, *Endameba dysenteriac* tends to spread in the margins of ulcers of the colon into capillaries and smaller veins, and thence may make its way into the capillary net of the liver, through the heart to the capillary net of the lung, and thence into the systemic circulation." This new conception of chronic amebiasis stimulated a new interest in these diseases and led to more detailed pathological studies of amebic lesions, the findings of which have been published in papers during the past several years.

The present paper will present an account of the pathology of amebic lesions resulting from researches on the cultivation of *Endameba histolytica*

*Presented at the Pasadena Meeting of the California Medical Association, May 5, 1942

in kittens in 1924 and 1925,⁷ and also notes of certain other studies carried out in collaboration with Dr. C. E. Forkner in Boston on a number of persons with Hodgkin's disease. The latter work was supervised by Dr. George R. Minot, of the Collis P. Huntington Memorial Hospital, and by the late Dr. Francis W. Peabody, director of the Thorndike Memorial Laboratory of the Boston City Hospital. In the discussion it will be shown that the results of these studies may provide a pathological basis for the clinical concept of chronic amebiasis.

PATHOLOGY OF AMEBIC LESIONS

Prior to the year 1891, much confusion existed among pathologists concerning the lesions found at autopsy in the so-called "follicular form" and in the "diphtheritic form" of dysenteries. In 1891, Councilman and Lafleur⁸ first accurately described the pathology of amebic lesions and established the differentiation between colitis of amebic origin and that of bacterial origin. By extensive review of the literature they showed that many of the cases of "follicular" and "diphtheritic" colitis, as previously described by American, English, French and German physicians in the tropical countries, were probably instances of amebic infection.

The work of Councilman and Lafleur was confirmed and amplified by that of other investigators, Rogers,⁹ Kuenen,¹⁰ Viereck,¹¹ and Woolley and Musgrave.¹² More recent investigators have studied the lesions in the intestines and liver of kittens experimentally infected with these parasitic amebae. Their studies revealed the identity of

the gross and microscopic amebic lesions in kittens with those in man. Furthermore, the finer pathological details of the very early lesions of amebiasis were more clearly described. We now know, as a result of these later studies by Dopter,¹³ Jürgens,¹⁴ Wenyon,¹⁵ Dale and Dobell,¹⁶ Sellards and Theiler,¹⁷ Boeck and Drbohlav,⁷ Rees,¹⁸ and Martin,¹⁹ that in experimental amebiasis in kittens, as in human amebiasis, there occurs not only an erosion-ulceration of the mucosa, often with the formation of a diphtheritic membrane, that may later invade the deeper coats of the colon, appendix and terminal ileum, but also invasion and destruction of solitary lymph follicles. We shall now briefly consider the microscopic appearance of the intestinal lesions found in amebiasis.

Intestinal Lesions. In stained sections of tissues of the colon, amebae may be found upon the surface of the epithelium (figure 1) and less frequently in the glandular crypts. They appear to secrete a toxic and proteolytic substance or substances that cause a cytolytic and liquefying necrosis of the tissues they invade. They first produce an erosion-lesion of the surface epithelium and sometimes form, with the aid of a secondary bacterial invasion, a diphtheritic membrane composed of fibrin, mucus, cellular remains, bacteria, and amebae (figure 1). This membrane was noted in the early observations of Finger (1849), Lyons (1856), Parkes (1860), Woodward (1880), and Maclean (1886), cited by Councilman and Lafleur.⁸

Following the destruction of the epithelium by the formation of erosion-ulcers, the amebae may continue to de-

stroy simultaneously both the interstitial tissue of the tunica propria and the epithelial covering of the glands. They may often, however, be seen passing into and down the lymphatic channels of the tunica propria into larger lymphatics in the submucosa. There they seem to be arrested in their progress,

bacterial invasion of variable amount may occur in many of the larger ulcers and the deeper erosion-ulcer lesions. The results of this complication are marked polymorphonuclear infiltration and a purulent exudate.

Liver, Lung and Brain Abscesses. With the formation of deep ulcers in

FIG. 1. Erosion-ulceration by amebae, with formation of diphtheritic membrane. x 150.

creating a localized area of necrosis and forming abscesses. As this area grows the overlying mucosa may slough with the production of a large deep ulcer (figure 2). The amebae in the bottom of the glands cause necrosis of the adjacent epithelial cells of the crypt and invade the mucosa above the muscularis mucosae; later a larger ulcer develops from the sloughing of the mucosa above the lesion. Secondary

the submucosa, the amebae may find their way into the blood capillaries and may thus be carried by the portal circulation to the liver. Here, in some cases, a hepatitis occurs which may progress, by proteolytic and liquefying necrosis of the liver parenchyma, and result in single or multiple amebic abscesses. A pulmonary abscess may be produced from this focus in the liver most frequently by direct extension

through the diaphragm and occasionally by blood stream invasion. In rare cases further blood stream invasion has caused an embolic brain abscess or an abscess of the spleen. These instances, however, have nearly always been associated with an older abscess of either the liver or lung and gen-

tissues are also important because of their probable relationship to the symptoms present in cases of chronic amebiasis.

Lesions in Lymph Follicles. Opportunities of observing several progressive stages in the early invasion, as well as the gradual and ultimate de-

FIG. 2. Deep submucosal amebic ulcer with complete destruction of intestinal mucosa.
x 75.

erally with a previous amebic colitis. This, in a general way, characterizes the manner and progress of amebic infection in the intestine, liver and lungs, with the exception of lesions in the lymphoid tissues. The pathology of the lesions in lymphoid tissues has not been studied as extensively as that of the ulcerative lesions of the intestine, although lesions in the lymphoid

struction of the lymph follicles, were afforded by lesions occurring in Peyer's patches of the terminal ileum of five kittens experimentally infected with *Endameba histolytica*. The amebae showed an apparent selective action in attacking the follicles, as was evident from an initial necrosis of the epithelium covering the tip of the solitary follicle. The adjacent epithelium

of the intestinal mucus glands was not affected (figures 3 and 4). Following the destruction of the epithelium over the follicle, the amebae moved down into the body of the follicle, and a sinus tract was formed. The lymphoid cells of the follicle and the interstitial cells

tered polymorphonuclears, large mononuclear cells, and a proliferation of connective tissue elements, attempting to wall off the lesion. In the center of the gland there was progressive destruction of the lymph cells by the amebae, resulting in much cellular de-

FIG. 3. Very early amebic abscess in solitary follicle, with destruction of epithelium over tip of the follicle, and downward migration of amebae—adjacent epithelium normal. $\times 100$.

of the reticulum underwent necrosis, the nuclei becoming pyknotic and the cytoplasm undergoing gradual dissolution or liquefaction (figure 5). There was practically no evidence of any cellular reaction to the infection in the early stages of the invasion, but later stages showed an infiltration of the submucosa at the outer limits of each follicle, with plasma cells chiefly, scat-

tritus. The amebae, as they multiplied and formed a localized abscess, appeared as large cells within a nest of lymphoid cells (figures 6 and 7). The abscess thus produced continued to grow until the whole follicle was destroyed. Later, the mucosa overlying the abscess in the submucosa may, in some cases, slough off and produce a large deep ulcer (figure 8). There

was no evidence of bacterial invasion of the follicles in the early stages of the amebic invasion.

The follicles in the colon also showed early invasion by amebae. This condition, too, was noted by pathologists studying lesions from the human colon. Such an invasion of lymphoid tissue

lymphoid follicles of the colon and terminal ileum in human cases. Although these early investigators felt that the disease often began in these structures, Councilman and Lafleur considered the amebic invasion of the follicles a passive action. Somewhat later Kuenen¹⁰ reported the death of a

FIG 4 Same as figure 3, except higher magnification, to show amebae in lymph follicle and normal adjacent epithelium. $\times 200$.

may, however, go on simultaneously with the erosion destruction of the mucosa adjacent to the follicle or elsewhere, depending upon the location of the amebic invasion (figure 9).

The observations of Lyons (1856), Parkes (1860), Woodward (1880), and Maclean (1886), cited by Councilman and Lafleur, also showed abscesses or ulcers occurring first in the

patient due to peritonitis from a perforation of the ileum by amebae invading a Peyer's patch. This same patient also had typhoid fever, so the cause of the perforation may have been of typhoid origin, the amebae being present in the lesion and passing through into the abdomen. Very recently Hegner, Johnson and Stabler²⁰ reported amebic invasion of lymph follicles in

an appendix removed at operation from a patient in whose stools *Endameba histolytica* had been previously found.

The very recent studies made by various investigators of lesions of the lymphoid follicles occurring in kittens and monkeys experimentally infected

vessels and produce submucous abscesses in the follicles." He felt that the follicular abscesses were of bacterial origin, amebae wandering into and around them after death of the kitten. Hegner, Johnson and Stabler, who studied experimental amebic lesions in monkeys, were of the opinion

FIG. 5. Amebic abscess in lymph follicle, showing sinus tract to lumen of intestine—no ulceration of adjacent epithelium. $\times 50$.

with *Endameba histolytica* are not in agreement as to whether such lesions should be attributed to amebic or to bacterial action.

Hiyeda²¹ found no amebae in follicular ulcers, and thought that the lesions were due to bacterial invasion. Ratcliffe²² believed that: "The apparent rôle of the amebae is superficial destruction of the mucosa which allows pyogenic bacteria to invade the lymph

that the follicular abscesses were of bacterial origin because they found no amebae in them. On the other hand, Dopter, Jürgens, Martin and the author have recorded observations in which the amebae were found in the abscesses of the lymph follicles. We may conclude, therefore, that follicular abscesses may be of either bacterial or amebic origin. Abscesses of both types may occur in the same subject. Of

FIG. 6. Peyer's Patch, frontal section, showing nest of amebae in each follicle. $\times 30$.

FIG. 7. Amebic follicular abscess, from figure 6, higher magnification. $\times 75$.

such a nature were some of the cases reported in early writings on "follicular" colitis. It may be that the very early lesions as reported by Jürgens and the author were not observed by Hiyeda, Ratcliffe, nor by Hegner and his associates.

writer's observations and those of Jürgens indicate that these glands are very early attacked by the amebae, even before the adjacent epithelium is damaged, and long before there is any evidence of bacterial invasion such as Ratcliffe maintained. It is also signifi-

FIG. 8. Large sloughing follicular abscess. x 75.

Jürgens was the earliest investigator to note that in kittens the amebae seemed to invade the lymph follicles first while the adjacent intestinal epithelium remained intact and apparently healthy. Although Martin also observed amebic abscesses in the follicles, he did not feel that these structures were predisposed to the attack of *Endameba histolytica*. He did not, however, observe early stages in the invasion of these glands. The present

cant that the appendiceal infection with *Endameba histolytica*, reported by Hegner, Johnson and Stabler, showed, as the only evidence of microscopic damage, two small early amebic ulcers in the lymph follicles.

To summarize, the pathology of amebic lesions indicates that there are two distinct, fundamental lesions produced by these parasites; first, an early erosion-ulcer which is the result of the invasion and destruction of epithelial

tissue of the intestine (this is also true when other epithelial structures are attacked); second, an abscess which is produced in solitary lymph follicles, the liver, lung, brain and spleen. There is considerable pathological evidence

These glands contained certain cells which were interpreted as *Endameba histolytica* by the authors. Later they reported that amebae were found in the stools of 18 out of 20 cases of Hodgkin's disease studied by them.

FIG. 9. Solitary follicular amebic abscess, with erosion-ulceration and diphtheritic membrane above. $\times 75$.

that the amebae may attack the lymph follicles of the colon, appendix and terminal ileum before producing much or any damage to the adjacent epithelium.

AMEBIASIS AND HODGKIN'S DISEASE

Kofoed, Boyers and Swezy,⁸ in 1922, reported on several cases of Hodgkin's disease confirmed by pathological examination of excised lymph glands.

Dr. C. L. Forkner and the author, while in Boston, studied a number of cases of Hodgkin's disease from two aspects. Dr. Forkner was interested in the diagnosis of diseases, such as Hodgkin's and malignancy, by glandular puncture. The affected glands were punctured with a needle in the lumen of which was a coarse dental broach. The rotation of this broach and its subsequent withdrawal brought away cellular material which could then be

stained with supravital dyes and studied in the warm chamber. The report of this part of the study has been published by Dr. Forkner.^{23,24}

The author's part in this investigation was the search for *Endameba histolytica* in the lymph node material. Culture media were inoculated to grow any amebae that might be present; and hematoxylin-stained smears were studied microscopically. The stools from many of these patients were also examined for *Endameba histolytica*. Some of the cases studied were not, however, included in the published reports of Dr. Forkner.

All the cases studied had had definite pathological diagnoses which, with few exceptions, coincided with the results obtained from gland puncture. The author collaborated in a study of fifteen cases of lymphoblastoma, of which nine were diagnosed as Hodgkin's disease; three as lymphoblastoma of the rapidly growing type; and two as lymphoblastoma of the leukemic type. In none of the cases of lymphoblastoma reported by Forkner, nor in any of the additional cases studied and not reported, was *Endameba histolytica* ever observed either among the living cells stained with vital dyes, or in the stained pathological sections of the glands. Biopsy material obtained from the nine cases of Hodgkin's disease was inoculated in culture media, but these cultures also proved negative for amebae.

The stool examinations of these patients revealed that *Endameba histolytica* was present in the stools of but one of these cases. *Endameba coli* was also present in this case. Of the remaining eight cases, *Endameba coli* occurred in one case, *Endolimax nana* in one case, and *Giardia lamblia* in one

case; the other five cases were negative for intestinal protozoa. Three stool examinations were made in one of these cases; and six stool examinations in each of the other eight cases. The results of the stool examinations were in marked contrast with those obtained by Kofoed, Boyers and Swezy⁶ who found *Endameba histolytica* in the stools of eighteen out of twenty patients having Hodgkin's disease.

To summarize this investigation of the nine cases of Hodgkin's disease: amebae were absent in the stained pathological sections, in the living cells obtained by gland puncture, in this same cellular material stained with hematoxylin, and in culture media inoculated with this cellular material.

DISCUSSION

The clinical concept of chronic amebiasis held by Boyers, Kofoed and Swezy and others has not, for several reasons, met with general acceptance by physicians and pathologists. Their attempt to ascribe an etiological rôle to chronic amebiasis in symptom complexes characteristic of what is usually termed neuresthenia, and in such disease processes as iritis, neuritis, arthritis deformans and Hodgkin's disease could only be justified by proof of the presence of *Endameba histolytica* in the tissues of such cases.

Pathologists have failed to identify any of the cells in lesions of arthritis deformans as identical with *Endameba histolytica*. Likewise, the progressive pathology of these destructive lesions of bone is not in any way suggestive of amebic invasion, since no liquefying necrosis occurs with local abscess formation, such as is found in amebae-infested tissues. Further, the forma-

tion of bony lipping and spurs is not consistent with amebic pathology.

The presence of amebae in the enlarged lymph nodes of Hodgkin's disease has not been confirmed by other pathologists who have made a careful study of this disease. The author's investigations, as well as those of Jürgens, Martin and others, have shown that when amebae invade lymphoid follicles abscess formation results and that in such lesions amebae are easily detected. Abscess formation is very unusual in the lymph glands of Hodgkin's disease if it occurs at all. Moreover the cells in Hodgkin's glands, which Kofoid, Boyers and Swezy believed to be amebae, were difficult to find. The author's investigations on nine cases of Hodgkin's disease, together with those of Forkner and more recently those of Twort²⁵ in 1930, covering 61 cases of Hodgkin's disease, have failed to show that *Endameba histolytica* is present in the enlarged glands or in cultures inoculated with material from these glands.

All previous investigators have found little evidence of generalized systemic invasion with *Endameba histolytica*. Liver abscess, it is true, has for about 40 years been assumed to be due to ameba reaching the liver through the blood stream. However, even in India where this complication is most frequently seen, it occurs in only 20 per cent of the cases of amebic colitis. The liver is usually an efficient filter which prevents amebae from entering the blood stream. The fact that even a small amount of bile in cultures is fatal to amebae may account in part for the effective defensive rôle of the liver. Councilman and Lafleur,⁸ Manson-Bahr,²⁶ Clark²⁷ and others have shown

that when lung abscess occurs it is more usually as a result of direct extension from a liver abscess than by invasion of the lung by amebae carried in the circulating blood. Amebic abscesses of the brain, spleen and kidneys, which are evidence of invasion of the systemic circulation, are quite rare. Therefore, to assume that systemic amebic invasion occurs with such frequency as to be accountable for such relatively common diseases as arthritis deformans, Hodgkin's disease, iritis, etc. is contrary to all previous knowledge of the pathology of the disease.

Because, then, of the lack of confirmation of their findings and because of the inherent improbability of their conception of systemic invasion, physicians and pathologists generally have not accepted the views of Boyers, Kofoid, and Swezy.

Another conception of the relationship of general constitutional conditions to chronic amebiasis was brought forward by Barrow. He first suggested that chronic amebiasis and arthritis may be related, as Ely, Reed and Wyckoff later stated, but he held that the relationship was due to the probable presence of small lesions in the intestine that permitted the absorption of toxins, and not to the presence of amebae in the bone marrow in cases of arthritis deformans.

This particular conception of chronic amebiasis finds a definite pathological basis in the studies of the lesions of the solitary lymph follicles. All infections of *Endameba histolytica* must be considered potentially dangerous to health even in the so-called carrier cases of chronic amebiasis, as has been known for a long time. For the reasons given above, it is hardly probable

that in such chronic cases the amebae reach the bone marrow or lymph glands. They may, however, cause slight erosion-lesions of the intestinal mucosa, and may invade the solitary lymph follicles, causing abscesses such as have been previously described. These small lesions, which would not be detectable in the sigmoidoscope, represent definite portals of entry into the lymphatic system for the absorption of toxins from the colon. Hence each lesion is a focus of infection. The toxins may be liberated either by the amebae, or by the bacteria in these lesions. The toxins from the bacteria may be the more important etiological factors in the production of inferior health and chronic disease in individuals infested with *Endameba histolytica*.

The clinical application of these pathological observations is clear and indicates that all patients who are in poor health and underweight, those with nervous and physical exhaustion, and those who may be subject to recurrent attacks of arthritis and other diseases for which focal infections are

believed to be partly responsible, should be thoroughly examined for *Endameba histolytica*, just as they are examined for infected tonsils, abscessed teeth and other foci. If an amebic infection is discovered it should be eradicated by thorough treatment. Too much in the general improvement of the patient should not be expected, in view of the fact that there are most likely multiple factors at work.

To summarize, it has been shown that there are two fundamental kinds of amebic lesions: first, erosion-ulcers of the epithelium which may become deep and undermining in character, often secondarily invaded by bacteria; second, a localized abscess in lymph follicles, liver, lung, brain and spleen. Further investigations on cases of Hodgkin's disease have failed to show any amebae present in the enlarged lymph nodes. It is suggested that the small erosion-ulcers of the epithelium, and especially the localized abscesses seen in the solitary lymph follicles, provide a pathological basis for the clinical conception of chronic amebiasis.

Variations in the Volume and in the Acid Content of Gastric Secretion of Normal Individuals Following Stimulation by Histamine*†

By FRIEDRICH ENGELBACH, M.D., and CHARLES L. BROWN, M.D., F.A.C.P.,
Ann Arbor, Michigan

DURING the last few years the analysis of gastric contents obtained after stimulation by histamine has come into general use.

The work of Bloomfield and Poland^{1,2} on the acidity of gastric juice following histamine stimulation has shown that the volume and acidity rapidly increase, the maximum being reached in 20 to 30 minutes after injection, after which time the volumes diminish, while the acidity maintains its high level throughout the test of an hour's duration. They found a constancy of response of volume and acid after giving repeated doses of the same amount of histamine to a given individual.

Gompertz and Cohen³ have shown that as little as 0.25 mg. of histamine hydrochloride will give a gastric secretory response, and that in using larger doses (0.5 mg., 0.75 mg., 1.0 mg.) a greater response is usually obtained, but that the results are not mathematically proportional to the size of the dose.

Kinsella,⁴ after reviewing the literature concerning the acidity at the cardiac and pyloric ends of the stomach, reports that he finds the gastric contents usually more acid at the cardiac than at the pyloric end if saliva is excluded.

The gastric secretion after stimulation by histamine has been studied in two healthy men aged 28 and 32 years. In aspirating the gastric secretion the Rehfuess tube was used, the 60 cm. mark being kept at the incisor teeth. Continuous aspiration of the gastric secretion was performed at a negative pressure of 15 to 20 cm. of mercury, maintained by a water driven suction pump. A 15 minute fasting sample (fasting contents and any gastric secretion over 15 minutes' time) was obtained; then histamine (ergamine phosphate) was administered subcutaneously, 0.1 mg. per 10 kilograms of body weight, and the subsequent gastric secretion obtained was divided into six 10 minute samples. The volume of each sample was measured, and free and total acidity of each sample was determined using dimethylamino-azobenzol (Topfer's reagent) and phenolphthalein as indicators, the acidity being expressed in terms of 0.1 normal

acid per 100 c.c. of gastric juice. The study was carried on over a period of eight months, 16 analyses being done on one subject and seven on the other. In each of the charts the solid lines indicate the response to 0.1 mg. histamine per 10 kilograms of body weight; the broken lines to half this dose; and the dotted lines to one-fourth the first mentioned dose. All of the analyses were done by the same two individuals, thereby tending to minimize errors due to variations of technic.

Charts 1, 2, and 3 on subject F. E. show: (1) that the maximum acidity and the maximum volume per 10 minute period were always reached in the 10 to 20 minute or in the 20 to 30 minute samples, usually in the former; (2) that after the maximum acid secretion is reached, the acid rapidly diminishes, tending to approach the fasting level at the end of an hour after the administration of histamine, while there is less diminution noted in the amount of secretion per 10 minute period; (3) that a close relationship exists between the free and total acid;

Broken line = 0.05 mg. histamine per 10 kilograms body weight.

ute period were always obtained by the end of 40 minutes after the injection of histamine, usually in the 20 to 30 minute or in the 30 to 40 minute samples; (2) that after the maximum acid secretion and the maximum volume per 10 minute period were reached there

CHART V. C. L. B. Total Acidity Curves.
Solid lines = 0.10 mg. histamine per 10 kilograms body weight.
Broken line = 0.05 mg. histamine per 10 kilograms body weight.

was a tendency for both acid and volume to diminish but not as rapidly as in subject F. E.; (3) that a close relationship exists between the free and total acid; (4) the maximum free acid varied from 75 to 106, the maximum total acid varied from 87 to 113, and the maximum volume per 10 minute period varied from 42 to 84 c.c.; (5) one-half of the dose of histamine did not elicit the average full dose response in either volume or acid.

Since continuous aspiration removes practically the entire secretion of the stomach it is possible to obtain from the results of these tests a quantitative measure of gastric secretory function. The influence of regurgitation of duodenal contents was probably of no significance in these tests since none of the samples was stained with bile. The amount of free or total acid, expressed as 0.1 normal acid, secreted during the hour test period is calculated in the following manner: the volume in c.c. of each 10 minute sample is multiplied by the amount of acid, in terms of 0.1 normal acid, per c.c. of that juice, and the sum of the values of each of the

CHART VI. C. L. B. Volume Curves.

six samples gives the total acid secretion for the hour. Table 1 shows the volume and the quantity of free and total acid secretion in the hour following stimulation by histamine. A considerable variation of acid secretion in the same individual given the same dose of histamine on different days is shown by these figures.

samples usually had the greater free and total acidity. We believe that this experiment indicates that the tube at 60 cm. removes practically all of the gastric secretion and that the secretion obtained from the cardiac end of the stomach usually has a greater acidity than that removed from the pyloric end.

Table 2 shows the results on subject F. E. when two Rehfuß tubes were used at the same time with simultaneous and continuous aspiration, the tip of one being 60 cm. and the other 72 cm. from the incisor teeth, these tube tips being found by X-ray examination to be in the cardiac and pyloric ends of the stomach respectively. It will be noted that almost all of the secretion was obtained from the tube in the cardiac end of the stomach and that these

Our studies show less constancy in both volume and acid secretion in the same individual after repeated doses of the same amount of histamine than was found by Bloomfield and Pollard. The gastric contents were usually more acid at the cardiac than at the pyloric end of the stomach. Smaller doses of histamine, while they elicit some gastric secretion, do not seem to be as satisfactory as a dose of 0.1 mg. per 10 kilograms of body weight.

SUMMARY

1. A study of the variations in the volume and acid content of gastric secretion of two normal individuals, following stimulation by histamine (ergamine phosphate), is presented.
2. A maximum in volume and in acidity of the gastric secretion is obtained, on the average, about 30 minutes after the administration of histamine.

3. There are distinct variations in the volume and in the acidity of the gastric secretion of the same individual given the same amount of histamine on different days.
4. When gastric secretion is removed from the pyloric and cardiac ends of the stomach at the same time, the acid content of the secretion obtained at the cardiac end is usually greater.

Orthostatic Albuminuria

A Comparison with Other Types of Albuminuria*†

By EDWARD G. THORP, M.D., and E. G. WAKEFIELD, M.D.,
Rochester, Minnesota

AFTER rather completely reviewing the extensive literature of the last twenty years on orthostatic albuminuria, it is apparent that many clinical impressions have been accepted as fact without proper critical study. Few authors have presented sufficient data on carefully studied series of cases to lend weight to their conclusions.

In an effort to obtain some accurate information about orthostatic albuminuria, its effect on the patient's health, the relation it bears to glomerulonephritis, the type of patient affected, and if possible its etiology, the records of 185 patients seen at The Mayo Clinic over a period of approximately ten years were carefully analyzed. The results were tabulated at length, and the tables made are summarized in table 1. The cases studied have been divided into four groups: (1) orthostatic albuminuria; (2) albuminuria with an orthostatic response; (3) latent glomerulonephritis, and (4) chronic glomerulonephritis.

The diagnostic criteria for inclusion of cases in the first group have been the occurrence of albumin in the urine when the patient was in the erect position, whereas a specimen excreted while the patient was lying down, or the night specimen, must have been entirely free from even traces of albumin by the usual method of detection. It is possible that this rule has excluded certain cases of orthostatic albuminuria from our first group, since, in genuine cases of this sort, the albuminuria has been demonstrated to persist a short time after the patient has lain down. The sediment in such cases is usually free from erythrocytes and casts, but it should be remembered that occasional erythrocytes or granular casts may be found in normal urine. There must have been no history suggestive of nephritis or nephrosis, nor any of the physical signs which are commonly associated with nephritis, such as changes in the vascular system, including retinitis. A slight to moderate degree of anemia, without evidence of renal or vascular disease, was considered permissible. The criteria for a diagnosis of albuminuria with an orthostatic response have differed from those of the first group only in that the albuminuria must have been constantly present in all positions, although increased in grade or amount while the patient was standing. For a diagnosis of chronic latent glomerulonephritis, there must have been a his-

tory of acute nephritis which apparently had subsided, although albuminuria had persisted. Although it might have been impossible, without the history, to distinguish this condition from uncomplicated orthostatic albuminuria, traces of albumin in the night specimen of urine frequently have occurred. The albuminuria of chronic glomerulonephritis needs no definition.

In the tables when blood pressure is given, it is the average reading, if more than one observation was made, and is expressed in millimeters of mercury. Hemoglobin was estimated in per cent (Dare). Blood urea was expressed in milligrams of urea in each 100 c.c. of blood, as determined by the aeration method. Excretion of phenol-sulphonphthalein was determined according to the modified method of Rowntree and Geraghty. Albumin was

determined by the sulphosalicylic acid method, and was graded from 1 to 4. Specific gravity was obtained by use of the mercury urinometer of Exton.

ORTHOSTATIC ALBUMINURIA

We studied 100 cases of orthostatic albuminuria. Of these patients 62 per cent were males. However, it is unfair to compare the incidence by sexes, since we do not know the reasons that originally brought the patients to the clinic. Many came because of the discovery of albuminuria in the course of examination for life insurance, and it is probably safe to assume that more males than females apply for life insurance. The average age when the patients were first seen in the clinic was eighteen and twenty-seven hundredths years, while the average age at the time when albuminuria had been

discovered was seventeen and twenty-four hundredths years. The oldest patient was aged 47 years, and the youngest, four years. Twenty-six per cent of the patients were aged 12 years or less, while 7 per cent were aged 30 years or more. The survey disclosed, also, that orthostatic albuminuria is occasionally seen in late middle life, a fact which needs emphasis. Lordosis was recorded as being present in 21 cases and absent in 11; in the remaining 78 cases nothing concerning it was recorded, but it is probably fair to assume that lordosis was absent in most cases.

Forty-nine patients were either observed repeatedly or were known to have had albuminuria previously, and in these cases the average duration of known albuminuria was six and fifteen hundredths years. Seven of the 49 patients responded to a questionnaire, and indicated that they enjoyed good health and had no symptoms of renal disease over an additional average period of five and eighty-nine hundredths years; results of urinalysis were not reported in their answers. Fifteen patients were observed once only; and they answered the questionnaire, an average of six and one-tenth years later, indicating that they were in good health, but they did not report the results of urinalysis. Thus, 64 patients were traced over an average period of six and eleven hundredths years. The remaining 36 patients were observed once only. One patient with persistent orthostatic albuminuria, one of the 64, was observed over a period of 26 years.

Of the 64 patients traced, 63 (98.4 per cent) were in good health after an average interval of six and eleven hundredths years. One of the 64 pa-

tients (1.6 per cent) had symptoms of renal disease, but urinalysis was not reported in this case. Of the 49 patients who were repeatedly observed, 16 (32.7 per cent) had negative urinalysis after an average interval of six and fifteen hundredths years. Thirty-three of the 49 patients (67.3 per cent) still had albuminuria after an average interval of six and fifteen hundredths years. In 11 cases of the 64, casts or erythrocytes were transiently found in the sediment. In four cases, the value for urea was from 40 to 45 mg. in each 100 c.c. of blood, and in three of these cases excretion of phenolsulphonphthalein was normal.

Ophthalmoscopic examination gave evidence of arteriosclerosis in only two cases of the 100. One of these cases was associated with essential hypertension (blood pressure 170 systolic and 130 diastolic), but in this case, six and a half years before, there had been recorded a normal blood pressure and albuminuria of indeterminate type, although tests for orthostatic albuminuria had not been carried out. Albuminuria and occasional casts persisted for three and a half years after the second observation, although there were no symptoms of renal disease. Retinitis was never noted in any case in this group. Only one other patient, and this one was aged ten years, had any evidence of hypertension; blood pressures of 145 and 90 were recorded. This determination was noted as "totally unreliable" however. Ten per cent of the 100 patients had low blood pressure.

ALBUMINURIA WITH AN ORTHOSTATIC RESPONSE

In a second group we studied 43 cases, in all of which the diagnosis of

orthostatic albuminuria was entertained. Patients of this group were observed during the same interval as that during which the first group was observed. It is not permissible to make too strict a comparison between this group and the first group, since only those patients who were traced over a period of years are included here.

Males constituted 74.4 per cent of this group. The average age at which the patients were first seen was nineteen and nineteen hundredths years, and the average age at which the albuminuria was discovered was seventeen and seventy-nine hundredths years. These figures are similar to those noted in the first group. The youngest patient was aged four years; the oldest, 46 years. Thirty-nine per cent of these patients were aged 12 years or less, and 14.3 per cent were aged 30 years or more. There was much less notable segregation of cases between the ages of 13 and 29 in this group than in the previous one. Lordosis was present in 44.5 per cent of the cases, absent in 9.3 per cent, and not specified in 46.2 per cent. Thus, among patients of the second series, lordosis was twice as prevalent as among patients with orthostatic albuminuria.

Forty-two of these patients either were observed repeatedly or were known previously to have had albuminuria. The average duration of observation in this group was seven and seven-tenths years. Two patients were in good health an average of six years after observation, but no report of urinalysis was obtained. One patient was observed only once, and responded to the questionnaire four and one-half years later with the information that there was no difficulty but he gave no

report of urinalysis. Thus, 43 patients were traced over an average period of seven and fifty-six hundredths years. Of these patients, 95.4 per cent were in good health, so far as renal or associated diseases are concerned, after an average interval of seven and fifty-six hundredths years; 4.6 per cent (two patients) had symptoms or urinary findings suggestive of renal disease, after the same interval of years, 39.1 per cent of 42 patients had negative urinalysis after an average interval of seven and seven-tenths years.

This group of patients was similar in many ways, to the series of Maclean,¹ of Lee,² and of Diehl and McKinlay.³ However, certain differences may be noted: (1) the patients were all sufficiently concerned about their general health to consult a physician on their own initiative; the patients in the group observed by each of these other writers underwent a required examination; (2) in our series, the albuminuria was usually persistent, in contrast to the observations of Lee and of Diehl and McKinlay; (3) many of Lee's cases were definite examples of orthostatic albuminuria, and cases of orthostatic albuminuria undoubtedly were present in each of the other series; (4) all of the patients in the cases included by the cited writers were males, whereas our series constituted a mixed group; (5) physical exertion as a factor in producing albuminuria did not obtain in the present series, since many of the patients were at rest in bed in the hospital, and (6) it is well to state that no cases of albuminuria following administration of drugs, serums, or albumin were included in our study.

LATENT GLOMERULONEPHRITIS

Table 2 contains data concerning a group of 17 patients who were known to have had acute nephritis, either in the past or while under observation. The ages ranged from six to 32 years, and only three of the patients were aged more than 21 years. After an interval of eight and six hundredths years, which was the average duration of the time of observation over which results of urinalysis were obtainable, half of the patients were found to have no albumin in the urine, and all were in good health. Lordosis was noted in 41.1 per cent.

Seven of these 17 patients had had scarlet fever, some of whom gave histories suggestive of postscarlatinal nephritis. The remainder gave histories which suggested that they had had acute nephritis, which was either latent when they were first seen at the clinic, as evidenced by the absence of erythrocytes in the urine, or which became latent during the period of observation. Their blood pressures, ophthalmoscopic findings, values for hemoglobin and blood urea and excretion of phenolsulphonphthalein were all within the limits of normal variation.

The principal object in presenting this group is that, aside from the history, 10 of these 17 cases, on a single observation, were in every detail classical examples of orthostatic albuminuria. Such are case 1; case 3, second visit; case 4, second visit; case 5; case 7, second visit; and cases 8, 9; case 10, third visit; 14, and 16. It is of significance that in all of the 17 cases there was an orthostatic response in the albuminuria, and further, that the renal function, so far as it was deter-

mined, was normal in all instances except for the specific gravity determined during the concentration test in two cases. Erythrocytes were observed in the sediment in six cases, in two of which there was acute nephritis at the time. In all but one of these 17 cases there were negative sediments subsequently and there was a question of essential hematuria in this case. Consequently, we feel justified in saying that in this group there was latent nephritis, and in assuming that many of the patients, by the present time, have completely recovered. Furthermore, in these cases which presumably followed acute nephritis there was a period during which, in the process of recovery, an orthostatic response in the albuminuria was a favorable prognostic omen.

Study of the foregoing group shows that often, during the course of latent glomerulonephritis there was an orthostatic element in the albuminuria. Further, during the process of healing, latent glomerulonephritis may exhibit all the characteristics of true orthostatic albuminuria.

CHRONIC GLOMERULONEPHRITIS

A study was made of 25 patients with chronic glomerulonephritis (table 3). Here we were concerned with the relationship of excretion of albumin to the degree of renal insufficiency as evidenced by tests of renal function. Usually, in cases of glomerulonephritis, the blood pressure becomes elevated sooner or later, during the course of the disease; in cases 2, 3, 9, 10, 11, and 22 (table 3) blood pressures were elevated. Ophthalmoscopic examination disclosed retinal changes in cases 10 and 22. Anemia was present in cases 2, 6, 8, 14, and 18. The value for

*Retinal changes present in cases 10 and 22 only.

blood urea was elevated in cases 14, 18, and 21, whereas elimination of phenol-sulphonphthalein was diminished below the lower limits of normal in cases 5, 18, and 21. In all cases except 20, 21, 22, and 25, albuminuria persisted while the patient was reclining. Impaired concentrating or diluting power of the kidneys was seen in cases 1, 3, 5, 7, 8, 13, 14, 16, 18, 19, 20, 21, 22, and 24. Erythrocytes were noted in the sediment in cases 1, 3, 5, 8, 10, 12, and 14, and in cases 18, 19, 20, 22, 23, 24, and 25 inclusive.

It is important to note that, in all these cases, the glomerulonephritis was sufficiently mild (at least on first observation) to warrant considering the possibility of orthostatic albuminuria. Case 21 fulfilled all the requirements of orthostatic albuminuria on first observation, although fifteen months later renal function had become markedly impaired. This is the only instance of this sequence.

It is apparently possible to make a correlation between the impairment of renal function, as shown by the usual tests of function, and the response of the kidneys to the orthostatic test. Thus, in 19 of the 25 observations (76 per cent) a direct relationship between diminution of excretion of albumin in the horizontal position, as compared with that in the erect position, and the degree of renal impairment as measured by dilution and concentration tests, may be noted. If there was diminution in the amount of albumin excreted, renal function was adequate as measured by the other tests; and, conversely, when albumin did not diminish, renal function was impaired as measured by the other tests. In eight cases there was no diminution in albu-

min in the presence of impaired renal function, and in 11 cases there was diminution of albumin in the presence of good function, a total of 19 cases. In one case there was no diminution of albumin, but good function; and in five cases there was diminution with poor renal function. In grouping these cases allowance was made for the effect on specific gravity of large amounts of albumin.

FOCAL INFECTION AND WEIGHT IN ALBUMINURIA

Calvin, Isaacs, and Meyer⁴ commented on the high incidence of focal infection among patients with orthostatic albuminuria. In our study, foci of infection occurred with practically the same incidence in association with orthostatic albuminuria, and in association with albuminuria with an orthostatic response. Removal of foci did not appreciably influence the albuminuria in either group. By "foci of infection" we refer to obviously diseased tonsils, teeth, sinuses, or prostate gland, or to a chronic suppurative process, such as bronchiectasis or otitis media. Border-line cases were not included.

Practically all observers have recorded the typical asthenic habitus of patients with orthostatic albuminuria, and the implication is often noted that, with gain in weight after adolescence, albuminuria tends to disappear. In order to gain some accurate information on this point, the recorded weight in each case of orthostatic albuminuria has been compared with the standard normal weight of persons of the same age, sex and height, as given in the tables based on medical actuarial statistics. This has been recorded in percentage of variation above and below

the average normal. Figure 1 shows the averages in the cases of orthostatic albuminuria, and figure 2 the averages in the cases with other forms of albuminuria. It will be seen that there is no striking difference between these groups, both falling chiefly in the normal to minus 10 per cent zone. With

been strengthened by the observations of Russell⁶ and of Weiss-Eder.⁷ Fishberg⁸ inclined somewhat to this view. We are able to add a series of seventeen cases in which true orthostatic albuminuria, or albuminuria with an orthostatic response, dated presumably from acute nephritis. We assume that

FIG. 1. Average percentage variation, above and below normal, of weight of 95 patients with orthostatic albuminuria. Each spot represents the patients of one age-group. Seventy-nine of the 95 patients were between the ages designated by the positions of the arrow heads, and the weights of most of these 79 patients were within the normal to minus 10 per cent zone.

the passage of years, there is no constant relationship between change in weight and persistence of the albuminuria in cases of orthostatic albuminuria.

COMMENT

Among the conflicting reports, the only hypothesis concerning etiology, which has not been refuted, is that of Senator,⁵ who reiterated many times in the course of several years, that albuminuria detectable by ordinary clinical tests is never "functional". This hypothesis concerning renal injury has

orthostatic albuminuria or albuminuria with an orthostatic response means persistent renal injury which frequently heals completely. We believe that the burden of proof rests with those who ascribe orthostatic albuminuria to causes other than renal injury. In one case in the first group, the injury presumably went on to nephritis, and cases 20, 21, and 22, in table 3, were definitely cases of chronic glomerulonephritis, although albumin was absent from the night urine.

It is possible to avoid error, to a great extent, by insisting on the fol-

lowing points before making the diagnosis of orthostatic albuminuria: (1) absence of even traces of albumin in the urine excreted with the patient recumbent; (2) absence of persistent erythrocytes or casts, or more than an occasional erythrocyte or cast in the sediment; (3) absence of a history or of physical signs of nephritis or ne-

more so than the other patients studied, and changes in weight have no effect on the incidence of albuminuria. It should be noted that the albuminuria may persist through middle life.

Among patients who have albuminuria with an orthostatic response, the prognosis is almost as good, but the diagnosis must be established with the

FIG. 2. Average percentage variation, above and below normal, of weight of 80 patients with albuminuria of other than orthostatic type. Each spot represents the patients of one age-group. Sixty-four of the 80 patients were between the ages designated by the positions of the arrow heads, and the weights of most of these 64 patients were within the normal to minus 10 per cent zone.

phrosis or associated vascular changes; (4) normal renal function, as measured by the usual tests, and (5) observation of the patient over a period of several months. A correct diagnosis of orthostatic albuminuria carries with it a prognosis of good health and longevity in 99 per cent of cases, and a probability that, in 33 per cent, the urine will become free of albumin. There is no evidence that foci of infection play any part in the causation of orthostatic albuminuria. The patients are slightly underweight, but no

same care as in orthostatic albuminuria. We believe that albuminuria with an orthostatic response indicates a more marked degree of renal injury.

When a diagnosis of latent glomerulonephritis is considered, a period of several months of observation is necessary, to be sure that one is not dealing with slowly progressive chronic glomerulonephritis. Although the outcome in our small group of cases of latent glomerulonephritis was as good, or was better, than that in the groups of cases of orthostatic albuminuria, or of cases

of albuminuria with an orthostatic response, we feel that, in general, the prognosis should be more guarded. The presence of an orthostatic element in all of our cases may well have a relationship to their unusually good outcome. The development of orthostatic albuminuria in the course of acute nephritis seems to indicate partial recovery, and may be of aid in establishing a prognosis.

Although the existence of an orthostatic element in chronic glomerulonephritis has been frequently observed, we are not able to find record of any attempt to correlate it with tests of renal function.

The etiology of orthostatic albuminuria is not known. However, a few facts about man's excretion of urine due to his upright position, may help to explain orthostatic albuminuria. For instance, excretion of water by normal kidneys has been shown to be decreased by the upright position.⁹ There is some evidence in favor of the belief that excretion of such a substance as urea may, also, be so affected. If some sort of mild renal injury is assumed, then the following concepts are applicable: when the patient is recumbent, function is enhanced, water and such substances as urea are excreted more easily, and albumin not at all. As soon as the upright position is assumed, the kidney is not able to readjust itself, and there is loss of albumin. Furthermore, in support of this view, we have shown that in chronic glomerulonephritis, when

renal injury progresses sufficiently to be demonstrable by the usual tests of function, the element of orthostatic albuminuria disappears. Also, in selected cases, during recovery from acute nephritis, a period characterized by orthostatic albuminuria is not uncommon. Therefore, orthostatic albuminuria is probably in the range of mild renal pathologic physiology.

CONCLUSIONS

1. Strict diagnostic criteria must be observed before a patient is considered to have orthostatic albuminuria.

2. The prognosis is excellent in cases of orthostatic albuminuria, although the albuminuria may persist through middle life.

3. The diagnosis of albuminuria with an orthostatic response requires similar careful consideration, and carries almost as good a prognosis.

4. Among patients who have had acute nephritis, the development of an orthostatic element in the albuminuria apparently indicates partial recovery and a good prognosis.

5. In chronic glomerulonephritis there is some evidence that the presence of an orthostatic element in the albuminuria indicates adequate renal reserve, and its disappearance may be a sign of renal insufficiency.

6. From the data presented regarding the etiology of orthostatic albuminuria it would appear that the burden of proof rests with those who do not consider it due to renal injury.

Addison's Disease and Its Relation to Experimental Adrenal Insufficiency*†

By GEORGE A. HARROP, M.D., F.A.C.P., *Baltimore, Maryland*

ALTHOUGH the first accurate description of the adrenal glands is usually accredited to Eustachius, in 1563, very little further progress was made in the study of their structure or physiological significance for nearly three centuries and practically all of the further additions to our knowledge have been made within the past eighty years. Modern interest in the adrenals dates from Addison, who published in 1855 the clinical observations on the disease which bears his name.

In all mammals, including man, the adrenal glands are paired organs, each composed of two distinct parts. The outer layer, or cortex, forms roughly two-thirds to three-quarters of the whole, and this surrounds the inner portion, or medulla, which is of distinct and separate embryological origin. Until very recently the attention of most investigators has centered upon the medulla, which has been shown to be closely related in its origin to that of the nerve cells of the sympathetic ganglia and in its later

development and functional significance to the sympathetic nervous system.

There is both an anatomical and a physiological reason for the greater interest which has been displayed in the adrenal medulla. In 1865 Henle first showed the peculiar affinity of the medullary tissue for the salts of chromic acid, and the characteristic brownish-yellow staining reaction of these chromaffin, or chromaphil cells when treated with this chemical was of prime importance in their identification.

The second reason for the greater interest in the adrenal medulla lies in the fact that extracts of this chromaffin material possess peculiar and characteristic physiological properties, readily observed and measurable with relative ease, although with uncertain accuracy. The substance itself which we now know as adrenalin was finally obtained in crystalline form and subsequently produced synthetically just about thirty years ago. For a number of years the discovery of adrenalin naturally focused attention upon the adrenal medulla to the exclusion of interest in the cortex, since it was demonstrated with reasonable conclusiveness that adrenalin originates solely in the medulla, its presence in the cortex being due to postmortem diffusion. The advances which followed the isolation

*Read before the Medical Section, New York Academy of Medicine, January 19, 1933.

†From the Chemical Division of the Medical Clinic, the Johns Hopkins Hospital and University, Baltimore.

of adrenalin furnish a striking example of the fact that progress in knowledge of any endocrine gland secretion is in direct proportion to the availability of a simple quantitative measure of its physiological effects.

Chromaffin tissue is widespread in its distribution. Stilling, and later Kohn, showed that groups of cells occur throughout the course of the sympathetic nervous system, either as microscopic clusters in the ganglia or as macroscopic bodies in the sympathetic plexuses called "paraganglia". In addition to similarity in morphology and in the chromaffin reaction, extracts obtained from this extra-medullary tissue exhibit similar physiological properties to like preparations derived from the medulla itself. Indeed, according to Biedl, in the new-born, in whom very little adrenal medulla exists, the action of these extra-adrenal extracts, particularly those from the abdominal chromaffin body, are more effective upon constriction of blood vessels than those from the adrenal medulla itself. This abdominal chromaffin body remains of considerable size until the child is one year of age, after which it degenerates. In other forms, as in the dog, cat, and rabbit, it is an organ of significant size throughout life. Kohn showed by accurate determinations of the respective weights that the abdominal chromaffin body in the adult dog may represent as much as one-quarter of the total weight of the medulla itself.

Studies leading to such knowledge as we now possess of the physiological significance of the cortex really antedate those on the medulla, although they were not at the time so recognized. The original description of Addison's disease was the stimulus which

led Brown-Sequard in 1857 to test the effect of removal of the adrenals in a number of different species, including rabbits, dogs, guinea-pigs and cats. A fatal result invariably followed their bilateral removal within thirty-seven hours and this led him to the view that the adrenals are essential to life. There is no doubt that this correct conclusion, in the light of present day knowledge, was based upon experiments in which the animals died, not of adrenal insufficiency, but of surgical shock or of sepsis. It is possible with proper surgical technic, using dogs, even when both glands are removed at one operation, to have survival without any treatment for at least seven days. The effect, however, is ultimately that described by Brown-Sequard. If insufficient accessory adrenal tissue is present, the animal invariably dies.

The question then arose as to whether the part of the gland indispensable for life was the medulla, the cortex or the adrenal tissue as a whole. Through the efforts of a considerable group of observers it has been shown during the past two decades that the cortex of the gland is the vital structure, since destruction of the medulla by extirpation or by a number of other means, such as cauterization or radiation, permits the animal to live on. So long as the cortex, or at least a fraction of it (from one-fourth to one-eighth), is left intact, the animal does not seem to suffer ill effects. It has, therefore, been generally accepted in recent years that the cortex is the essential structure. The medulla and the chromaffin tissues generally have been tacitly relegated to a position of minor importance. This view has undoubtedly been strengthened by the success

substitution therapy with lipid soluble extracts of the cortex in totally adrenalectomized animals, as demonstrated by Hartman, by Swingle and Pfiffner, and by others within the past two or three years.

It is well to bear in mind, however, that the question of the importance to life of the chromaffin tissues as a whole has never been brought to rigorous test. Owing to their widespread distribution they cannot be completely extirpated, as can the cortex in most forms, where accessory cortical tissue in significant amounts does not exist. We must conclude that the indispensability of the medulla yet remains to be disproven, and that it is at the present moment unknown whether the close juxtaposition of these two portions of the adrenal gland differing so widely in origin, morphology, and chemical properties, is pure accident or is of vital and fundamental significance.

Certain facts, however, have been gathered which make it appear that the close approximation of these two tissues in the mammal may not be altogether a coincidence. In some of the lower vertebrates, as in the elasmobranch fishes, the tissues which correspond to the adrenal cortex and medulla are separated, the cortex being represented by the interrenal body and the medulla by the paired bodies which lie close to the ganglia of the sympathetic chain. In birds and reptiles, and in amphibians, the renal and adrenal tissues interlock. It is only in mammals that the same condition is found as in man—the adrenal is composed of a central medulla with an enclosing cortex.

In most mammals, as is well known, the cortex is divided by the morpho-

gists into three zones. The cells in the central portion are arranged mainly in columns, the zona fasciculata. The portion next to the medulla is a network of trabeculae, the reticularis. At the surface the columns end in rounded terminations, the so-called glomerulosa.

The blood supply of the adrenal gland is of particular interest. Per unit of weight it is more abundant than that of any other body organ, being estimated as 6 to 7 c.c. per minute for each gram of tissue, higher even than the thyroid, which comes next with 5 c.c. per gram per minute. The arteries divide in the cortex into capillary plexuses which fuse into sinuses in the reticularis, the innermost zone of the cortex, and go over by numerous and free communication into the venous sinuses of the medulla. A second supply to the medulla is from branches which perforate the cortex without division. Present evidence indicates that a very considerable proportion of the adrenal blood supply passes first through the cortical layers of the gland and thence into the medulla, so that materials given off into the blood stream in the cortex, in large part, at least, have opportunity to come into contact with the cells of the medullary portion of the gland. The blood from both regions unites to pass out in the same venous channels.

Because of the fact that it has been shown to be an indispensable portion of the gland, attempts to isolate an extract which would prolong the lives of adrenalectomized animals have usually been made with material from the dissected adrenal cortex alone. The medulla, containing the bulk of the adrenalin, was discarded. Improved technical methods, however, have recently

made it possible to get rid of adrenalin and other toxic products with comparative ease, so that the whole glands may be used for the manufacture of the extract, thus avoiding the laborious preliminary separation of medulla and cortex.

Pfiffner and his collaborators at Princeton, using the method of biological assay of the cortical hormone, which was devised last year in our laboratory at Baltimore and which is based upon the minimal per kilo maintenance dose in the adrenalectomized dog, have recently shown that extracts prepared according to the Pfiffner-Swingle method from whole beef adrenal glands have several times the potency of extracts made from dissected beef cortex alone, based on equivalent weights of tissues. This remarkable fact we are able to confirm. Extracts of dissected cortex material alone have an assay value of six to ten dog units per c.c. of material, while extracts prepared from whole beef adrenal glands may have an assay value of forty units per c.c. or even more. The method of assay which we have employed is, we believe, accurate to within 25 per cent of the true value. If well-nourished animals in prime condition are used the results under these conditions are readily reproducible.

This increase in the potency of extract prepared from the whole glands as compared with that from the dissected cortex is somewhat difficult to interpret on the basis of the long held assumption that the cortex as a whole is the site of origin of the hormone essential to life. This difficulty is increased by a recent paper by Cleghorn,¹ who found that extracts of the (skate)

elasmobranch interrenal body, which as we have stated above is distinct in this form from the segmentally arranged chromaffin bodies, and may be dissected quite separately from them, is without effect in reviving or maintaining the adrenalectomized cat.

In an attempt to throw further light on these puzzling and conflicting findings, my associates, Dr. J. H. Trescher, and Dr. L. J. Soffer, and I have undertaken comparative assays of extract made from: (1) cortical tissue prepared free of medulla by taking thin slices from the periphery of the gland cleaned and dissected away from the surrounding tissues and fat; (2) cortical tissue prepared in the usual manner by splitting the gland longitudinally and dissecting out the medulla; (3) the medulla tissue dissected quite free of cortex; and finally (4) the whole gland material. The material for this study was obtained on the slaughtering floor of one of our large abattoirs immediately after removal from the beef carcass. As rapidly as it was dissected out it was thrust into 95 per cent alcohol to prevent destructive enzyme activity, and frozen solid with carbon dioxide snow. The following assay values on glands so prepared and derived from the same source have been obtained for equivalent weights of tissue:

PREPARATION OF EXTRACT

1. Cortical tissue from the periphery, not in contact with medulla, less than 3 dog units per c.c.
2. Cortical tissue prepared in the usual manner, 8 dog units per c.c.
3. Medullary tissue, 8-10 dog units per c.c.
4. Whole gland tissue, 15-20 dog units per c.c.

These results indicate the higher

concentration of the potent principle as we approach the medulla and the relatively low concentration in the outer part of the cortex of the beef adrenal. Complete separation of cortex and medulla is very difficult. Portions of medullary tissue must be present in the dissected cortex prepared according to the original technic, while the dissected medullary tissue undoubtedly contains fragments of cortex, especially of the reticular layer.

In the light of our fragmentary knowledge both of the chemical properties and of the function of the new hormone, it is most plausible to account for its greater concentration near or in the medulla on the supposition either that it is stored in the larger venous sinuses, or that it is bound to some protein or other structure present in the medulla, so that diffusion from cortex into medulla may continue and increase its concentration in the latter portion of the gland.

It may be interesting, however, to draw your attention to another possibility to account for this curious and unexpected distribution of the hormone within the gland. This is that the site of final activation of the so-called cortical hormone (or "cortin") actually lies in the outer portion of the medulla itself, or in the reticular layer of the cortex which immediately adjoins it. The findings are compatible with the assumption that the cortex elaborates a precursor which is converted into the active substance in this region of the gland. The blood supply of the adrenal gland, in which blood from medulla and cortex are joined together in this border area would favor such a possibility.

The mechanism above outlined would explain not only the indispensability to life of the interrenal body of the elasmobranch, as shown by Biedl, but, on the other hand, the seemingly contradictory finding that extracts of this organ, according to Cleghorn, do not contain the "life" hormone. It will also explain the variations in amount of active material in the several parts of the gland as found above. The survival of animals in which the medulla of the gland has been destroyed or removed, leaving the cortex intact (assuming that such complete elimination is really possible) may be explained by the presence of accessory medullary tissue which, as I have just stated, occurs in large amounts. The presence of smaller amounts of the hormone in the outer layers of the dissected cortex could then be explained in the same manner as the occurrence of adrenalin in the cortex, namely, as due to diffusion into the outer cortical portion of the gland post mortem. The enhanced potency of material derived from the whole adrenal glands prepared in the usual way may well be due to the intimate admixture of the chopped-up tissue during the course of preparation of the extract, or to lessened exposure to the air.

The main cause of Addison's disease is bilateral tuberculosis of the adrenal glands. It was formerly believed that the adrenal infection is primary, but it is now realized that this lesion is usually associated with latent or active tuberculosis elsewhere in the body, probably in most instances in the lungs. Tuberculosis of the adrenals is a relatively rare disease having, it is said, about the same incidence as tubercu-

losis of the skin. The tuberculous lesion appears to attack the medulla first and later the cortex. The latter always seems to be affected, however, in reliable reports of Addison's disease. Wiesel found in a fifteen-year-old tuberculous patient with complete destruction of the medulla, but intact cortex, no symptoms of the disease, although the paraganglia, significantly enough, were much enlarged.

In approximately one-fifth of the published cases but in a larger proportion of our present series, the lesion found at autopsy in the adrenal glands is that of primary cortical atrophy. A very considerable number of such cases has now been reported, and it is of interest to note that in them, in contrast to the cases of tuberculosis of the adrenals, it is the cortex which is first and principally affected while the medulla is seriously altered only at a later period. Our fatal cases of Addison's disease associated with this primary cortical atrophy have been studied by Duff and Bernstein²; we have had four come to autopsy. The destructive process was a progressive necrosis of cortical cells with collapse of the stroma. The reticular zone disappeared first and of the two other zones the outer one, the glomerulosa, persisted longer. Regeneration appeared as islands of newly formed cells at the periphery. More or less dense infiltrations of lymphocytes were always present in the medulla and among the remains of cortical tissue. The necrosis of the cortical cells was accompanied by relatively little fibrosis, the outer capsule simply collapsing down to the medullary tissue.

Duff was able to find four less ad-

vanced cases of adrenal atrophy in which a similar destruction had taken place, with small lymphocytic accumulation and without changes in the medulla. In these cases without symptoms of Addison's disease, the primary lesion was in the cortex, and the reticular zone was most susceptible, the glomerular most resistant, to destruction.

It seems to us of importance from the point of view of therapy that areas of regeneration occur in the injured glands. The quick response of the remaining cortical tissue to the stimulus of deficiency is striking. In the experimental animal, after removal of one gland, hypertrophy of the remaining adrenal gland is very rapid, and quite definite in the dog within three or four weeks. This hypertrophy is decidedly greater in the presence of infection, distemper in the dog being an especially effective stimulus. It is not unusual in such cases to find the second gland double the weight of the one first removed. This increase is confined so far as we can determine to the cortical portion. When sufficient extract is supplied to the adult male dog from which one gland is removed this hypertrophy is not found, indicating that lack of this material is the adequate stimulus for production of the hypertrophic change. Injections of the extract will not, however, prevent hypertrophy of the remaining gland in a growing animal, or in the presence of malnutrition, or of an intercurrent infection, even in doses per kilo of body weight which are otherwise effective in the healthy adult. We believe this to be suggestive evidence that products of the cortical tissue are required in greater amounts by the growing animal,

as well as by the animal during the course of an infection, and that further studies along this line may be of help in reaching a better understanding of this phase of cortical function.

One of the cardinal features of Addison's disease is pigmentation. In many it is the first symptom observed and often one finds that the earliest change the patient notes is that of a summer's tan which does not fade. It may be present for many years and it has been repeatedly observed that such cases are apt to be more prolonged and to run a more benign course than those ushered in by asthenia and muscular weakness. A recent case observed by us is of interest:

G. F., a white man of 55, works for a life insurance company which gives periodic health examinations to its employees. Owing to this it is known that he has had low blood pressure since 1917. During 1917 and 1918 he was in a sanitarium for sixteen months with pulmonary tuberculosis. One daughter has died of pulmonary tuberculosis, but the contact with the patient was not close. He has felt quite well. There have been no gastrointestinal symptoms and no muscular weakness prior to his present illness. He came to the hospital this autumn with influenza complicated by pneumonia and there it was noted that he had marked and characteristic pigmentation of lips and buccal mucosa, which he stated on questioning had been present for many months. During recovery from his influenzal infection the asthenia has improved and at the present time he is free of symptoms. He has never received cortical extract.

We have here a patient whose history and appearance is highly suggestive of Addison's disease, with proven hypotension for many years and with pigmentary changes for many months. It seems quite possible that in this instance we are dealing with tuberculosis of the adrenals and that the process

has so far attacked chiefly the medulla while the cortical portion is as yet largely unimpaired.

Speculation as to the relationship of the pigmentation to the disease has naturally centered about the close similarity of chemical structure between adrenalin and the skin pigment, melanin. It has been suggested that failure of the gland to utilize the natural adrenalin precursors to form adrenalin has led to their vicarious utilization in the skin in the formation of increased amounts of melanin. The supposed precursor most popular in the minds of investigators is dioxyphenylalanin or "dopa", which has been studied by Bloch and his pupils. Unfortunately, it has not been possible to produce such skin pigmentation experimentally by removal of the adrenal glands in animals and the positive results reported from time to time cannot be regularly reproduced. Scars, pressure, exposure to various chemical and physical agents, including light, produce no pigmentation not also to be observed in control animals. The injection of dioxyphenylalanin itself in rats and in dogs without adrenal glands is without effect. Patients with Addison's disease during the relapse often show marked increase in pigmentation, and improvement is frequently but not regularly associated with its partial disappearance. With the aid of Professor Max Brödel and his pupils we have been measuring the depth of pigmentation in our patients over definite skin areas during the various phases of the disease. We find that when these changes are measured by such objective criteria our clinical impressions have often proved very faulty. Increases appear rather quickly especially during re-

lapses but disappear very slowly, probably by wearing away of the basal cell layer in which the pigment is deposited in the natural course of skin growth. Differences measured over the course of months are indeed quite definite, but no marked disappearance of the pigmentation has occurred even after much extract has been given.

Now as to the results of treatment of patients with the new cortical extract. We have treated during the past two and one-half years thirteen patients whom we regard as definitely suffering from Addison's disease. Of these, seven have died. The diagnosis in all of them was confirmed by autopsy. (Table 1) C. L., the first case

assay, probably due to imperfect preservation of the glands at the abattoir during the hot weather. F. R. died at a sanatorium of disseminated tuberculosis throughout the body. His condition was hopeless from the outset and the wisdom of treating such cases, when limited supplies of the extract are available, is of course open to grave doubt. The other four fatal cases were those due to cortical atrophy and the lesions found have already been discussed.

It is quite evident that the hopes aroused three years ago as to the value of the cortical extract or cortin in the treatment of Addison's disease have not met with as complete satisfaction

TABLE I
CASES OF ADDISON'S DISEASE TREATED WITH ADRENAL CORTICAL HORMONE
WITH FATAL OUTCOME

Patient	Age	Sex	Duration of illness before treatment	Duration of treatment	Number of relapses	Weight gain after treatment	Outcome Autopsy Diagnosis
C.L.	50	F	6½ yrs.	8 wks.	4	No increase	Tuberculosis of adrenals
E.S.B.	34	M	22 mos.	8 mos.	3	No increase	Cortical atrophy with symptoms of asthma
R.M.C.	36	F	8 yrs.	9 mos.	6	No increase	Cortical atrophy; cirrhosis of liver with jaundice
M.S.	37	F	4½ yrs.	15 mos.	4	No increase	Cortical atrophy; acute fibrinous pericarditis
M.D.	35	F	6 mos.	10 mos.	2	No increase	Cortical atrophy.
G.K.	48	F	4 yrs.	23 days	1	No increase	Tuberculosis of adrenals and cold abscess of rib
F.R.	42	M	11 mos.	80 days	3	No increase	Tuberculosis of adrenals, lungs, kidneys and liver

treated in the fall of 1930, did not receive adequate amounts of extract according to our present standards. G. K. was treated for twenty-three days last summer with an extract of low potency, as was later found on

as was originally anticipated. There can be no doubt, we believe, of the value of the material in the acute relapse of the disease. It should be given in large amounts at as early a time as possible. We have never seen evidence

of overdosage in the experimental animal. We have administered 100 c.c. intravenously to an 8 kg. dog without the slightest evidence of toxicity and we have never noticed any harmful effect clinically from the use of any of the extracts prepared in our own laboratory. It appears possible that the extract alone in certain cases without the aid of any accessory agent can relieve the acute crisis, as is indicated by

circulatory collapse. Insofar as the cortical hormone appears to restore the blood volume and blood pressure to a normal level, the regulation of these functions either directly or indirectly must be regarded as one of its essential rôles.

On the other hand (table 2), the value of continued treatment with cortical extract during the intervals of comparative well being and adequate

TABLE II
CASES OF ADDISON'S DISEASE TREATED WITH ADRENAL CORTICAL HORMONE
SHOWING IMPROVEMENT

Patient	Age	Sex	Duration of illness before treatment	Duration of treatment	Number of relapses	Blood pressure change	Gain in weight	Present condition	Clinical Diagnosis

the recent report of Albright and Baird.³ Our experience leads us to agree with Loeb⁴ in his conception of the Addisonian crisis as a condition of shock, and we believe the value of the usual measures to combat shock and particularly the importance of intravenous saline and glucose solutions is definitely proved. The crisis of Addison's disease is strictly analogous to the condition of insufficiency in the adrenalectomized dog following withdrawal of extract and responds to the same treatment. In all essential particulars they are identical with the condition of shock as seen in both surgical and medical practice. Untreated, death occurs as a result of tissue dehydration, hemoconcentration, and

circulation must be regarded with greater reserve. We have now under observation two patients treated for approximately twenty months. The condition of one of the two is essentially stationary while the other shows slight improvement. Gain in weight has not been striking; no marked change has occurred in the blood pressure, and the pigmentation, while less in amount, is not decidedly improved in either of these patients. Two other cases, both under extract treatment now for about one year, are in very good condition. A comparison of the cases with fatal outcome with those in which more or less improvement has taken place indicates that in the latter group fewer relapses have occurred.

It seems altogether likely that in the prevention or amelioration of repeated relapses by the early use of the cortical extract when symptoms first appear, a definite step may be taken towards the prolongation of life. The average duration of the disease in our group at present under treatment is a little over two years. In a large proportion of cases the disease has an essentially chronic character, although the average duration of life in patients untreated in the large Mayo Clinic group is said to be 16.5 months. Actual prolongation of life therefore has not yet been conclusively demonstrated. It is quite evident that a much greater experience is needed for the proper evaluation of this therapeutic agent upon the eventual course of the disease and its ultimate prognosis.

In determinations of the minimal amounts of extract required for maintenance of the adrenalectomized dog, we have found that the use of certain oils by mouth often permits of lower extract dosage than would otherwise be required. Of the oils so far examined, cotton-seed oil has proved most effective. The action of cotton-seed oil in enhancing the effect of the cortical extract upon the adrenalectomized dog has led us to apply this material to the treatment of our patients with Addison's disease during the intervals of comparatively good condition. We believe that the clinical improvement and absence of relapses under such treatment is sufficiently suggestive to merit further study of its efficacy. The employment of these oils is of little or no value during the relapse, when the extreme nausea and vomiting make their use by mouth very difficult if not impossible. The reasons for the effec-

tiveness of these oils is at present under study. One point only may be observed. The maintenance of good nutrition in the experimental animal is of great importance in lowering the extract requirements. We administer clinically as large doses of the oil as may be tolerated without great distaste, nausea or other undesirable symptoms.

Most important of all as an adjunct to the treatment of the acute relapse with the cortical extract, is the use of large amounts of sodium chloride. If tolerated it should be given by mouth, but it must be administered intravenously and subcutaneously if necessary. Stress must be laid on early treatment. Most patients tolerate well two or three one-gram capsules of sodium chloride when given immediately after the ingestion of food or fluids. Great care must be exercised to avoid increasing the nausea which is inevitably associated with this condition. It is quite definitely shown that patients in relapse usually have marked dehydration and that this underlies the condition of shock. Our unpublished data collected over the past three years, as well as the recently published paper by Loeb⁴ indicates that the acute relapse is characterized by marked loss of sodium and chloride from the blood plasma, and, especially in the earlier stages, increased excretion of these substances in the urine. Even where the plasma chloride content has dropped to 75 mil. eq. per liter (435 mgs. as NaCl per 100 c.c.), sodium and chloride are still excreted in the urine. Further, we have been able to produce an acute relapse in two patients merely by placing them on a salt free diet for four

days. Patients should be cautioned to use ample salt in their diet, and indeed one of our patients (M. S.) particularly craved salt pork, stating that she felt much better when she ate this food.

In conclusion we may summarize our findings as follows: A comparison of the phenomena observed clinically during the relapse of Addison's dis-

conditions in both medical and surgical practice.* It would appear that these are symptoms due primarily or secondarily to a deficient supply of a substance elaborated in the adrenal cortex. (Table 3).

When we come to the maintenance of patients as well as experimental animals not in a condition of shock, however, the points of resemblance are

TABLE III
COMPARISON OF THE PHENOMENA PRESENT IN MEDICAL OR SURGICAL SHOCK, IN THE RELAPSE OF ADDISON'S DISEASE, AND IN ADRENAL INSUFFICIENCY PRODUCED BY WITHDRAWAL OF CORTICAL EXTRACT IN THE ADRENALECTOMIZED ANIMAL

	Medical or Surgical Shock	Relapse in Addison's Disease	Adrenal Insufficiency in the Adrenal- ectomized Dog
Body temperature	Low	Low	Low
Hypotension	Frequently present	Present	Present
Blood non-protein-nitrogen, urea, red cell count, hemoglobin and hematocrit.	Frequent	Common	Present
Pulse	Increased	Increased	Increased
Blood non-protein nitrogen, urea, plasma proteins	Frequently increased	Usually increased	Increased
Nausea, vomiting	Common	Common	Common
Plasma chlorides, bicarbonate, total base and sodium		Low	Low

ease with those of adrenal insufficiency in adrenalectomized dogs after withdrawal of extract, reveals important similarities. The points of resemblance are the extreme muscular weakness, the anorexia, vomiting and diarrhea, the lowered general bodily activity associated with lowered body temperature, blood pressure and general metabolism, the increased concentration of the blood, and finally, the changes in certain chemical constituents of the blood some of which are fairly characteristic of the condition of shock as met with in a variety of pathological

not so striking. Adequate dosage of cortical extract in the dog appears to maintain normal nutrition and weight and to preserve life indefinitely. The blood pressure is normal, there is no hypoglycemia, no increased pigmentation and no change in the basal respiratory metabolism. It has seemed that over a long period of time a moderate grade of secondary anemia develops.

*These changes consist in lowered plasma total base, sodium, bicarbonate, and chloride concentrations. The concentrations of plasma potassium, magnesium, proteins and inorganic phosphate are increased.

In contrast, the patient with advanced Addison's disease, not in relapse, even when given large amounts of a potent preparation of cortical extract continues to exhibit hypotension, usually hypoglycemia, and no striking amelioration in the pigmentation which is characteristic of the disease and without which we are unable to make a diagnosis. The effect on weight and nutrition is variable and sometimes very slight. The basal metabolic rate is lowered in most patients. Well marked anemia is uncommon.

It is a striking fact that the pathological phenomena singularly unaffected by administration of the cortical

hormone in Addison's disease in man, namely, hypotension, hypoglycemia and pigmentation, are just those which do not occur during treated suprarenal deficit in the dog. They are phenomena which a considerable body of experimental evidence associates with disturbance of medullary function and particularly with that of adrenalin. We believe that the evidence is increasing that Addison's disease is probably dependent on disturbed function of both cortex and medulla, and that these two portions of the adrenal gland have reciprocal relations of such a nature that damage to the one produces disturbance of function in the other.

The Influence of Age in the Experimental Production of Hypertrophic Arthritis*

Preliminary Report

By ARTHUR D. GOLDBAFT, V.M.D., LILLIE M. WRIGHT, M.A., and
RALPH PEMBERTON, M.D., F.A.C.P., *Philadelphia, Pennsylvania*

IN a previous communication, evidence has been adduced by the present writers which indicates that it is possible to induce an overgrowth in the patella of dogs, characteristic of hypertrophic arthritis, by ligation of the blood supply to that structure. The changes resulting consisted in a marked increase in size of the patella which reached its maximum about nine months after operation. Control experiments showed that this result was not due to the trauma of operative procedure. The phenomena accompanying overgrowth were essentially those characterizing hypertrophic arthritis as seen in human beings, but there were also some evidences of atrophic arthritis, such as slight erosion or rarefaction of the margins of the patella together with general thickening and adhesions of the soft structures of the joint as a whole, making dissection difficult.¹

Following increasing recognition of the two main types of arthritis first emphasized in this country by Nichols and Richardson² in their classic monograph, studies have been conducted by many workers, having for their aim

determination of the etiology of the two types of the disease. These studies have usually indicated, with some exceptions, that arthritis constitutes a syndrome having diversified pathologic manifestations and many etiologic factors. This point of view is that which Nichols and Richardson endeavored to establish, although a few subsequent workers have held a rather more dogmatic attitude which regards the two types of the disease as wholly distinct and referable to quite different etiologic causes. Supporting evidence for the former view is found in the accepted etiologic importance in both types of the disease of such factors as heredity, bodily configuration, imbalance of the nervous system, and dysfunction of the gastrointestinal tract, as well as in the common response of these types to certain forms of therapy. Focal infection, which has long and properly been emphasized, is now regarded as constituting often a precipitating or additional factor only, and one which, although contributory to poor health, may, even when demonstrably present, have little or nothing to do with the actual arthritic process. The most significant advances recently made in

*Received for publication November 11, 1932.

treatment center around this broader appreciation of the subject.

Notwithstanding this widened outlook, there is avowedly much to be determined as to the extent to which the two types of arthritis, atrophic and hypertrophic, overlap; the extent to which they constitute separate processes; and the extent to which they require different forms of therapy. It is accepted that the clinical phenomena of the two types, as well as the osseous picture by X-ray or "en gros", offer sharp contrasts, but some of the considerations enumerated above strongly suggest some commonality of etiology and of certain physiological deviations underlying the disease as a whole. One of the outstanding observations relating to arthritis as seen in the human being is the fact that atrophic arthritis is, by and large, a disease of the first half of life, and hypertrophic arthritis, by and large, is a disease of the latter half of life. There are exceptions to this, in that atrophic arthritis may appear as late as the eighth decade and hypertrophic arthritis may appear early in mid-life, or, according to some recent observations of Matz,³ even earlier. In general, however, any observations of a large series of arthritics will show that atrophic arthritis tends to disappear at an age at which hypertrophic arthritis tends to begin. It is difficult to see why atrophic arthritis should largely leave the stage at mid-life and why hypertrophic arthritis enters it then, unless these disease states reflect or represent in some way different age responses to the exciting factors. The influence of age as a determining factor in disease of those particular expressions which certain morbid proc-

esses or entities take, is illustrated by disease of the pituitary gland which in youth may express itself as gigantism and in the latter decades as acromegaly. Recent observations by Jaffe and Bodansky⁴ have shown that in guinea pigs age determines the response of the animal to parathormone to such an extent that it is possible by means of injections of parathormone to produce osteitis fibrosa cystica in young animals but not at all in old ones. The expression which renal disease takes in the young offers some contrasts to that which is seen in older persons, and certain differences of the same order are to be observed in connection with cardio-vascular pathology. Again, diabetes in the young exhibits some differences as compared with the disease encountered in the more elderly, and much the same comment can be made regarding tuberculosis. It is thus clear that age introduces factors which may importantly condition the final expression of that deviation of physiology which may underlie any large syndrome, and it becomes pertinent to determine if possible the extent to which this is the case in the syndrome of arthritis. Apart from the clearer concept of the disease which would be afforded by observations elucidating this influence, certain definite and important therapeutic procedures would be given greater or less emphasis. If it could be shown that the surface phenomena of atrophic or hypertrophic arthritis are conditioned in part or largely by age, a wider outlook would have to be entertained upon the problem as a whole, and emphasis upon the separate identity of the two types would be more difficult of justification.

In view of the clear-cut results characteristic of hypertrophic arthritis which followed attempts at reproduction of some of the phenomena of arthritis by ligation of the blood supply to the patella of adult dogs, it seemed desirable to repeat these experiments making use of young dogs only. If it were shown that the response of the tissues differed markedly in young and old animals, the implication would be strong that age constitutes a decisive factor in the induction of hypertrophic arthritis. One starting point in the experiments to be cited was the observation that one of the dogs in the first series operated upon presented ununited epiphyses and that

this animal showed after operation less overgrowth of the patella than developed in the other and older dogs. Experiments were accordingly undertaken upon a series of five dogs, the results of which are set forth in the accompanying protocols. Of five experiments, only three were successful; two failed because of the death of the animal or other accident. In view, however, of the long time required to carry through experiments of this nature, in view of the many hazards to which very young dogs are subjected in the course of such experiments, and in view of the fact that upwards of a year must elapse before further data could be forthcoming, it seems justifi-

Patella of dog "Wire-haired", eight and three-quarters months after ligation of its blood supply. Note absence of distal growth.

patella of the right leg was ligated, resulting in lameness of that leg. The lameness almost disappeared in one week.

Roentgen-rays of the leg operated upon on the following dates showed:

October 31, 1929. A normal knee joint, epiphyses not united. The roentgen-ray was taken before operation.

February 22, 1930. A slight change in the shape of the patella. The epiphyses are uniting.

May 10, 1930. No change from the roent-

left leg and patella and a right leg that seemed normal on dissection, had no thickening of the tissues nor adhesions, but that showed a slightly deformed articular surface of the patella. The right patella could be dissected and stripped as easily as a normal patella and it split with as much difficulty. It was smooth and shiny on its articular surface, but slightly livid in color. The sheath of the proximal tendon had grown somewhat down over the patella and up around its sides, almost merging with the articular sur-

face and covering an area of erosion on this articular surface. The patella showed no overgrowth, only a change in shape.

Dog No. 8—A female mongrel fox terrier, named "Pup", four months old, 10 pounds

in weight, was operated upon November 4, 1929. The blood supply to the patella of the right leg was ligated, resulting in lameness of that leg. The lameness almost entirely disappeared in one week. (Figures 3 and 4)

Normal patella of dog "Pup".

FIG. 3

Patella of dog "Pup" eight and three-quarters months after ligation of its blood supply. Note the spike-like but localized overgrowth distally.

FIG. 4. Photograph of the patellae of dog "Pup" showing overgrowth of the patella on the left, twelve and one-half months after ligation of the blood supply to it. The overgrowth consisted of a spike rather than of the patella as a whole.

Roentgen-rays of the leg operated upon on the following dates showed:

October 31, 1929. A normal knee joint, epiphyses not united. The roentgen-ray was taken before operation.

February 22, 1930. A distal overgrowth, consisting of a spike from the outer edge of the patella.

May 10, 1930. A slight increase in the length of the spike distally, erosion of the patella making the spike appear longer.

July 25, 1930. No change from the roentgen-ray of May 10, except that the epiphyses are almost united.

November 22, 1930. No change from the roentgen-ray of July 25.

On November 22, 1930 the dog was sacrificed

Examination after death showed a normal left leg and patella. The right leg dissected out normally; it showed no thickening of the tissues and only slight adhesions above the patella. There was, however, an area of erosion on the left side of the condyle of the femur at the knee joint. The right patel-

and giving the overgrowth a shelf-like appearance, and adding to its apparent length.

Dog No. 17—A female mongrel fox terrier, named "Cleo", five months of age, 15 pounds in weight, was operated upon September 1, 1931. The blood supply to the patella of the left leg was ligated, resulting in lameness of that leg. (Figures 5 and 6)

Roentgen-rays of the leg operated upon on the following dates showed:

July 26, 1931. A normal knee joint, epiph-

FIG. 5

Normal patella of dog "Cleo".

la dissected out easily, but was slightly more difficult to strip than the normal one. The articular surface was smooth and glistening, but at least one millimeter shorter than the normal one. The right patella itself showed an overgrowth of about one millimeter, but only of the part of the patella that adhered to the tendon. There were areas of erosion under the articular surface of the patella, the one at the distal end being the largest

FIG. 6. Photograph of the patellae of dog "Cleo" showing overgrowth of the patella on the right, nine months after ligation of the blood supply to it.

yses not united. The roentgen-ray was taken before the operation.

October 24, 1931. No change from the roentgen-ray of July 26.

January 29, 1932. Epiphyses almost united, otherwise no change from the roentgen-ray of July 26, 1931.

February 8, 1932. No change from the roentgen-ray of January 29.

June 23, 1932. A very slight overgrowth distally, epiphyses united.

On July 8, 1932 the dog was sacrificed.

Examination after death showed a normal right leg and patella and a left leg that seemed normal on dissection, showed no tissue thickening and only slight adhesions around the patella. Both patellae were equally difficult to dissect free and strip. The left patella showed a slight overgrowth distally of the whole patella of about one millimeter (7 per cent). There were also places on the non-articular surface of the left patella that had remnants of suture material imbedded.

Dog No. 20—A female mongrel fox terrier, named "Spotty", three months of age, 8 pounds in weight, was operated upon February 19, 1932. The blood supply to the patella of the left leg was ligated, resulting in lameness of that leg.

Roentgen-rays of the leg operated upon on the following dates showed:

February 8, 1932. A normal knee joint, epiphyses not united. The roentgen-ray was taken before operation.

July 1, 1932 (after death). No change from the roentgen-ray of February 8.

On April 7, 1932, she died of an infection due to a cystic calculus.

Examination after death showed a normal right leg and patella, the epiphyses not united, and a left leg that dissected out easily, showing no tissue thickening and no adhesions around the patella. The left knee joint showed some discoloration due probably to hemorrhage following the operation; also its epiphyses were not yet united. The left patella showed no overgrowth. Both patellae split with slight difficulty and showed inside a brownish coloration of the bone, which was slightly larger in area in the normal patella. Both patellae stripped very easily.

A review of the above protocols shows that a difference apparently exists between the response of older dogs subjected to ligation of blood supply to the patella and that of younger animals chosen before union of the epiphyses. While some overgrowth of the patella may occur, in none of the three young dogs carried along for ten months or a year was there an overgrowth strictly comparable to that seen in all of the older animals; and in two of the young dogs the overgrowth was practically negligible or not to be detected at all.

It has been suspected by some students of arthritis that hypertrophic arthritis appears at mid-life because of the differing response of the tissues consequent upon some factor such as arteriosclerosis, or its vascular precursors, which is present in greater or less degree in all humans or animals that reach that age. In the three experiments just detailed there is a definite suggestion that prior to the appearance of the vascular or other changes of maturity, the end result falls short of the frank picture which is seen in the older animals.

The influence of age upon the type of arthritis cannot be regarded as settled on the basis of one line of experimentation, but one inference that may be drawn is that the phenomena of hypertrophic arthritis may represent a response due to the particular condition of the tissues rather than the effect produced by the action of any type-specific etiologic factor.

This general deduction must be correlated with the evidence that a number of factors often underlie both types of the disease, etiologically and therapeutic.

tically. As already mentioned, some of these factors in human beings are the influence of heredity, the bodily configuration, imbalance of the nervous system, a condition resembling vasoconstriction at the periphery, anatomical and physiological deviations of the gastrointestinal tract, and the influence of a balanced but restricted dietary.^{5,6}

To this list might be added the influence of focal infection though some observers believe that infection has no relation to hypertrophic arthritis. Final proof of this is difficult, however; and it is probable that most dispassionate students regard focal infection as at least contributory to the syndrome of hypertrophic arthritis, although having less obvious and flagrant consequences than in atrophic arthritis.

To these considerations must be added the further fact that there is present in ossifying tissue, though only in

traces in unossified cartilage, the enzyme phosphoric esterase shown by Robison⁷ to be concerned in the formation of bone.

SUMMARY

Preliminary report is made of experiments in which the attempt to produce hypertrophic arthritis in young dogs by curtailment of the blood supply to the patella is accompanied by slight or negative results as compared with similar attempts carried out upon mature animals. Taken in conjunction with other data the observations here cited seem, so far as they go, to add cogency to the view that hypertrophic arthritis is, in part at least, a function of the kind of response which the more adult tissues yield rather than exclusively a response to distinct etiologic factors basically different from those which are present in atrophic arthritis.

A Correlation of the Hemodynamics, Function, and Histologic Structure of the Kidney in Malignant Arterial Hypertension with Malignant Nephrosclerosis*†

By SOMA WEISS, FREDERIC PARKER, JR., and GEORGE P. ROBB,
Boston, Massachusetts

THE correlation of the functional behavior and the structural characteristics of the blood vessels with the physiological units of the kidney is one of the most significant advances in the knowledge of kidney diseases during the past two decades. Evidence is accumulating that in the majority of instances of bilateral kidney disease of adult life the failure of the kidney function depends on a primary disease of the renal blood vessels. These cases are now variously classified as hypertensive renal disease, benign or malignant nephrosclerosis, and arteriosclerotic kidney disease. Contrariwise, in acute and chronic glomerulonephritis an "infectious process" is believed to involve primarily the glomeruli and tubules. The pathological state of the blood vessels in these latter cases, particularly in chronic glomerulonephritis, also plays a significant rôle in the mechanism of disturbed kidney function.

*Received for publication December 27, 1932.
†From the Thorndike Memorial Laboratory, Second and Fourth Medical Services (Harvard) and the Department of Pathology, Boston City Hospital; and the Department of Medicine, Harvard Medical School, Boston, Mass.

In this rather simple but somewhat arbitrary grouping of bilateral kidney diseases, the classification of malignant nephrosclerosis is particularly difficult. Vollhard and Fahr,¹ and Löhlein² separated this condition from the larger group of glomerulonephritis on the basis of the age of the patients, the rapidly fatal course, certain laboratory findings, and the "acute" histological changes in the glomeruli. The infectious character of the glomerular lesions was emphasized by Vollhard and Fahr without sufficient consideration of the vascular lesions. Recently, through the efforts of Fahr,³ the significance of the necrotizing arteriolitis, productive endarteritis and periarteritis of the kidneys and other organs has been receiving a new interpretation. He believes that the glomerular changes, which often predominate in the histologic picture, represent secondary effects of prolonged ischemia produced by vascular damage. Löhlein,² Jores,⁴ Bell and Clawson,⁵ and Shapiro⁶ have claimed that the fundamental mechanism of benign and malignant nephro-

sclerosis is of identical nature, and that these conditions differ only in the rate of their development. These authors believe that the more rapid decrease in the blood supply in malignant nephrosclerosis results in glomerular ischemia and in more acute histological changes resembling those of an infectious process. Stern,⁷ Fishberg,⁸ Murphy and Grill⁹ also agree that both benign and malignant nephrosclerosis are due to vascular sclerosis.

Volhard¹⁰ in 1923 relinquished his toxic theory of the etiology of malignant nephrosclerosis and attributed the histological changes to a general vasoconstriction associated with an intense capillary spasm of the glomeruli. According to him, the capillary ischemia thus caused tends to produce degenerative and proliferative changes. This concept was rejected recently by Klemperer and Otani,¹¹ who pointed out that if in the pathogenesis of this condition the capillary system were the seat of primary disturbance, the changes should be distal to the glomeruli, whereas in reality the vascular changes lie in the afferent arterioles as well as in the glomeruli. They traced the origin of the glomerular changes to thrombotic or proliferative occlusion at some point in the afferent arterioles. Meyer-Stettin,¹² Sternberg,¹³ Ask-Upmark,¹⁴ and others have, on the other hand, brought forward evidence against the identical sclerotic character of benign and malignant nephrosclerosis. It is evident, then, that at present a detailed interpretation of the changes in the blood vessels and in the kidney units in malignant nephrosclerosis is not possible.

An unusual coincidence of events,

to be described below, has permitted us to conduct observations on malignant nephrosclerosis which allow for the first time a correlation between the hemodynamics of renal circulation and the structure of the blood vessels and the function and structure of the kidney. Some data concerning the natural history of the disease have also been obtained. Below we present the clinical course of the disease as observed in a patient, followed by functional and histological studies.

I. CLINICAL COURSE

R. J. W., a 27-year-old male white truck driver, was admitted to the hospital November 16, 1930. His *chief complaint* was "blood in the urine". He was "in perfect health" until six months previously when he experienced hematuria, abdominal discomfort, and blurring of vision.

The hematuria occurred at first about every two weeks and lasted for about a day. These attacks gradually increased in frequency, intensity and duration until two months before entrance to the hospital. Since then hematuria had been continuous but with changing severity. No retention or incontinence of urine, chills, fever, or edema was observed. The abdominal discomfort was generalized, rather constant, and of mild degree. Heat, rubbing and simple medications did not relieve the pain. Blurring of vision was rather diffuse. In addition to these three main symptoms, he also suffered from headache, nausea, and vomiting, which were attributed by the patient to the consumption of alcohol. He had been a heavy drinker for the past three to four years. He claimed some correlation between alcoholic debauches and renal hemorrhages.

Dyspnea, experienced on moderate exertion, developed six months previous to admission. Periods of palpitation lasting 10 to 15 minutes had been occasionally observed. No other noteworthy changes in the function of organs were noticed.

The patient had suffered in the past from infrequent attacks of tonsillitis. The history

as to other infections was essentially negative with the exception of the occurrence of gonorrhea. His mental makeup was natural. No history of familial diseases was obtained.

Because of the free unilateral renal bleeding observed during cystoscopy, and because of certain changes in the roentgen-ray shadow of the kidney pelvis, a surgeon had been led to inform the patient of the possible existence of a malignant tumor of the left kidney. Following an attack of profuse

hematuria, the patient was rushed to the hospital for an immediate nephrectomy.

A left-sided nephrectomy under novocaine spinal anesthesia was performed November 18, 1930. The observations made during this operation will be reported further on.

The *physical examination* the day following the nephrectomy revealed a rather thin, ivory pale adult with prominent shiny eyes, comfortably lying flat in bed. The pupils reacted normally. The ocular fundi were

FIG. 1. Cortical surface of the left kidney removed surgically. Numerous small sub-surface hemorrhages are visible. X 1.3.

edematous with swelling of both discs and pronounced blurring of the margins. Numerous small, irregularly shaped, whitish areas were visible over both retinas. The small arteries were narrow and both these

any evidence of engorgement. The thyroid gland was not palpable. The superficial veins of the upper chest anteriorly were somewhat dilated. The lungs were normal. The apex beat of the heart in the fifth costal interspace was

FIG. 2. Surface of the longitudinal cross section of left kidney removed surgically. Scattered minute hemorrhagic areas. X 1.3.

and the small branches of the veins were tortuous. Arterial compression of the large veins was observed. The mucous membranes of the mouth were rather pale. The tonsils were small and innocent in appearance. No exudate could be squeezed out. The veins of the neck showed normal pulsations without

rather prominent. The maximal left diameter of the heart was only 10 cm. in the fifth interspace. The entire precordium was elevated through the force of the systolic impulse of the heart. The first heart sound was of normal intensity and quality and was continued by a short high-pitched systolic

murmur over the apex. The second sound over the apex was loud. At the base there was a reduplication of the second sound. The aortic second sound was metallic in character and loud. The heart rate was regular. The radial pulse was small, well sustained, and forceful. There was no evidence of arteriosclerosis. The arterial blood pressure was 185 mm. of mercury systolic and 120 mm. diastolic. The abdomen showed some resistance. No organs were palpable. There was a very slight cyanotic pallor of the nail beds of the fingers. The extremities, otherwise, were negative. The neurological examination revealed no abnormal signs. The rectal temperature was normal. The specific gravity of the urine was 1.008. The blood contained 3,330,000 red blood cells and 15,000 leukocytes per cu. mm. with 70 per cent hemoglobin. The diagnosis following operation was *malignant hypertension with nephrosclerosis*.

It is of interest that the first specimen of urine obtained following operation, contrary to the one obtained before, was free of blood. The chemistry of the blood and the kidney function tests, however, indicated for about two weeks after operation a progressive impairment of the kidney function. The urea clearance test reached as low a level as 3.4 c.c., or 6.4 per cent of the average normal clearance with a blood urea content of 142 mg. per 100 c.c.; and the creatinine clearance 8.1 c.c. of filtrate of urine with 11.6 mg. of creatinine in 100 c.c. of blood. Simultaneously with these changes the blood pressure rose to 200 mm. of mercury systolic and 130 mm. diastolic. The degree of edema of the retinal discs increased. Nausea and vomiting were occasionally present. The patient received a diet containing 20 gm. of protein with an adequate caloric content. The fluid intake was liberal. From the seventeenth day after the operation onward the kidney function showed progressive improvement and simultaneously the patient felt very much better. The appetite became voracious. The edema of the optic discs decreased. Toward the end of December his general condition was excellent and the blood urea fell as low as 47 mg. per 100 c.c. of blood.

Beginning soon thereafter, however, the blood pressure rose again to from 200 to 210

mm. of mercury systolic and 130 mm. diastolic. This was followed in four days by severe headaches, puffiness about the eyes and a decrease in the functional capacity of the kidney with unchanged urinary sediment. On January 8th headache was intense, and nausea and vomiting were also present. No explanation could be found for this attack of cerebral vascular crisis, which could not be relieved with luminal and pyramidon. The next day the manifestations of the cerebral crisis improved except for the facial edema. The following night a severe attack of cough and dyspnea developed. The patient sat up in distress and raised frothy blood-tinged sputum. This, together with the moist râles heard over the entire chest, suggested an attack of "paroxysmal nocturnal dyspnea" (cardiac asthma) with pulmonary edema. Morphine (gr. 1/4) and atropine (gr. 1/60) relieved this distress promptly, and in the morning the patient felt comfortable. There was, however, impaired resonance of mild degree over the right side of the chest anteriorly and posteriorly with somewhat decreased excursion of the diaphragm. The breath sounds were diminished and there was an increase in the spoken voice and fremitus. The arterial blood pressure was 200 mm. of mercury systolic and 130 mm. diastolic; the vital capacity of the lungs was 4200 c.c. The liver and spleen were not palpated and ascites and edema were not observed.

In the evening of January 11th we had another opportunity to observe in detail the development of paroxysmal nocturnal dyspnea. The patient ate a good supper and was comfortable. At about 8 p.m. he felt a tight sensation beneath the manubrium sterni. He became restless and complained of inspiratory difficulty. The right side of the thorax now showed limited excursion with a few fine and medium consonating râles over that side. The arterial blood pressure was 205 mm. of mercury systolic and 136 mm. diastolic, the venous blood pressure 12 cm. of water. The condition grew rapidly worse. The patient was pale and cold and covered with sweat. The "tightness in the chest" and the dyspnea became so severe that a marked degree of orthopnea developed. There was extreme apprehension of death. The pa-

tient coughed with considerable distress, raising red frothy sputum with occasional red streaks of blood. The heart sounds became rapid, and while before the attack the aortic second sound was loud and metallic, now the relationship changed and the pulmonary second sound became accentuated and louder than the aortic second sound. There was at the same time an almost complete fixation of the right side of the thorax with dullness and a definite increase in the intercostal retraction. The breath sounds were almost completely absent but numerous fine, medium and coarse râles were heard throughout the right lung. *While these physical signs indicated severe changes in the right lung, the physical signs of the left side of the chest remained essentially normal.* The heart rate rose to 150 per minute. The arterial blood pressure was 225 mm. of mercury systolic and 140 mm. diastolic.

Morphine (gr. 1/4) failed to give any relief. Blood pressure cuffs were then applied on the proximal end of the four extremities and the pressure was raised in each to the level of the diastolic blood pressure. Within one minute after the application of venous stasis the dyspnea, cough, and raising of sputum disappeared and the patient fell asleep. On relieving the pressure in the cuffs temporarily at ten-minute intervals, all the symptoms and signs returned though with decreasing intensity. After one hour the cuffs were removed and the patient remained comfortable. Physical examination now was essentially the same as before the attack. The loud metallic quality of the aortic second sound returned and the accentuation of the pulmonary second sound subsided. The patient was given tincture of digitalis in an amount equivalent to 2 minims per pound of body weight. Next day the patient was comfortable. The breath sounds were somewhat reduced over the right side. A few days later the patient suffered again from a similar attack of paroxysmal dyspnea. Between attacks, Cheyne-Stokes' type of breathing developed, with a sense of suffocation toward the end of the apneic stage. Intravenous administration, slowly, of 50 per cent glucose solution gave considerable relief for six hours. Ten days after the first attack of dyspnea, or on January 19th, the

patient appeared exhausted, and involuntary jerky movements of the extremities developed; Cheyne-Stokes' breathing was now marked with prolonged apnea and a protodiastolic gallop rhythm appeared. The pulmonary second sound became persistently louder than the aortic second sound. Râles were heard over the chest. The liver edge was 6 cm. below the costal margin. In order to relieve the manifestations of uremia a lumbar puncture was performed. The spinal fluid pressure was 280 to 320 mm. of water. The dynamics and oscillations of the fluid were normal. The intraspinal injection of 20 c.c. of a 10 per cent magnesium sulfate solution caused a temporary drop of fluid pressure to 200 followed by a rise to 280 mm. of water. Inhalation of a mixture of 10 per cent carbon dioxide and 90 per cent oxygen gave relief from the irregular periodic breathing. The patient during the following two days became more drowsy. There was increasing edema of the eyegrounds and the veins of the discs were more congested. A pericardial friction rub appeared. The blood pressure was 190 mm. of mercury systolic and 120 mm. diastolic, the pulse 130 per minute. The spinal fluid pressure January 19th was 350 mm. of water with normal dynamics. On January 20th the patient was very stuporous. The pulmonary edema disappeared although the general condition grew worse. On January 22nd the pericardial friction rub persisted. He was now growing weaker, although the blood pressure was still maintained as high as 180 mm. of mercury systolic and 120 mm. diastolic. The pulse was 136 per minute. Next day he was comatose, the blood pressure was 175 mm. of mercury systolic and 100 mm. diastolic, pulse 136. He died January 24th.

Obviously the left kidney of this patient was removed because of a mistaken diagnosis and because of the alarming unilateral renal bleeding. Considering that the patient had experienced six months previous to his admission such symptoms as hematuria, abdominal discomfort and blurring of vision, and considering that he lived two months after the operation, it may

be concluded that the course of this rapidly fatal disease was not significantly shortened in his case by the nephrectomy.

Attacks of paroxysmal dyspnea, such as this patient experienced, are not rare in malignant hypertension. They develop often independently of the kidney involvement, usually at an early stage of relative failure of the left ventricle. One of us (S.V.) has observed attacks of paroxysmal dyspnea in a child eight years old with malignant hypertension who died as a result of heart failure while still retaining normal kidney function. The changes in the clinical symptoms and signs which occurred during attacks in the case recorded in detail above, have been observed by us in a number of other similar cases. They depend on the circulatory changes, which, together with therapeutic measures in this syndrome, have been previously summarized.¹⁵

II. FUNCTIONAL STUDIES

The Hemodynamics of the Normal Kidney and of the Kidney with Malignant Nephrosclerosis. If the human kidney is exposed surgically, blood from the renal vein can be obtained easily under sterile conditions and with apparent safety. In puncturing the vein it is essential that no more than gentle traction be made upon the kidney, so as not to interfere with the normal free flow of the blood. We have punctured the renal vein in five cases without any resultant bleeding. The composition of the arterial blood throughout the body is identical so that if simultaneously with obtaining blood from the renal vein blood is collected from the femoral artery and the specimens studied chemically, information

can be obtained concerning the blood flow through the kidneys. Table 1 presents the results of such observations on the oxygen and carbon dioxide content of the blood, obtained under oil, from the patient with malignant hypertension and nephrosclerosis and from three individuals with normal kidney function who had one kidney exposed for surgical suspension. The 10 to 20 c.c. of renal vein blood were drawn slowly during a period of from two to three minutes so as to represent a sample of a relatively large amount of blood flowing through the kidney. In addition to obtaining blood from an artery and from the renal vein, blood was also obtained from the femoral vein in order to form a comparative estimate of the blood flow through the kidney and through a lower extremity. In order to ascertain whether or not spinal anesthesia exerts an influence on the blood flow, in two of the control cases and in the patient with nephrosclerosis, blood was obtained from the femoral vein during anesthesia and again after the effect of the anesthetic wore off. Obviously if the metabolism of an organ remains unaltered or becomes increased, a decreased oxygen difference between the arterial and venous blood indicates an increased blood flow. The data given in table 1 demonstrate that the oxygen difference between the bloods obtained from the femoral arteries and veins with and without anesthesia was essentially unaltered in the patient with hypertension, while it was increased definitely in one, and essentially unaltered in the second control "normal" cases. The arterial blood pressure was distinctly lower during the spinal anesthesia in the patient with nephrosclerosis, but it

*Assuming that the gaseous content of the blood from the femoral artery is the same before and during spinal anesthesia.

did not change appreciably in the control cases. The most significant observation is, however, the low oxygen difference between the blood from the renal artery and vein in the control cases. This, in view of the fact that the metabolism of the kidney as compared with other organs is high, corresponding to 8.2 per cent of the total energy consumption in rats, and 7.9 per cent in dogs,^{16,21} conclusively indicates the existence of a rapid blood flow through the kidney. The average oxygen difference between the arterial and venous blood of the kidneys of the control subjects was 2.37 vol. per cent. The arterial blood, therefore, lost an average of 13 per cent of its oxygen content during its passage through the kidney. Rhoads, Van Slyke, Hiller and Alving¹⁷ reported that the proportion of oxygen removed from the blood by the kidney of the dog was 10 to 20 per cent of the arterial oxygen content. This indicates a fair degree of agreement between the rapid blood flow through the kidney of the dog and of man. In all three normal kidneys the arteriovenous oxygen difference was distinctly less in the kidney than in the lower extremities.

In the case of the patient with ne-

phrosclerosis, there was no apparent utilization of oxygen by the kidney. On the contrary, the oxygen content of the blood obtained from the renal vein was slightly higher. This surprising finding of somewhat higher blood oxygen content in the renal vein cannot be attributed to technical error in the analysis. This belief is supported by the finding of a higher oxygen capacity of the venous blood (12.66 vol. per cent) than of the arterial blood of the kidney (11.97 vol. per cent). Our interpretation is that the rate of blood flow through the kidney in this case was unusually great, even when compared with the relatively rapid renal blood flow in the control cases with normal vascular systems and normal arterial pressures. The slight increase in the oxygen capacity of the blood in the renal vein was probably due to an increased hemoglobin concentration produced by the loss of water content of the blood in its passage of glomerular capillaries. That the data (table 2) were obtained while the kidney was functioning is supported by the fact that the urea and creatinine clearance tests during spinal anesthesia in the control case were essentially normal. In the case of nephrosclerosis these

TABLE II
A COMPARISON OF CHEMICAL CONSTITUENTS OF THE RENAL ARTERIAL AND VENOUS BLOOD
IN THE CASE OF MALIGNANT NEPHROSCLEROSIS AND IN A CONTROL SUBJECT

Condition	Source of Blood Specimen	Non- Protein- Nitrogen	Urea Nitrogen	Crea- tinine	Chlo- rides
		mg./100 c.c.	mg./100 c.c.	mg./100 c.c.	mg./100 c.c.

	Kidney vein	58	32.5	4.9	597
(Control)	Kidney artery	—	13.0	1.4	605
	Kidney vein	—	10.0	1.3	611

tests were about the same as the tests obtained five days later under entirely natural conditions (table 3).

The average 2.4 vol. per cent oxygen difference between the blood of the renal artery and vein observed in the three control cases is smaller than that observed in other organs studied in man. Weiss and Lennox observed an oxygen difference of 7.1 vol. per cent between the blood of the cubital arteries and veins of the arm, and in a study of the brain they noted an average difference of 6.2 vol. per cent between the blood of the internal carotid artery and the internal jugular vein.¹⁸ In the leg, Weiss and Ellis observed an oxygen difference of 4.1 vol. per cent between the blood of the femoral artery and vein.¹⁹ In the heart there has been found 5.3 vol. per cent difference between the arterial and venous blood of the ventricles.²⁰

The Chemical Composition of the Arterial and Venous Blood of the Kidney. Table 3 presents data concerning the comparative content of certain constituents of the arterial and venous blood of the kidney. The differences of the values between the arterial and venous blood are exceedingly small. In view of the unusually rapid blood flow through the kidney, such a small loss of waste products during the passage of blood is not surprising. The amount of the chemical substances in the venous blood, with the exception of chlorides, was less than in the arterial blood, although at times the differences fell within the error of the analysis.

Dunn, Kay and Sheehan²³ observed in rabbits that each 100 c.c. of blood containing originally 30.2 mg. of urea

TABLE III

lost 2.5 mg. in passing through the kidney. Their study, performed under more ideal experimental conditions, is in harmony with our findings in man. It is, however, contrary to the earlier observations of Picard²⁴ in dogs that the urea content of the blood from the renal vein was half that of the blood from the artery. Picard's findings would suggest a blood flow through the human kidney of 150 c.c. per minute, a figure undoubtedly low. Sheehan's recent finding²² in the rabbit would suggest an average corresponding blood flow of 750 c.c. per minute through the kidneys in man which, even if high, is probably close to the actual state of affairs. As the combined weight of the two kidneys in man is only 1 to 240 in proportion to the body weight, the blood flow through the kidney must be great when compared with other organs.

The Secretory Function of the Kidneys. Table 2 presents the urea clearance tests of the kidneys during surgical operation under spinal anesthesia. In the control case, the urea clearance test measured according to the method of Van Slyke was normal. The creatinine clearance was somewhat below the average normal value.

In the case of nephrosclerosis the urea clearance test during operation was 20 per cent of normal. The longer part of this clearance test fell within the period directly after nephrectomy; and since the clearance test five days later showed 13 per cent of normal, the kidneys during the surgical procedure under spinal anesthesia may be regarded as functioning adequately. Table 4 presents the urea and creatinine clearance tests of the right kidney after removal of the left one. During the three months of observation, we

performed on this patient 12 urea clearance tests according to the Van Slyke method,²⁵ and 11 creatinine clearance tests according to Rehberg's method.²⁶ The results of these two tests paralleled each other fairly closely. It is of interest that, in accordance with the history of the case, these tests indicated considerable fluctuations in the functional capacity of the kidney during the period of three months. Following operation the urea nitrogen content of the blood rose from 35 to 143 mg. per 100 c.c. of blood as the clearance dropped from 20 to 6 per cent of the normal. Simultaneously the blood creatinine rose because the glomerular filtrate decreased. With the subsequent improvement in the kidney function the urea clearance rose to 12 per cent, and the creatinine clearance to 15 per cent of the normal value. Following this temporary improvement, the kidney function showed further impairment. When the urea clearance reached about 3 per cent, and the creatinine clearance about 5 per cent of the normal values, clinical manifestations of uremia developed.

Concentration Dilution Tests of Kidney Function. On two occasions, a concentration dilution test was performed on the patient with nephrosclerosis by the method described.²⁷ In order to study the concentration power of the kidney more specifically, in addition to the specific gravity of the urine, the creatinine concentration of the blood and urine were also measured. These data allow the calculation of the concentration index between the blood and the glomerular filtrate. The results of one of these tests are presented in table 5. Obviously the water elimination, as well as the concentra-

tion capacity of the kidney was seriously impaired. Notwithstanding the ingestion of a large amount of water, the water elimination showed only slight variations. The creatinine concentration index varied between 2.8

and 6.8, while in control subjects under identical conditions it usually reached the levels between 200 and 300. The results of this test indicate that in this case of malignant hypertension with nephrosclerosis both the volume

and the concentration of urine were fixed.

Urinary Sediment. The urinary sediment was studied daily. The most significant observations were the sudden variations from time to time in the number of white and red blood cells as well as in the character of the casts. A sediment with hyaline or granular casts and normal elements changed rapidly within a day or so to a sedi-

Microscopic Examination: There were foci of increased connective tissue infiltrated with many lymphocytes, some plasma cells and large mononuclears. In places, fairly numerous polymorphonuclear neutrophils were present. In such areas of sclerosis the tubules were narrowed. Scattered through the pyramids were numerous foci of hemorrhage, apparently capillary in origin. The glomeruli showed varying degrees of involvement. Some of them were normal, others showed acute lesions and still others more chronic changes. The acute lesions appeared

ment rich in red and white blood cells and casts containing red cells. The albumin content of the urine changed from a small to a heavy trace as the disease progressed.

III. STRUCTURAL STUDIES

The kidney removed at operation appeared as follows:

Gross Description: The kidney weighed 213 gm. The capsule stripped easily. The cortex averaged 5.5 mm. in thickness. The cortical tissue was yellowish grey with a waxy texture. The pyramids in the upper pole showed evidence of small hemorrhages. Several of the pyramids had pearly white, diffuse, firm areas in the region of the kidney pelvis. The entire organ appeared to be edematous.

in various forms. The most common was a hyaline droplet degeneration of the tuft and, to some extent, also of the capsular epithelium, associated with a marked proliferation of the epithelium, especially of the capsule. In some instances this lesion involved the whole tuft with obliteration of the capsular space; in others it affected only a portion of the tuft.

The majority of the tufts in these lesions, when stained with Mallory's anilin blue stain (Lee Brown modification),^{28,29} showed a meshwork of intracapillary fibers described by McGregor³⁰ as characteristic of glomerulonephritis. When only a portion of the tuft epithelium was involved, only the loops adjacent to this area showed such changes, the other loops remaining normal (figure 13). Other glomeruli showed necrosis with fibrin formation and infiltration of varying

numbers of polymorphonuclear leukocytes. A less frequent type of lesion was a necrotizing arteriosclerosis with an associated involvement of the glomerulus, accompanied by an infiltration of a considerable number of polymorphonuclear neutrophils. The more chronic changes in the glomeruli consisted

tained hyaline and granular casts and in places masses of red blood corpuscles and also numerous polymorphonuclear neutrophils and some large mononuclears. In view of the large number of leukocytes in the tubules the sections were carefully examined for organisms but none were found.

FIG. 13. Right kidney. Glomerulus showing focal lesion with localized reaction on part of epithelium. X 300.

of diminution in size with thickening and wrinkling of the basement membrane, described by McGregor as characteristic of hypertension.³¹ Other glomeruli showed adhesions between the tuft and capsule, and still others were completely sclerosed.

The tubules in the areas showing fibrosis appeared atrophic. Elsewhere the cells of some of them contained hyaline droplets in their cytoplasm; in others the cytoplasm was more granular than normal. The tubules con-

The larger blood vessels showed no pathological changes. Many of the medium-sized and small arteries showed marked fibrous thickening of their walls. Numerous arterioles had thickened, hyaline walls. Some of the smaller arteries and arterioles showed widening of their lumens and necrosis, occasionally with hemorrhage into the surrounding tissue. Fat, demonstrated by staining, occurred especially in the atrophic tubules but was also present in non-atrophic tubules,

artery walls, and glomerular epithelium. Fat also occurred in the casts.

NECROPSY

Gross Description. The autopsy was performed two hours after death by Dr. J. B. Hazard. Only the essential findings are given below.

in thickness. The auricles and the right ventricle were markedly dilated, the ventricle being 0.25 cm. thick. The muscularis was pale red, and of firm consistency with no gross areas of scarring. The endocardium was smooth and all valves were negative. Lungs: Both lungs were enlarged and heavy. Section of the lungs revealed a firm, dark,

FIG. 15. Pancreas. Artery containing organizing thrombus. Wall degenerating and containing nuclear debris. X 250.

Pleural Cavities: There were about 500 c.c. of clear fluid in the right pleural cavity and 200 c.c. in the left. The surfaces of the cavities were smooth and glistening. **Pericardial Cavity:** Both parietal and visceral pericardial surfaces were covered with a layer of fibrin. About 150 c.c. of clear amber fluid were in the cavity. **Heart:** Weighed 690 gm. The wall of the left ventricle showed marked hypertrophy and measured 2.1 cm.

reddish grey tissue composing all lobes. A quantity of froth and dark red fluid could be expressed. **Liver:** Weight 1930 gm. Section revealed a dark brown tissue of soft consistency with a fine red mottling.

Kidneys: Left kidney was absent. The right kidney weighed 165 gm. The capsule stripped with moderate ease, leaving an irregular pale surface, speckled with many pin point, dark red spots. The cut surface

was pale pink and of soft consistency. In the cortex were several small irregular, red areas measuring up to 0.1 cm. in diameter. The cortex was uniformly thinned, measuring 0.4 cm. in thickness. The pyramids were not remarkable save for their pale color. The pelvis was negative. There was no dilatation of the ureter.

was old and was in the stage of organization. In places the organization process was beginning, in others it was advanced, or complete. This process was taking place, not only in the alveoli but also in the atria and bronchioles. Elsewhere the alveoli were normal or distinctly dilated. The blood vessels appeared normal. Spleen: The germ-

FIG. 3. Cortical surface of the right kidney at necropsy. Numerous small hemorrhages. X 13.

Aorta: It appeared smooth and yellowish white throughout. The elasticity was good.

Microscopic Examination. **Heart:** The muscle fibers were increased in thickness. There was a certain amount of lipomatosis and rarely a large mononuclear and mast cell in the connective tissue. The blood vessels appeared normal. The pericardium showed an acute fibrinous pericarditis. **Lungs:** The alveoli contained red blood cells, fibrin, and some large mononuclears. The fibrin

inal centers were not prominent and were inactive. A few contained a hyaline fibrinoid material. The central arteries showed a hyaline thickening of their walls; rarely, there was an infiltration of large mononuclear cells in the wall. The pulp contained numerous polymorphonuclear neutrophils, a considerable number of plasma cells, and a rare megakaryocyte. **Pancreas:** Many of the glands were dilated and contained a pink-staining material, often concentrically arranged, sug-

gesting concretions. In addition, many glands contained polymorphonuclear neutrophiles in their lumens. There was an occasional necrotic acinus invaded by polymorphonuclear leukocytes. The connective tissue stroma was diffusely infiltrated with polymorphonuclear neutrophiles, lymphocytes and large mononuclears. A considerable number of

sis as evidenced by loss of liver cells and sclerosis. In addition, an active, acute central necrosis, in places hemorrhagic in type, was present. An occasional arteriole in the portal areas showed hyaline in its wall.

Right Kidney: There was a marked increase in connective tissue with a moderate infiltration with lymphocytes; these cells

FIG. 4. Surface of the longitudinal cross section of the right kidney at necropsy. Numerous small hemorrhages. X 1.3.

the small arteries and arterioles showed a thickening of their walls, often with a deposit of hyaline. Occasionally one showed necrosis of its thickened wall. Several small arteries contained thrombi partially occluding their lumens. In one such artery (figure 15) the thrombus was undergoing organization while the vessel wall showed necrosis and hemorrhage. Rarely the thickened vessel wall contained fat.

Liver: There was a healed central necro-

were, however, much less numerous than in the kidney removed surgically. The glomeruli showed lesions of both an acute and more chronic nature. There was a considerable number of normal glomeruli. The number of glomeruli showing thickened and wrinkled basement membranes was considerably increased over that in the left kidney removed two months before. The acute changes in part resembled those in the first kidney. They consisted in hyaline droplet degenera-

tion of the tuft epithelium, often associated with marked proliferation of the capsular epithelium, with fusion between the tuft and capsular epithelium. As in the first kidney, the lesion sometimes involved the whole tuft and sometimes only a portion of it. The tufts themselves showed the same changes

the majority of these tubules contained only granular material, some had hyaline casts and others red blood corpuscles in their lumens. Similar groups of dilated tubules were found deeper in the cortex but here their number was considerably smaller. Hyaline droplets in the cytoplasm of the tubu-

FIG. 10. Right kidney. Arteriolar hemorrhage. One vessel is cut longitudinally and can be followed into the hemorrhage. X 360.

described in the first kidney. In addition, there were some lesions of a more fulminating character. Such lesions consisted in necrosis of the arteriolar wall with necrosis and hemorrhage into the tuft and an infiltration of polymorphonuclear leukocytes, the lesion being essentially an infarct. In such glomeruli, there was associated capsular proliferation. Groups of tubules in the cortex under the capsule were dilated and their epithelium tended to be flattened. While

lar epithelium were quite common. In the sclerosed areas, the tubules were narrowed and collapsed. A few tubules contained polymorphonuclear leukocytes and in some of the collecting tubules in the pyramids there were hyaline casts and casts whose structure and staining reaction resembled hemoglobin. The blood vessel changes were essentially the same as in the other kidney: normal larger vessels, fibrous and hyaline thickening of the smaller arteries and arterioles and in

some areas a necrotizing arteriolitis. There were scattered focal hemorrhages in the pyramids. In sections stained for fat, essentially the same amount was found as in the first kidney examined, and with a similar distribution.

Adrenals: Beneath the capsule, in the

there was sclerosis. In the peri-adrenal tissue, some vessels showed lesions consisting of degeneration and hemorrhage into their walls; others contained fresh thrombi and still others were filled with organized and canalized thrombi (figure 17). There was an infiltration of lymphocytes, plasma cells,

FIG. 11. Right kidney. Necrosis of glomerular tuft with hemorrhage. At the right can be seen a necrotic arteriole. X 275.

outer layers of the zona glomerulosa, there were numerous arterioles undergoing necrosis with fibrin formation in their walls. Other arterioles in this same region showed hyaline thickening of their walls. Adjacent to one necrotic arteriole (figure 16), there had been disappearance of the adrenal cells with an accumulation of large mononuclears containing fat. Scattered throughout the cortex were several focal collections of fat-laden macrophages and in one or two similar areas

and macrophages containing hemosiderin in the peri-adrenal connective tissue which appeared increased in amount. The walls of a number of thickened vessels contained a considerable amount of fat.

Aorta: There was a rare large mononuclear cell in the intima.

Bone Marrow (Vertebral): There was a normal number of cells of the erythrocytic, granulocytic and megakaryocytic series. A fair number of the last looked de-

FIG. 12. Right kidney. Necrosis of arteriole and glomerulus. X 500.

generated. Focal collections of stem cells were noticeable. Plasma cells were rather numerous. Only a few arterioles could be found and they appeared normal.

Bacteriology: Cultures of the heart's blood were negative.

Quantitative and Comparative Histological Observations. We had a unique opportunity

than in the right kidney at autopsy. While the majority of the cells in the right kidney were lymphocytes, there were also numerous polymorphonuclear neutrophils, especially in foci and in the lumens of the tubules. Indeed, the number of leukocytes, many of which were necrotic, in the tubules was so great that a pyelonephritis was suspected.

FIG. 16. Adrenal. Necrotic arteriole. Loss of parenchymatous cells below with infiltration of fat-laden macrophages. X 300.

to study the renal lesions at two different periods since one kidney was removed two months prior to the autopsy. In comparing the two kidneys, the most noticeable differences were found in the cellular infiltration of the stroma, the tubular changes, the glomerular lesions and the size of the kidneys.

The cellular infiltration in the left kidney removed surgically was much more marked

However, careful search of the sections failed to reveal any bacteria. Gross and histological study of the bladder and ureters also failed to reveal changes indicating infection.

The islands of dilated tubules found in the cortex of the autopsy specimen were noticeable and probably represented a compensatory dilatation. In this particular case there was great demand for compensatory func-

tion on the part of the remaining kidney since its load was suddenly doubled with the removal of the first kidney. The physiological studies described above demonstrate that it was able to carry on such a function during a comparatively short period.

In an effort to gain an idea of the relative

different types of lesions in the two kidneys. Obviously in both kidneys there were a number of normal glomeruli, but this number was considerably greater in the kidney removed surgically than in the kidney removed at the time of death two months later. The hypertensive type of glomerulus with thick-

FIG. 17. Adrenal. Two arteries in periadrenal tissue. The one on the left shows hemorrhage into its wall, the one on the right contains an organized canalized thrombus. X 175.

frequency of the different types of glomerular lesions in the two kidneys, 300 glomeruli were studied in each kidney, after staining the sections with Mallory's anilin blue stain (Lee Brown modification). In this study several sections from different areas of each kidney were utilized. The results are given in table 6.

The data obtained by such a procedure serve to indicate the relative number of the

ened and wrinkled basement membrane was present in considerably larger numbers in the second kidney. Likewise hyaline, sclerotic glomeruli were more frequent in the autopsy specimen. It is of special significance that the type of glomerular lesion with an intracapillary meshwork of fibers and associated epithelial degeneration and proliferation was present in both kidneys but was somewhat less frequently found in the kidney

removed at autopsy. On the other hand, necrotizing arteriolitis and glomerular infarction were both much more prominent at the time of death.

The surgically removed (left) kidney weighed 213 gm. and was obviously considerably enlarged. The other kidney at the time of the patient's death weighed 165 gm. The size of the first was not due to operative clamping of the pedicle with resultant congestion since no evidence of this was found. It is interesting that the right kidney, in spite of its theoretical compensation, weighed almost 50 gm. less. There was no evidence

what appeared from the character of certain of the casts to be hemoglobinuria.

The acute disintegration of the glomeruli is considered a natural consequence of the thrombotic processes in vessels, with secondary acute or subacute ischemia. That under such circumstances leukocytic infiltration and other microscopic indications of an inflammatory process develop, is not unexpected. Such an abundant leukocytic infiltration was also noted by Shapiro.⁶ One may compare this histological picture in the glomeruli with the changes in the myocardium following coronary thrombosis. Infection and, partic-

that this kidney was congenitally hypoplastic; therefore, presumably its weight approximated that of its mate at the time of the nephrectomy. This decrease in weight might be accounted for by the diminution in the acute inflammatory exudate and by the loss of kidney parenchyma.

The vascular hemorrhages in this case were confined to the kidneys. It is possible that some may have occurred in the brain, but unfortunately permission to examine this organ could not be obtained. Histological examination revealed that the hemorrhages in the kidney were of three types—capillary, arteriolar and intratubular. The numerous capillary hemorrhages occurred in both kidneys and were almost entirely confined to the pyramids. The arteriolar hemorrhages, on the other hand, were found in the cortex. We attach special significance to the observation that hemorrhage into the tubules was common and marked in both kidneys, and in the second kidney was associated with

ularly, the presence of bacteria in such "inflammatory reactions" is not essential. A search for local infections in the kidney in this condition, therefore, may be futile, and perhaps the wrong approach to the problem.

It was stated above that there was evidence, as judged from the clinical course and laboratory tests, of an acute exacerbation with remission and a second flare-up of the acute process in the kidneys. Interestingly enough, this was confirmed by the histological findings. In addition, a similar picture was observed also in the lungs, liver, pancreas, and adrenals. The lungs showed an organizing process, as well as recent hemorrhages. The liver showed both a healed and an acute hemorrhagic central necrosis, thus pointing to at least two acute injuries, one some time prior to the other. In both the adrenals and the pancreas, areas of sclerosis as well as active focal lesions were present. In the peri-adrenal tissue there were several vessels containing organized and re-

canalized thrombi; in addition, in the adjacent connective tissue were numerous macrophages containing hemosiderin, evidently the remains of a hemorrhagic process. One vessel in the pancreas contained an organizing thrombus (figure 15), and its wall was degenerated and filled with nuclear debris. In brief, then, there were signs of healed

steady progressive nature of the disease. However, the sudden fluctuations in the clinical course suggest periodic healing and later exacerbation of the entire process in various organs with new and diffuse involvement of areas of minute vessels, rather than the progressive spread of the vascular disease into new areas.

FIG. 5. Cortex of left kidney. Lack of dilated tubules. Infiltration of connective tissue with leukocytes. X 40.

lesions and acute lesions in various organs of the body indicating that there had been at least one acute attack in the past which had subsided and which was followed by another acute process found at the time of the patient's death. It is possible that with the progress of the disease more and more vascular units became involved. Thus, some minute vessels already showed chronic lesions at a time when others first became involved. Such an interpretation would indicate a

The changes noted in various organs illustrate once again that the lesions in malignant nephrosclerosis are by no means confined to the kidney but involve other organs as well. In our case, the vascular and parenchymatous involvement of the pancreas and adrenal was severe.

The acute and subacute changes in the bronchioles, atria and alveoli of the lungs with a normal state of the pulmonary blood vessels suggest that this pulmonary process

FIG 6. Left kidney. Degeneration and proliferation of epithelium of glomerulus. One mitosis in lower lefthand corner. X 250.

was not related to the specific pathology of malignant hypertension. A bronchiolitis obliterans in chronic Bright's disease has been observed recently.³² In view of the cardiac asthma and our interpretation of it, we are inclined to attribute the pulmonary changes to circulatory alterations resulting from relative and acute periodic failure of the left ventricle of the heart with secondary increased pulmonary pressure and transudations of plasma

GENERAL DISCUSSION

The occurrence of an unusually rapid blood flow through the kidney in advanced malignant hypertension aids in the interpretation of the pathogenesis of the disease. This increased flow of blood existed, notwithstanding the fact that there was present partial and complete occlusion of nu-

merous afferent arterioles and capillaries of the glomeruli. It is probable that the increased blood flow through the kidneys was maintained by the elevated systemic arterial pressure. Although the earlier experimental obser-

In our case the high arterial oxygen saturation of the blood in the renal vein together with the ruptured capillaries in the kidney indicate also that the glomerular capillary pressure was increased. The presence of dilated

FIG. 7. Left kidney. Necrosis of arteriole and portion of glomerulus. Infiltration with polymorphonuclear neutrophils. Proliferation of glomerular epithelium. X 250.

vations of Landergren and Tigerstedt³³ suggest that blood flow through the kidney has no relation to the level of the blood pressure, the more recent studies of Ozaki³⁴ and Moritomo,³⁵ with more reliable methods, reveal that a rise in arterial pressure increases the blood flow through the kidneys in animals.

afferent arterioles and capillaries of the glomeruli, an observation made also by Shapiro,⁶ suggests an elevated pressure in the minute vessels of the glomeruli. Our finding of ruptured tubular capillaries suggests that the elevated pressure involved the tubular capillary system also, at least in a number of kidney units.

Although the histological structure and the exact distribution of the renal capillary system is not definitely established, a number of histological^{36,37,38,39} and physiological studies⁴⁰ have furnished definite evidence that the emerg-

latory mechanism makes possible an increase of the capillary pressure in the glomerulus without necessitating a change in the pressure of the tubular capillary system. Such an independent change in the pressure relations be-

FIG. 14. Lung. One area of organized fibrin. Alveoli filled with red blood corpuscles. X 150.

ing portion of the efferent vessels of the glomeruli possesses special structures, which, probably through a sphincter-like function, allow the regulation of the blood flow through the physiological unit of the kidney. As the majority of the tubular capillaries are continuations of the glomerular capillaries,³⁹ the function of the regu-

tween the minute vessels of the glomeruli and tubules will result in better functional economy and increased filtration of urine without interference with reabsorption, so far as the latter can be influenced by hemodynamics. Depending on the degree of constriction of the efferent vessels of the glomeruli and on the simultaneous level of the

arterial blood pressure and on the size of the lumen of the afferent vessels, the glomerular capillary pressure may become elevated without a simultaneous increase or even with a decrease in the volume of blood flow through the kidney unit.

In the first place a number of the physiological units are completely eliminated. In a number of others there is a distinct structural change in the form of a thickening of the basement membrane. In these latter glomeruli, increased capillary pressure with nor-

FIG. 18. Liver. Central sclerosis. X 250.

In this case of malignant nephrosclerosis, the increased blood flow together with the increased capillary pressure may be considered as a useful compensatory factor in the elimination of the waste products of the blood. In the light of the histological observations such an increased filtration pressure is beneficial for two reasons: (1)

mal or increased blood flow should improve filtration. (2) In the remaining number of normal glomeruli the circulatory changes, mainly through hypertension, induce an increased amount of filtration which compensates for the damaged glomeruli. Thus, the irregularly distributed morphological lesions of varying degree, that some-

what resemble focal glomerulonephritis, together with the observations on the functional state of the kidney suggest that in various units of the kidney the local hemodynamics as well as the secretory functions differ.

The increased volume of urine formation with fixed low specific gravity observed in the case is, therefore, not so much due to the impaired reabsorptive power of the tubules, as to the fact that in the 27 per cent of normal glomeruli, at the time the nephrectomy was performed, the volume and the velocity of the filtrate flow through the tubules was increased to a degree that prevented a correspondingly increased reabsorption by the tubules. The dilated and thin tubules in this and other cases are indications of increased filtrate flow under high intratubular pressure. In the physiological units with mild or severe lesions of the glomeruli the filtrate was probably less in volume and, therefore, as judged from the relatively normal histological appearance of the tubules, reabsorption may have occurred in a relatively more normal manner than filtration. The observation that the urea and creatinine clearance tests paralleled each other is also in harmony with this interpretation. The specific gravity, fixation of the urine volume per hour, and of the creatinine concentration index between blood and glomerular filtrate regardless of the water intake, also indicate that the kidney function was maximal in any given time. This, in view of the above findings on the hemodynamics of the kidney, is also to be expected.

Shapiro,⁶ on the basis of his observations that in malignant nephrosclerosis the afferent arterioles and capillaries of the glomeruli were dilated, and that in-

jected India ink entered the wide afferent vessels of the glomeruli with ease, although the resistance of the kidney vessels was considerably increased, concluded that the pathogenesis of kidney changes depends "not on glomerular ischemia or on arteriolar occlusion, but on a hyperemia associated with a retardation of flow". This retardation is explained by him in accordance with Ricker's theory of a neurogenic dissociation in reaction between arterial constriction and peripheral dilatation. Shapiro does not offer any histological or other evidence, however, "for this neurogenic dissociation" nor for the existence of outstanding constriction of the larger or smaller arteries. His explanation would also fail to offer any rational explanation for the presence simultaneously of dilated and normal caliber individual glomerular capillary loops within the same glomerulus and hence supplied by the same small artery. The explanation offered by him would also necessitate the inference that the capillary pressure is decreased or at least not particularly increased in the glomeruli, a concept which is difficult to harmonize with frequent rupture of the kidney capillaries in this condition.

We realize that the evidence available from Shapiro's observations and the studies presented here do not permit at present the formation of a concept supported by sufficiently detailed direct observations; nevertheless, we favor the following working *hypothesis*, which in our opinion harmonizes all of the observations so far made.

The state of affairs in different units of the kidney in malignant nephrosclerosis at a given time differs considera-

bly. In the early stage of the disease a moderate constriction occurs in a certain number of efferent vessels of the glomeruli. These portions of the kidney capillary system have a rather specific structure, and the rôle of this vascular portion is similar in the kidney to that of the arterioles of other vascular areas. Their constricted state would correspond to the constricted arterioles in other organs observed in malignant hypertension. In accordance with the histological nature of malignant nephrosclerosis the degree of constriction is irregularly distributed. This focal scattered distribution of the histological lesions which was emphasized in this case has also been observed by us in a number of other cases. In the kidney units with severe vascular constriction which is out of proportion to the height of the arterial blood pressures relative stasis with increased pressure in the minute vessels, for reasons discussed above, will lead to dilatation of the vessels central to the emerging efferent portion of the glomerular vessel. It is this absolute or relative stasis with increased pressure in the glomerular vessels that leads to imbibition of metabolites by the adjacent structures, with resulting changes in the basement membrane as well as in the vessel wall itself. Simultaneously with these marked changes, in some of the glomeruli, with the progressively increasing arterial hypertension, the above described compensatory changes with rapid local blood flow and increased glomerular filtration occur. As the pathological process advances, involving larger numbers of vascular units, the number of normal units becomes so few that effective compensatory

elimination cannot be maintained and uremia ensues. Thus, near to the time of death there may be perhaps a decrease in the total blood flow through the kidney, while earlier the total blood flow, as was the case in this patient, is considerably increased. But even if the total blood flow is less than normal near to death, the volume flow through the remaining individual normal units must be increased considerably. This concept is in harmony with the general character of the circulation in arterial hypertension⁴¹ and satisfactorily accounts for all the abnormalities detected in malignant hypertension.

It is obvious that the mechanisms of benign and malignant nephrosclerosis show a certain degree of similarity. There are, however, a number of differences in the clinical course and in the histology of the kidney in the two conditions. The youthful age of the patients, the fulminating fatal course, the markedly irregular distribution of the vascular lesions, and the character of the eyegrounds all suggest essential differences.

It is rather unfortunate that, because of the similarity in the mechanism of the two conditions, often no distinction in the etiology is made. The etiology of malignant hypertension is unknown. From the history and clinical study of a number of cases of malignant hypertension, we have been impressed with the frequency of severe infections. Tonsillar and peritonsillar abscesses, severe follicular tonsillitis, rheumatic fever, perinephritic abscess, pyelitis, and pyelonephritis were found in the cases observed by us in the past. Since it has been observed that the infection had often subsided at the time

when symptoms of malignant hypertension developed, one may justifiably assume that in malignant arterial hypertension an acute tissue response exists, which has a relation to infection, but which, if once precipitated, proceeds independently of infection. This indirect relationship between infection and malignant hypertension is apparently similar to the relation that exists between infection and certain allergic states.

SUMMARY

1. A study of malignant arterial hypertension with malignant nephrosclerosis is reported from observations on a case in which left nephrectomy was performed because of unilateral bleeding and suspected malignancy. The clinical course of the disease and the hemodynamics, function, and histological structures of the kidneys are analyzed and correlated.

2. Observations on the hemodynamics of the kidneys in three cases with normal kidney functions and cardiovascular systems, in which surgical suspension of the kidneys under spinal anesthesia was performed, served as controls.

3. The oxygen difference between the arterial blood and the blood from the renal vein in the three control subjects varied between 1.3 and 3.0 vol. per cent with an average of 2.4 vol. per cent. The average amount of oxygen taken from the blood by the kidney was 13 per cent of the average oxygen content of the arterial blood.

4. A comparison of the arteriovenous oxygen difference in the kidneys in these three subjects with that in the brain, heart, arm and leg indicates a

low oxygen difference and a relatively rapid blood flow through the kidneys.

5. No oxygen difference existed between the arterial blood and the blood from the renal vein of the patient with nephrosclerosis, which is interpreted as an indication of unusually rapid flow through the kidney.

6. The urea nitrogen changed from 13.0 mg. to 10.0 mg. per 100 c.c. in renal artery and vein in one of the control subjects and from 36.1 mg. to 32.5 mg. in the patient with nephrosclerosis. The urea and creatinine clearance performed during the surgical operation indicated adequate kidney function. The concentrations of creatinine and chlorides in the renal arterial and in the renal venous blood samples showed no demonstrable differences either in the control case or in the case with nephrosclerosis.

7. The nature of the functional disturbance of the right kidney after left nephrectomy was studied with repeated and simultaneously performed urea and creatinine clearance tests, and with the concentration and dilution tests.

8. The structures of the glomeruli of the left kidney were quantitatively compared with those of the right kidney; and it was demonstrated that within 67 days the number of glomeruli with thickened basement membrane and complete sclerosis increased considerably. The vascular sclerosis also became more extensive during this period.

9. Appearance of blood in the urine was caused by rupture of the minute blood vessels of the glomeruli and tubules as a result of increased pressure. The source of blood in the urine in ma-

lignant nephrosclerosis may be unilateral.

10. It has been demonstrated again that malignant hypertension is a diffuse disease of the vascular system with characteristic lesions in a number of organs.

11. The clinical course of the disease, the function of the kidney, and the histological analysis of the minute blood vessels of the kidneys and other

organs in this case of malignant hypertension indicated a tendency to fluctuate between improvement and relapses.

12. A concept is presented which correlates and interprets functional and structural changes observed in malignant nephrosclerosis with arterial hypertension.

We are indebted to Dr. F. B. Mallory for the photomicrographs used in this paper.

Changes Observed in the Heart Shadow in Toxic Goiter before and after Treatment*†

By O. J. MENARD, M.D., and L. M. HURXTHAL, M.D., F.A.C.P.,
Boston, Massachusetts

THE object of this study was to determine what changes take place in the size and shape of the heart before and after subtotal thyroidectomy for hyperthyroidism. One hundred and fifteen cases were observed in which roentgenograms were taken before and at various phases during and after treatment.

CLINICAL MATERIAL:

ROENTGENOGRAPHIC METHOD

The group of patients studied in this report do not represent a consecutive series. Forty-six cases were followed from a consecutive series of one hundred¹; the remainder were isolated cases which we have collected during the past five years. Roentgenograms were taken when the patient was first seen at the Clinic or within twenty-four hours after admission to the hospital. There were a few cases in which this was felt to be unwise owing to the patient's critical condition. The delay in such cases was rarely longer than two or three days. In seven cases, roentgenograms were taken again be-

fore operation and in the remainder, observations were made from one month to two years after operation, the majority within one year. Fluoroscopic observations were made in many of these patients, but orthodiagraphic tracings were not made.

Exposures were made with the subject standing at a seven-foot distance, during quiet breathing. The length of exposure time varied somewhat in the different hospitals but this could not account for the large differences in size found in some cases, nor for the changes found when all roentgenograms were made by the same person and with the same machine.

Measurements were made in the usual way and were then rechecked when all the films on each subject were available for comparison. This made possible a more uniform method of placing the points from which measurements were taken. When fluid was present in the chest, measurements were either impossible or less accurate than in the usual film. For this and other reasons, measurements alone cannot always be used to draw conclusions as to the change in the size of the heart shadow.

Comparisons of films were made in the following way: The contour of the

*Read before the Symposium on Thyroid Heart Disease of the American Heart Association in New Orleans, May 1932.

†From the Medical Department of the Lahey Clinic, Boston, Massachusetts.

heart, great vessels, diaphragm, and lateral chest wall were outlined (on all but nine films). The transverse processes at the root of the first rib and the first rib on the two films were superimposed and the lateral chest walls were made to coincide as nearly as possible. The outline of the heart on the underlying film could thus be seen plainly through the superimposed film, upon which it was then traced. Thus, on one film the outlines of both films were registered and the difference in the transverse diameter of the chest, the height of the diaphragm, and the changes in size and position of the heart could more clearly be seen and compared.

Even by this method of comparison and measurement, the statement that the heart shadow has changed in size is in many cases a statement of opinion and not of fact.

For instance, while a lower diaphragm and a relatively larger heart shadow in a follow-up plate mean an absolute increase in the size of the cardiac shadow, a lower diaphragm and a smaller heart shadow may or may not indicate a decrease in size. Thus all factors must be considered in each case.

AVERAGE HEART MEASUREMENTS BEFORE AND AFTER OPERATION

We obtained 46 roentgenograms after operation from a series of 100 consecutive cases of toxic goiter that had been roentgen-rayed before operation. The transverse diameters of the heart and the transverse diameters of the chest were averaged in these cases. In this group the transverse diameters of the heart after operation were larger

in 19 cases and smaller in 23 cases and the same in four cases.

The average transverse chest diameter before operation was 23.97 centimeters and after operation 24.56 centimeters. The transverse heart diameters averaged 13.07 centimeters before operation and 13.18 centimeters after operation. These averages would tend to indicate that the transverse diameters remain essentially unchanged and that the transverse diameters of the chest were increased by .6 centimeter. Such averages are misleading in considering individual cases, yet indicate the general trend that very little change takes place in the group as a whole. It would be possible, of course, for a true decrease in size of some cases to be offset by an apparent increase due to higher diaphragms in others, with a consequent maintenance of the same average transverse heart diameters for the group. Where this occurred the average transverse measurement of the heart would remain the same, though the average heart size was actually decreased. Our data could not safely be interpreted in this way.

From superimposed films it was concluded that the heart shadows of two of this series of 46 cases were larger, five questionably larger, and five smaller. Most of the cases with smaller shadows postoperatively in this series of 46 unselected patients had been admitted with congestive heart failure and auricular fibrillation.

A study of all the cases showing larger heart shadows after operation revealed that the majority had hypertension, coronary disease, rheumatic heart disease, persistent auricular fibrillation, or borderline myxedema. Large

gains in weight might reasonably be expected to be followed by larger heart shadows. Actually this was not conclusively demonstrated, although the evidence was quite suggestive in several cases.

INFLUENCE OF RHYTHM AND OF CONGESTIVE FAILURE IN CHANGES IN CARDIAC MEASUREMENTS

Normal Heart Rhythm without Congestive Heart Failure. Roentgenograms were taken on admission to the hospital and no sooner than two months later after operation in 80 cases of hyperthyroidism with normal rhythm. Twenty-three of these showed apparent changes in the heart shadow in the second plate as follows: In nine instances the heart was definitely larger and in six more questionably larger; in only six cases was the heart shadow definitely smaller; in two others the decrease in size was questionable.

Normal Heart Rhythm with Congestive Heart Failure. Seven cases showed congestive heart failure and normal rhythm. In one, the heart shadow was questionably larger when the patient was symptom-free, in two there was no definite change, and in four the heart shadows were probably smaller after clearance of heart failure. Three of these latter showed pleural fluid so that the measurements were only approximate, but comparison of the films showed obvious reduction in size. All of these cases showed coincident cardiovascular disease.

Auricular Fibrillation without Congestive Heart Failure. All of the observed patients who had auricular fibrillation without congestive heart failure on admission to the hospital, and

subsequently resumed normal rhythm, were operated upon before the normal rhythm returned. Consequently, we have no evidence as to the effect on the heart shadow when the transition from auricular fibrillation to normal rhythm occurs before relief of thyroid toxicity. We have taken roentgenograms before, during, and after postoperative auricular fibrillation. The results suggest an increase in size of the auricles from this irregularity alone. We observed an increase in size of the heart shadow following the onset of auricular fibrillation in a patient with exophthalmic goiter, mitral stenosis, and normal rhythm, who developed an attack of acute recurrent rheumatism a few days after hemithyroidectomy. Parkinson and Cookson² have recently described several cases showing an increase in the size of the heart shadow after the onset of auricular fibrillation.

Of eight cases in this series with auricular fibrillation uncomplicated by congestive heart failure, three showed postoperatively a definite reduction in the size of the heart shadow after normal rhythm was restored. Decrease in size was possibly present in the five others because of smaller transverse heart measurements, but the higher position of the diaphragms in these cases made the interpretation doubtful. Because there was so little difference in the superimposed films, the evidence did not appear sufficient to warrant a definite statement. One case with persistent auricular fibrillation appeared to show a larger shadow in the second film.

Auricular Fibrillation with Congestive Heart Failure. There were 16 cases with auricular fibrillation and conges-

tive heart failure and one with auricular flutter and congestive heart failure. Of these, 13 showed normal rhythm when the roentgen-rays

larger shadow. The latter case had hypertension and coronary disease and had had a mild recurrence of congestive heart failure although normal

were repeated. Of these 13 cases, nine showed definitely smaller heart shadows (see figure 1), two showed questionably smaller heart shadows, one showed no change, and one showed a

rhythm was present. The questionable cases probably were smaller as shown by the superimposed shadows, but the presence of fluid in the chest rendered the conclusions untrustworthy.

Four of the cases with auricular fibrillation and congestive heart failure did not have a return of normal rhythm after operation. Of these, two were

Thus it seems probable that auricular fibrillation is attended by some dilatation of the auricles and, in some instances, by dilatation of the ventri-

questionably larger, one questionably smaller, and one definitely smaller.

In table 1 are shown the average measurements before and after treatment in this group of cases. It is to be noted that all measurements are smaller except the chest diameter.

cles. While we have made a sharp clinical distinction between patients with congestive heart failure and those without congestive heart failure, it is obvious, of course, that such a sharp differentiation cannot be made in all cases. Certainly, various degrees of

TABLE I
AVERAGE MEASUREMENTS BEFORE AND AFTER TREATMENT IN 16 CASES WITH AURICULAR
FIBRILLATION AND CONGESTIVE HEART FAILURE

	Average transverse diameter of chest in cms.	Average length in centi- meters	Average left border in centi- meters	Average right border in centi- meters	Average base in centi- meters	Average great vessels in centi- meters

After treatment	24.3	15.3	9.8	4.6	9.9	7.2

decompensation may be present before clinical signs of edema are manifest. When clear-cut congestive heart failure was present with auricular fibrillation, the heart shadow was larger than later when the fibrillating heart became well compensated. Further reduction seems to have taken place when normal rhythm was restored (figure 2).

CHANGES OBSERVED BEFORE OPERATION IN CASES WITH CONGESTIVE HEART FAILURE

Seven cases with congestive heart failure had roentgen-rays taken on admission and again after clearance of congestive heart failure. Five of these had auricular fibrillation and two had normal rhythm. Reduction in the size of the heart shadow in all cases was noted. In figure 2 is shown a case illustrating the successive changes in a patient with congestive failure and auricular fibrillation. Digitalis and Lugol's solution were given which, along with bed rest, cleared up congestive failure. (Normal rhythm was restored after operation and the heart shadow was further reduced in size.)

Congestive failure, in addition to auricular fibrillation, is undoubtedly partly responsible for the apparent

dilatation. Any treatment which clears up congestive heart failure, therefore, will probably produce a reduction in the size of the heart shadow. In some cases, Lugol's solution and bed rest will accomplish this result, but in others, in spite of this treatment, edema will increase, as we have frequently observed. Digitalis given at this point may produce marked diuresis. On the other hand, some cases with auricular fibrillation will show a reduction in ventricular rate following the use of digitalis but will not have diuresis until Lugol's solution is administered.

CHANGES IN THE SHAPE OF THE HEART

Attention has been called to the prominence of the pulmonary artery and other variations of the heart in toxic goiter.^{2,3,4,5} More recently Parkinson and Cookson² described the heart in this condition as ham-shaped. They state that this type of cardiac contour is due to a combination of prominence of the pulmonary arc, the left ventricle, and, to a minor extent, the right auricle.

The Pulmonary Arc. In this series we found the pulmonary arc to be prominent (i.e., straight or convex) in 52 cases on first observation. In 19 of

these we felt there was a definite reduction in size of the arc after operation or after clearance of heart failure. Prominence of the pulmonary arc was observed in some patients without auricular fibrillation or congestive failure; but the reduction in its size was

most marked in patients with congestive heart failure.

Transverse Diameter of Heart. By measurement, the transverse diameter of the heart was increased after operation in 48 cases. The change in position of the diaphragm accounts for a

FIG. 2. Heart shadows in a woman, aged 38, with exophthalmic goiter of 24 months' duration. Auricular fibrillation, mild congestive heart failure (positive Wassermann). Outline (1) before treatment. B.M.R. + 69, pulse 104, weight 109. Outline (2) after digitalis and Lugol's solution. B.M.R. + 40, pulse 90, weight 102. Outline (3) 18 months later. Normal rhythm present. B.M. R. (?), pulse 88, weight 123. Note generalized reduction of heart shadow after clearance of congestive failure and then further reduction of right border after restoration of normal rhythm.

large number of these increases. The right and left borders participated in this increase, but the left border accounted for the greater part, being influenced more by the position of the diaphragm. Superimposed films revealed that the ventricles, as well as the auricles, took part in the apparent dilatation. When decrease in the transverse measurements took place, the left border receded more frequently than the right border, although the latter often showed relatively large recessions, particularly after disappearance of congestive heart failure and cessation of auricular fibrillation.

Measurements of the Great Vessels and Base. The position of the great vessels in the chest underwent little change except in some instances of congestive heart failure where they appeared to be pushed upward. The measured width of the great vessels, however, showed changes. Reduction in this measurement was frequently seen in failure cases and probably most commonly was due to a decrease in the size of the pulmonary arc, which is included in the measurement. In a few instances a decrease in the measurement to the right was noted, which was probably accounted for by displacement of the aorta. Displacement of the aortic knob to the left may be due to intrathoracic goiter. Removal of the goiter allows it to return to its normal position. Increase in measurements of the great vessels after operation were seen in a few cases where there was an increase in blood pressure.

The measurements of the base were usually reduced in the cases which had had congestive heart failure, although this was by no means constant. The

difficulty in making this measurement in some cases renders it, in our opinion, of little value for comparative studies. The length of the heart appeared to be greater in cases associated with hypertension or other heart disease. In some cases the length of the heart showed a distinct reduction in the second film, especially, as in the case of the other measurements, after congestive failure had subsided.

Thus all measurements of the heart seem to be affected by the altered shape of the heart in congestive heart failure.

Other Changes Noted. Prominence of the superior vena cava was very infrequently noted. In one or two cases with mitral stenosis, the shadow of the vena cava was easily distinguished. Increased hilus markings were noted in many cases but more commonly in the failure cases. Diminution in the intensity of these markings after relief of failure or after operation occurred frequently. In cases with congestive failure, as a rule, the diaphragms were elevated. At times this seemed to be offset by the usual drop of the diaphragm from loss of weight so that very little change in position was noted in successive films. The cause of this elevation has been ascribed to enlargement of the liver. However, pulmonary congestion tends to render the lung tissue less elastic by virtue of the engorgement of the alveolar capillaries. In this way diminished vital capacity is brought about. Secondary atelectasis may occur. Thus it is reasonable to assume that the higher position of the diaphragm can be accounted for by these factors as well as by liver engorgement.

DISCUSSIONS OF FACTORS INFLUENCING THE SHAPE OF THE HEART IN HYPERTHYROIDISM

The cause of the prominence of the pulmonary artery in toxic goiter is unknown. There seems to be little doubt that it occurs, though the frequency of a straight or convex arc is rather high in patients without hyperthyroidism. In a consecutive series of teleoroentgenograms on 100 toxic goiter cases, 100 non-toxic goiter cases, and 100 non-goitrous individuals of approximately the same age and sex distribution, we found a straight or convex pulmonary artery region in 43, 30, and 32 per cent respectively. The most prominent arcs, however, appeared in the toxic goiter cases. Postmortem measurements made by Parkinson and Cookson² in six cases showed a 17 per cent increase in circumference of the pulmonary artery compared to normal standards. This should be confirmed by a larger series. This prominence must therefore be due to dilatation of the pulmonary artery presumably from increased pressure in this vessel.

Since enlargement of the pulmonary arc occurs without evidence of congestive heart failure, the origin of the increased pressure must be between the right ventricle and the pulmonary arterioles. Hyperthyroidism is characterized by a decreased peripheral arteriolar resistance but whether this drop also occurs in the pulmonary circuit is unknown. A vasomotor mechanism in the smaller vessels of the lung probably exists,⁶ but it is doubtful if the vascular bed in the pulmonary circuit would permit of vaso-dilation to such a magnitude as occurs peripherally. If this assumption

is true, then, with the increased output of the heart, the right ventricle would be working against a constant pressure in the pulmonary circuit. This inequality in pressures might soon lead to a gradually increasing intra-pulmonary arterial pressure and eventually dilatation of the pulmonary artery itself. In other types of heart disease increase in pulmonary pressure probably has its origin in the left ventricle and is transmitted backward to the pulmonary circuit or, as in mitral stenosis, it still begins in the left side of the heart but at the mitral valve. Thus in one, pulmonary pressure is elevated first at the pulmonary arterioles and transmitted back to the right side of the heart, and in the other the pressure begins at the arterioles of the systemic circulation, in the left heart or at the mitral valve and is transmitted back through the pulmonary veins to the pulmonary capillaries. Increase in pulmonary vein pressure may give rise to hemoptysis, paroxysmal dyspnea, and marked orthopnea. Increase in pulmonary artery pressure, as long as secondary effects do not take place, should not give rise to these manifestations. This seems to be borne out by clinical experience. Gallop rhythm is frequently seen in very toxic patients with hyperthyroidism and regular rhythm. Perhaps here too the relative inequality of pressure might play a part.

That the right ventricle becomes hypertrophied as well as the left is shown by postmortem examinations.² When gross left ventricular hypertrophy is seen in roentgenograms as indicated particularly by the blunt appearance of the ventricular shadow, hypertension is usually present and the

pulmonary arc is often less conspicuous. Enlarged auricular shadows contribute to the configuration of the heart in toxic goiter, the right probably more often than the left. When auricular fibrillation and congestive heart failure are present, dilatation of the auricles substantially alters the shape of the heart.

The incidence of the so-called ham-shaped heart is not great in our series. There are several explanations for this: First, surgical treatment is in more favor in this country than elsewhere, consequently, cases are referred for surgical treatment early in the course of the disease. Second, hyperthyroidism is generally more easily recognized than formerly, with the result that a larger number of patients over fifty, in whom hyperthyroidism is more difficult to diagnose than in those of younger years, are detected. Naturally, the incidence of other cardiovascular disease is high in these cases, the presence of which influences the shape of the heart.

SUMMARY*

Roentgenograms were made before and after treatment in 115 cases of

**Editor's note:* An extensive tabular report of cases is not published because of limitation of space.

toxic goiter. Comparisons of films were made by measurement and by superimposition. *Definite reduction in size* was observed after relief of congestive heart failure, and after cessation of auricular fibrillation, and in a few without these complications. Factors contributing to the shape of the heart in toxic goiter are enumerated and their probable causation discussed.

CONCLUSIONS

1. Superimposition of seven-foot roentgenograms of the heart is the most satisfactory method of judging changes in the size and shape of the heart.

2. Very little change takes place in the heart shadow in uncomplicated cases of toxic goiter with normal rhythm following removal of thyroid toxicity by subtotal thyroidectomy.

3. Cardiac dilatation as shown by roentgenograms takes place most frequently in congestive heart failure with or without auricular fibrillation.

4. Occasionally in cases of toxic goiter of sufficient duration, uncomplicated by other cardiovascular disease, certain changes in the heart shadow may be found which have been described as characteristic of hyperthyroidism.

Discussion of a Case of Gastric Carcinoma with Recurrent Colic*†

By JOSEPH G. WEINER, M.D., *Philadelphia, Pennsylvania*

NO reference is made in the literature to carcinoma of the stomach, producing attacks of pain resembling gall-stone colic. I wish to present such a case. The patient had attacks of typical gall-stone colic: sudden, severe pain in the right upper part of the abdomen under the costal margin, always requiring opiates for relief, and radiating always to the right shoulder region. Associated with this pain there were varying degrees of shock, manifested by pallor, rapid pulse, perspiration, weakness and prostration.

Pain is one of the common symptoms in cancer of the stomach. It varies considerably in its intensity, though the degree of distress is usually not excessive. In the early stages the patient may complain only of a sense of discomfort after meals, but as the condition progresses, actual pain manifests itself. There is nothing characteristic about the pain. It is usually of a dull, gnawing type; in some, it is of a burning character, and in others it may be sharp and lancinating. Cramp-like pains occur when there is associated pyloric

stenosis. In a few cases it may be so constant and severe as to be almost unbearable. Exceptionally, gastric carcinoma may occur with little or no pain. The pain may be intermittent or continuous. When intermittent it may occur only every few days or weeks. In not a few cases it is only nocturnal in its appearance.

A relation to food may or may not exist. Often foods increase the pain, especially if the cancer be pyloric, and in such instances, as in ulcer, it is usually relieved by vomiting. Or the pain may be continuous and bear no relation to the ingestion of food.

The site of the pain is usually in the epigastrium. It may, however, be complained of at the following sites: in the right upper quadrant, in the interscapular region, at the lower end of the sternum, low in the abdomen and at times in the left hypochondrium.

CASE HISTORY

S. P., age 58, peddler by occupation, reported to the Gastro-Enterologic Clinic at the Temple University Hospital on August 12, 1931. His past medical history was negative except for an attack of lobar pneumonia in 1917 and a double herniorrhaphy and appendectomy in 1919. He was perfectly well until one year ago when he had a nocturnal attack of sharp pain in the right upper quadrant, under the costal margin, which radiated to the back and the right shoulder area, and

*Received for publication November 11, 1932.

†From the Gastro-Enterologic Service, Temple University Hospital and Medical School, Philadelphia, Pa.

also across the abdomen to the left. The pain was of such intensity that a physician had to be called, and it was relieved only by the administration of a hypodermic of morphine. Since then he has had recurring attacks of similar pain, generally a few weeks apart, mostly diurnal and in each attack the pain was so intense that no relief was obtained until morphine was administered subcutaneously. There was no jaundice, chills or fever associated with the attacks, nor any urinary phenomena. The pain appeared without relation to food ingestion, or to physical exertion. His only worries were as to his health; he had no sorrows or griefs. There was no premonitory warning of an impending attack. An attack was never followed by any gastric disturbances such as nausea, vomiting or belching.

There was a loss of six pounds in weight in the past six months, and there was considerable loss in strength, so that for the last two months he felt he did not have sufficient stamina to carry on his work. His appetite lately was poor. There were no postprandial discomforts. The stools were light yellow to light brown in color and frequently contained mucus. There was never any blood in the stools.

Physical Examination. An adult Jew, of hyposthenic build, who appears to be about 60 years old. He is in no discomfort at the time of examination. Weight 125 pounds; height five feet, five inches. The pupils are equal and react normally to light and accommodation. The skin of the face is dry, weatherbeaten, and somewhat wrinkled. The tongue is clean, the teeth worn down and discolored, and the gums show food deposits. The tonsils are cryptic, the pharynx is congested, and there is a moderate cervical adenopathy. The thyroid is not palpable. The lungs are grossly negative; respiratory rate twenty. The heart is normal in size; the heart sounds weak; no murmurs present. The palpable arteries are slightly sclerotic. Blood pressure 140 millimeters of mercury systolic and 80 diastolic. Pulse rate 84.

The abdomen is scaphoid. There are two inguinal scars of a former herniorrhaphy. There is a tenderness in the epigastrium and over the gall-bladder region. There is no increased muscular tension anywhere nor is

any mass palpable. The liver edge is felt one centimeter below the costal margin. The spleen and kidneys are not palpable. The sigmoid is spastic. The rectal examination is negative except for external hemorrhoids. The knee jerks respond normally. Romberg test normal. Coördination normal. Babinski test negative.

The tentative diagnosis was cholelithiasis.

The routine studies made were as follows:—

Gastric. Fractional gastric analysis yielded a pearly-grey fasting residuum of ten cubic centimeters. There was no gross food retention, blood or pus present. Microscopically no Boas-Oppler bacilli or yeast cells were found, and there was no microscopic evidence of food retention.

The acid determination, employing an Ewald meal stimulus and one-half hourly extractions, was as follows:

	F	1	2	3	4
Free	0	0	22	22	32
Total	28	36	54	54	50
Bile	Pos.	Pos.	Pos.	Pos.	Pos.
Occult	Pos.	Pos.	Pos.	Pos.	Pos.
Blood	#1	#1	#1	#1	#1

As is seen, bile was present in the fasting and digesting stomach. The patient had taken the tube without gagging. According to Lyon¹ this is an abnormal finding and points either to disturbed physiology of, or to pathologic lesions within, the pyloro-duodeno-biliary apparatus. There are two exceptions to this: first, if the patient does not take the tube well but gags and coughs, bile may be regurgitated into the stomach; second, in cases of marked hyperacidity, the alkaline duodenal contents mixed with bile may be regurgitated into the stomach in a physiologic effort to lower the excessive acid. This latter mechanism is questioned by some observers.

We often find it difficult properly to evaluate the presence of occult blood. It is an abnormal finding if good tube technic is carried out. In office practice

where our technicians are properly trained and there is no hurry, the presence of occult blood is of considerable significance, and implies to us that we are dealing either with congestion, or erosion, or ulceration of the mucous membrane. But in clinic work, because of the large number of patients and the need for attention to as many as possible, tube technic is unfortunately not carried out with the same necessary care. We frequently find our technicians employing unnecessarily strong syringe suction in an attempt to extract a fraction hurriedly. Unless the benzidin reaction be very strong and the guaiac test positive, we attach no importance to occult blood reactions in the clinic. We grade our occult blood reactions plus one, two, three, and four. In plus one reactions we always think of trauma. In addition to trauma as a factor, we must also rule out mouth suction on the part of the patient. A good plan is to have the patient produce suction on his gums and then expectorate the material into a clean dish and test it for occult blood. The latter may also occur as a result of cricopharyngeus muscle spasm in the vagotonic type of individual. Physiologically, the two points of tonus in the esophagus, according to Jackson, are at the crico-pharyngeal orifice and at the hiatus. Vagotonics with excessive muscle strain can, during gagging, readily produce trauma at this upper point, and they often complain that they are sore, pointing over the cricoid cartilage, for some period of time after having had intubation of the stomach or duodenum. Even when the occult blood reaction is marked we must still keep in mind the possibility that we

may be dealing with a friable gastric mucous membrane. There is also the possibility that the presence of occult blood in any one fraction of the digesting stomach may be due to an abnormal amount of peristaltic contraction against the tip of the tube with consequent mucous membrane erosion.

We do not examine the gastric contents routinely for lactic acid because it is our opinion that it is not diagnostic of carcinoma. We do not agree with MacLean² who emphasizes the great value of its presence and who claims that it occurs frequently in large amounts at a very early stage in carcinoma. It is our conviction that lactic acid indicates only that stagnation has occurred and that gastric acidity is disappearing, and that it may accordingly be present not only in certain forms of gastric carcinoma but also in the benign pyloric stenoses when these cause a marked degree of obstruction, and may indeed be found in cases of marked motor insufficiency. This agrees with the findings of Murray and Robertson³ who reported that an investigation of test meals from 50 subjects, pathologic and normal, showed the presence of lactic acid in 74 per cent; it occurred more frequently in hyposecretion but was found present even in hypersecretion. Their conclusion was that lactic acid had no apparent clinical significance.

The Ewald meal was completely evacuated at about the two hour point, which indicates that gastric motility was normal. The final lavage revealed no food sediment remaining.

Biliary. A number of biliary drainages failed to show any cholesterol crystals or calcium bilirubinate pigment to be present.

The B fractions were of normal brown

color, and microscopy of all fractions failed to show evidence of any inflammatory involvement of the biliary system.

Bockus et al¹ have demonstrated that the finding of cholesterin crystals or calcium bilirubinate in the same bile is pathognomonic of gall-stones; and that the diagnoses of gall-stones based on the finding of cholesterin crystals without the characteristic pigment are 89 per cent accurate, and those based on bilirubin calcium pigment are 90 per cent accurate. It has been our experience that if in a number of successful drainages, i.e., those yielding good B fractions, we have failed to recover one of these two elements, especially in a centrifugated specimen, we may feel safe in saying that stone, in all probability, does not exist in the gall tract.

Urinalysis. Negative, except for trace of albumin. No pus cells or red blood cells were noted on a number of examinations.

Stool Study. The stools were of average size, light yellow in color, and of the usual fecal odor. There was no blood, gross or occult; no mucus, pus, nor grossly recognizable undigested food elements were present. Microscopy showed no free fat or undigested muscle fibers, indicating no failure of the external pancreatic or intestinal functions.

Blood Count. Hemoglobin, 85 per cent; red blood cells, 4,350,000; white blood cells, 7950. Differential white count, normal.

Van den Bergh Reaction. Direct, negative; Indirect, 0.2 unit.

Icterus Index. Six.

Liver Function Studies. Bromsulphalein: 2 milligram dose showed no retention at the end of 30 minutes. Galactose Tolerance, 3.3 grams. Urobilinogen, 1:5; Wallace and Diamond method, in which readings up to 1:10 are considered normal.

Blood Chemistry. Urea N 12 milligrams per 100 cubic centimeters; sugar 120 milligrams per 100 cubic centimeters.

Wassermann. Blood Wassermann and Kahn tests, negative. Spinal fluid Wassermann negative.

Blood Sedimentation. Normal horizontal line (Cutler graph).

The blood sedimentation test⁵ is a laboratory procedure which seems to have found a place as a valuable aid in diagnosis. When positive, it is an early indication of the presence of a destructive process as well as a measure of the intensity of the disturbance. Essentially the sedimentation phenomenon depends upon the amount of cellular destruction going on in the body. In healthy persons, as a result of the wear and tear of everyday life, a certain amount of tissue destruction is always taking place, and although this varies daily it remains within limits considered normal. Should, however, the amount of tissue destruction pass beyond the normal, then the stability of the blood is seriously disturbed and the red blood cells settle out quickly from the plasma. The rapidity of the settling of the red blood cells is in direct proportion to the severity of the underlying destructive process.

Roentgenologic Study (Dr. Chamberlain). No abnormality of the esophagus. The stomach is of average normal size, shape and position. Its outlines are smooth and regular throughout and its walls normally flexible. Gastric peristalsis begins soon after taking the barium meal and the stomach starts to empty in the normal manner. The outlines of the pylorus and the duodenum are likewise normal, but there is persistent tenderness in the right upper quadrant of the abdomen.

At six hours the stomach is empty and the barium is divided between the pelvic ileum and the cecum. The cecum is freely movable and not tender.

At 24 hours the distribution of the barium in the colon is normal and no abnormality of the large bowel is noted.

Films of the gall-bladder region, 13 hours after four grams of tetradol emulsion by

mouth, showed only a very faint gall-bladder shadow. To check up on this finding, the procedure was repeated on the following day. With the second examination we obtained 13 hour films which showed a gall-bladder of normal size and density, at the level of the disc between the second and third vertebrae. Films made two hours after a high fat meal showed the gall-bladder much smaller.

Conclusions. We have discovered no roentgen-ray evidence of organic disease in the gastrointestinal tract, and the findings in the gall-bladder suggest normal function.

*Gruskin Test for Malignancy.*⁶ Positive for carcinoma.

The Gruskin test is a flocculation reaction based upon the theory that, under normal conditions, epithelial and connective-tissue cells produce lysins that are antagonistic to each other and that due to their presence an equilibrium between these two types of cells is maintained. Because connective-tissue cells generate lysins which prevent the overgrowth of epithelial cells, carcinoma does not develop even though inciting factors (irritation, etc.) may be present. If, however, the connective-tissue fails to generate such lysins and the proper extrinsic factors are present, then carcinoma develops. The opposite condition holds true in the production of a sarcoma. That normal serum has the ability to autolyze cancer cells in vitro, whereas cancer serum fails to do so, has been demonstrated by Freund and Kaminer.⁷ In other words, in malignancy there is present in the blood stream a protein which is characteristic of the type of tumor, carcinoma or sarcoma, from which the patient is suffering, and this protein is typical for the type of embryonic cells of which the tumor mass is composed. When the serum of a patient suffering

with malignancy is brought in contact with an extract of embryonic cells of a homologous nature, flocculation takes place; when serum of a normal individual is thus tested, no such flocculation occurs.

Because of the positive Gruskin test and the normal sedimentation, we had to assume that malignancy, if present, was still in an early stage, that is, before tissue destruction had begun. A normal sedimentation rate is not conclusive evidence that there is no tissue destruction but it does show that disease, if present, is producing very little, if any, constitutional disturbance.

Because of the absence of positive findings, i.e., normal B fractions, negative bile microscopy and negative cholecystography, it was obvious, in spite of the fact that the symptoms were characteristic, that the diagnosis of cholelithiasis was probably not correct. There are a number of conditions that may produce attacks of pain resembling gall-stone colic. We therefore had to consider one of the following as a possible cause: cholecystitis; carcinoma of the gall-bladder; peptic ulcer, especially the perforating type; gastric crises of tabes; renal colic; appendicitis; pancreatitis; pancreatic calculus; lead colic; angina pectoris, and floating kidney. Weir and Partch have called attention to the fact that colicky attacks resembling gall-stone colic may also occur with cholangitis, cirrhosis and hepatitis, stricture of the common bile duct, and carcinoma of the pancreas.

Cholecystitis. Attacks of pain indistinguishable from gall-stone colic may occur in cholecystitis. The diagnosis is based on positive microscopic findings

of the biliary aspirates. The examination will reveal bile-stained, exfoliated, tall columnar epithelium often arranged in fan-shaped groups or rosettes; an excessive amount of mucus which may be encrusted with bile salts; an increased number of leukocytes proportionate to the extent of the inflammatory process; amorphous debris and occasional red blood cells. It must be remembered that negative findings do not necessarily indicate that there is no pathologic lesion, and in clinically suggestive cases if microscopy in the first study is negative the examination should be repeated.

Because of the absence of fever and leukocytosis, as well as the absence of positive microscopy over a number of drainages, and the presence of good function as demonstrated by cholecystography, the diagnosis of cholecystitis could not be supported.

Carcinoma of the Gall-Bladder. In the early stages, cancer of the gall-bladder often resembles cholelithiasis. In about 80 per cent of the cases gall-stones are found, and it is held by many that calculi are responsible for this condition. Because of the positive Gruskin test, this was a diagnostic possibility.

Peptic Ulcer. Gastric or duodenal ulcer, especially those with a tendency to perforation, may give rise to attacks of pain resembling gall-stone colic. Even with modern methods of study, mistakes in diagnosis between these two conditions are frequently made. As a rule the pain of ulcer has a direct relationship to food but so has the pain in certain cases of cholelithiasis, and in the latter the pain may be aggravated in some instances by dietary in-

discretions just as in ulcer. The pain of cholelithiasis in some cases may be present after every meal, and in cases of peptic ulcer there are usually well marked periods in which the patient is nearly or quite well. Hyperacidity speaks for ulcer, but according to Moynihan's statistics 22 per cent of his cholelithiasis cases showed hyperacidity, and in Rehfuess' experience more than one-half of his cases show hypersecretory findings. Though hematemesis and melena may occur in cholelithiasis it is an infrequent finding, whereas the presence of these symptoms speaks strongly in favor of ulcer.

The absence of such symptomatology in this case and the negative roentgen picture were against this as a diagnosis, although negative roentgen-ray findings do not exclude ulcer.

Gastric Crises of Tabes. The normal reflexes and the negative blood and spinal fluid Wassermann reactions excluded this condition as a possibility.

Renal Colic. The colic of nephrolithiasis is, as a rule, easily distinguished because of the radiation of the pain to the groin, the frequent micturition and the presence of blood, pus or albumin in the urine.

No stones were seen on flat plates. Urine examinations were persistently negative.

Appendicitis. Occasionally the cecum may be undescended, in which case the appendix lies close to the gall-bladder and an acute attack will be productive of pain simulating gall-stone colic.

The past history of appendectomy excluded this.

Pancreatitis. The pain in this condition is more directly in the epigastrium or to the left; there is a deep-seated

tenderness and resistance over the pancreatic area, and in an acute attack the shock and collapse is great and early in onset. Chronic pancreatitis may sometimes be detected by stool study; the movements are usually large, soft and pultaceous, and there is present free fat and undigested muscle fibers.

Normal stool findings over a number of studies, as well as the absence of such symptoms and physical findings as noted above, were against this condition being present.

Pancreatic Calculus. Colic may occur as the result of the passage of a calculus along one of the ducts of the gland. There is severe, deep-seated epigastric pain, generally associated with vomiting, glycosuria, steatorrhoea and azotorrhoea. The condition is rare and is usually mistaken for gall-stones.

The absence of the associated symptoms and signs did not favor such a diagnosis.

Lead Colic. Lead, by its stimulation of the motor nerves in the intestinal wall, causes violent spasm and contraction. The pain is felt about the umbilicus but often radiates from there into the right hypochondrium, suggesting biliary colic. The presence of anemia, a blue line in the gums, obstructive constipation, stippling of the red blood cells, tremor, palsies and an occupation involving exposure to lead suffice to make a clinical diagnosis.

The absence of the above symptoms exclude this from consideration.

Angina Pectoris. The pain of angina pectoris not infrequently may be referred to the epigastrium or to the right upper quadrant of the abdomen and may simulate an acute surgical abdomen. In such cases an acute coro-

nary occlusion is often the cause. In Heberden's angina pectoris the pain occurs or follows immediately upon effort; an attack may be induced by emotion and excitement, may follow upon exposure to cold, or may occur with gaseous distention after a heavy meal.

The patient was studied by the Cardiac Department and no cardiovascular lesion was found to be present. The electrocardiogram revealed no evidence of coronary disease.

Floating Kidney. That undue renal mobility, by producing traction on the duodenum and common bile duct or by kinking of the cystic duct, may induce attacks of biliary colic, has been pointed out by a number of observers. Marwedel⁸ states "a movable right kidney may produce all the symptoms of cholelithiasis—colic with or without jaundice—in the absence of diseases of the biliary passages". Moynihan⁹ refers to movable kidney as having caused confusion in diagnosis in some instances. Sherren¹⁰ has discussed this subject fully. He states "among thirteen cases in which symptoms suggestive of cholelithiasis were associated with movable kidney all except one were women. Gall-stones were present in two cases only. In none had urinary symptoms occurred. With regard to differential diagnosis this is difficult; even when the symptoms are due to movable kidney alone, tenderness will be present in the gall-bladder region during the attack, and Murphy's sign may be marked. When jaundice exists, the fact that the gall-bladder is distended should make us suspect that the movable kidney is the cause."

The attacks are almost always diurnal.

nal. The diagnosis depends on the detection of a floating kidney. The absence of a movable kidney in this case eliminated such a diagnosis.

Cholangitis, Cirrhosis and Hepatitis. The primary nature of cholangitis in some cases was pointed out by Judd and McIndoe.¹¹ This condition may progress to an obliterative process, giving the picture of stricture in the common bile duct with jaundice, or it may progress upward into the liver and lead to hepatitis or cirrhosis. Cholangitis may be the chief lesion in some cases; in others extensive hepatitis and cirrhosis is the predominant lesion. Weir and Partch¹² state that colicky pains occurred in more than 40 per cent of their cases. Jaundice often recurred repeatedly and chills, fever and sweats were not uncommon.

Negative biliary drainages, normal liver function tests, negative Van den Bergh reaction, and normal icterus index excluded the above as a possible cause.

Stricture of the Common Bile Duct. Most of the strictures occur postoperatively and follow upon cholecystectomy, choledochostomy, or both. In 50 per cent of the cases there is painless jaundice and in 40 per cent of the cases there is typical colic and jaundice.¹²

The absence of jaundice excluded this condition.

Carcinoma of the Pancreas. Pain is a common symptom and may or may not be associated with jaundice. If the head of the pancreas is involved, jaundice usually occurs early, whereas if the tail or body is primarily involved it occurs much later and pain is an early and more prominent symptom. Weir

and Partch report that colic typical of gall-stone occurred in five of their cases.

Because of the positive Gruskin test, carcinoma of the body or tail of the pancreas had to be considered.

A consideration of these facts led to the conclusion that we were probably dealing with carcinoma either of the gall-bladder or of the pancreas, and normal sedimentation rate and the absence of anemia suggested that the process was still in an early stage. We were cognizant of the fact that cancer of the gall-bladder, in about 80 per cent of the instances, occurs in association with gall-stones and the absence of stone tended to diminish the positiveness of such a diagnosis. Immediate operation was advised and the patient was admitted to the Babcock Surgical Ward. Operation was performed by Dr. Burnett September 24, 1931. His report follows:

The gall-bladder is whitish in color, only very slightly thickened, relaxed, and empties readily on pressure. No stones palpable. The cystic duct is not enlarged. The common duct is normal to palpation. The liver shows slight fibrosis and its edge is very slightly thickened. *Stomach:* The omentum is plastered over the lesser curvature. Underlying this area is a large mass saddling the lesser curvature; straightened out, the mass is about 10 by 4 centimeters. It lies about four centimeters proximal to the pylorus and extends to within six centimeters of the cardia. The mass has everted edges and feels like a malignant growth. No nodules are present in the gastro-hepatic omentum. Reëxamination of the liver shows no metastatic deposits to be present. The pancreas feels normal to touch and there is no evidence of fibrosis or growth.

The operation consisted of a gastric resection. The duodenum was partially mobilized and then resected below the pylorus and the distal and closed with Pagenstecher suture,

inverted and the adjacent mesentery ligated over the stump which was dropped; the jejunum was brought up and, at a point about fifteen centimeters from the ligament of Treitz, was anastomosed to the remnant of the stomach after the latter had been amputated on a radical line about three centimeters below the esophageal junction on the lesser curvature.

PATHOLOGICAL REPORT

Gross Description. The specimen is a rectangular piece of tissue 12 by 10 by 1 centimeters, removed from the wall of the stomach. In the central area, the continuity of the mucosal surface is broken and replaced by an ulcerative lesion 8 by 6 centimeters. The lesion is irregular in outline; its borders extend 1.6 centimeters above the mucosal surface and are hardened and eburnated. The base of the lesion is pale gray, rough, dull and moist. The surrounding mucosal folds are pink, moist and glistening; these too are thickened and hypertrophied. The external surface is rough, moist and glistening. Remnants of the mesentery are attached.

Microscopic Description. The mucosa is very much thicker than normal. On the inner surface there is a hyaline, structureless, mucus-like substance. The tubules are long and somewhat branched. Many mononuclear leukocytes lie in the tunica propria and there are a number of large lymph-follicles lying just above the muscularis mucosa. One end of the section, representing the edge of the ulcer, possesses tubules that are much less regular and very much more deeply stained than their fellows at the opposite end. About them, the leukocytic infiltration is intense. Everywhere beneath the muscularis there are masses of large, irregular, deep-staining cells with large reticular nuclei and pale-staining nucleoli. By higher magnification, many mitotic figures may be seen and it is noted that the cells are arranged somewhat in the form of glands. The reproduction is very crude. This cellular process is found even in the serosa.

Diagnosis. Carcinoma of the stomach.

COMMENT

The presence of carcinoma of the stomach in this case was an unexpected

finding, because to our knowledge attacks of pain resembling gall-stone colic have never been ascribed to cancer of the stomach and because none of our methods of study pointed to any gastric involvement. It demonstrated that gastric cancer may exist at a stage where none of our usual methods of study may give even suggestive information. Balfour¹⁸ informs us that by actual study 50 per cent of all cancers of the stomach are absolutely hopeless when seen by physicians in the Mayo Clinic, and one-half of the remaining 50 per cent are explored surgically and found hopeless. This means that only 25 per cent of all cancers of the stomach are within the possible reach of our best methods of treatment. Of all the diagnostic methods at our command the positive Gruskin reaction was the only one that detected the fact that we were dealing with malignancy. It was only our previous experience with malignancy-positive Gruskin reactions that warranted us to regard such a report with respect. That a malignant growth was present, even though the stomach had not been suspected, indicated that in the Gruskin reaction we have a method for the diagnosis of cancer that merits our attention.

Such a case is of interest because it once more compels us to ask ourselves how we are to diagnose the early case of gastric carcinoma. All of our present methods of investigation evidently are of little value in the diagnosis of cancer of the stomach at its incipient stage. The gastric analysis at the very earliest stage of the condition will reveal nothing. There is a latent period between the beginning of the carcinoma and the onset of symptoms. Radical

extirpation of the mass, at this stage, will result in cure. Our problem is to diagnose our cases in this latent stage. When gastric carcinoma produces the symptoms which we are taught are characteristic of carcinoma, then the condition has reached the inoperable stage. Palpable tumor mass, achlorhydria, lactic acid, Oppler-Boas bacilli mean that extension has occurred; anemia and cachexia imply that there is toxemia. It is necessary to emphasize that the early lesion of gastric carcinoma can exist in the presence of apparently perfect health.

Of all the methods at our disposal at the present time roentgen-ray examination stands preëminent in the diagnosis of cancer of the stomach. A positive roentgen diagnosis, however, can be made only if there is a defect present producing an anatomic alteration in the gastric contour. Roentgen-ray examination is very likely to fail us in the early stage of gastric carcinoma before a well developed lesion has occurred. When a defect has occurred 96 per cent of the cases, we are told, can be diagnosed in skillful hands by roentgen-ray.

Gastric analysis is practically of no value in the early stage of the disease. At this phase in its evolution there has as yet occurred no reduction in the gastric secretory output and the figures for both the free and total acid values are within normal limits. There may even be a slight increase in acidity at this stage in an otherwise healthy stomach; this is due to the irritation of the growth or its toxins. There may also be high acid figures especially in prepyloric carcinomas in the early

stage and in the malignant forms of ulceration almost to the end.

When pus, muco-pus and blood are present in the gastric contents the lesion is already definitely established. Minute particles of tumor tissue may be found on lavage and are perhaps conclusive evidence, but this is a very uncommon finding in early cases.

The objection might be raised that stone in the common duct was not excluded. We are cognizant of the fact that common duct stone may occur without jaundice. Clute¹⁴ reports that 39 per cent of the cases of common duct stone observed at the Lahey Clinic gave no history of jaundice in their previous attacks of pain and were not jaundiced at the time of operation. Judd and Marshall,¹⁵ and Jordan and Weir¹⁶ found that 20 per cent and 13.2 per cent of their cases respectively did not show jaundice before operation or at any time in their past history. Because of these facts the common duct should be explored more frequently at operation. Clute states that it is now his practice to open and explore the common duct in every patient: if it is dilated and thickened, whether or not stones can be palpated and regardless of any history of jaundice; in all patients who have had attacks of jaundice with pain, whether or not the duct is enlarged; in all cases in which there is much thickening of the head of the pancreas. Because at operation the common duct was not enlarged or thickened, or the head of the pancreas fibrosed, because there was no past history of jaundice associated with pain and because of the repeatedly negative bile microscopy, it was felt that there

was no need, nor any justification in view of the amount of major surgery already performed, to open and explore the common bile duct in this case.

PROGRESS NOTES

It is now one year since the patient was operated upon and he has not had a single attack of colic since. If any cause, other than his gastric lesion, was responsible for his attacks of colic it is not unreasonable to assume that he should have had a return of his attacks during the past year. This, I feel, proves the association between his carcinomatous lesion and the recurring attacks of colic. The mechanism involved in the production of the colic, in this case, cannot be definitely accounted for. We still are not able to explain adequately the cause of pain in the gastrointestinal tract. A summary of our present knowledge of the pathways along which abdominal pain travels is given by Alvarez.¹⁷ He states: "It seems now to be established that all afferent fibers in the sympathetic nervous system are connected with the posterior root ganglia of the spinal cord and are therefore no different from sensory nerves elsewhere in the body; they simply happen to travel in the same sheaths with bundles of sympathetic fibers. Most of those fibers which leave the upper part of the abdomen reach the spinal cord by way of the splanchnic nerves from the sixth to the ninth. In some persons the splanchnic nerves are connected also with the fourth, fifth, tenth, eleventh and twelfth segments of the dorsal cord. Blocking of the splanchnic nerves causes anesthesia of the visceral peri-

toneum and of the organs in the upper part of the abdomen.

"The vagus nerves carry so few sensory fibers that they can be ignored whenever efforts are being made to relieve abdominal pain. That these fibers are unimportant is shown by the fact that peritonitis is usually painless in the case of patients who have suffered injury to the upper part of the spinal cord, and by the fact that operations in the upper part of the abdomen can be done painlessly under splanchnic blocking.

"There are still other paths by which pain might conceivably leave the abdomen. One is by way of the ganglionated sympathetic chain, and the other is by way of the aortic plexuses and thence through the rami communicantes to the spinal cord in the upper dorsal region. That these sensory connections cannot be very important is shown by the fact already mentioned that when the spinal cord is severed in the upper dorsal region, disease in the abdomen usually runs a painless course."

The patient made an uneventful recovery following his operation. On leaving the hospital October 30, 1931 he weighed 115 pounds. November 16, 1931: His only complaint is weakness. Weight 116 pounds. December 17, 1931: Still complains of weakness; no digestive complaints. *Gastric Analysis*—no free hydrochloric acid; total acid 2.5 at end of one hour. *Blood Counts*—hemoglobin, 72 per cent, red blood cells 3,550,000, white blood cells 8100. *Sedimentation Rate*—average normal curve. *Van den Bergh*, direct negative; indirect 2 milligrams. *Icterus Index* 6. *Liver Function*—bromsulphthalein (2 milligram dose) no retention at end of 30 minutes. *Galactose*—3.0 grams. *Gruskin Reaction*—only very faintly positive; not even a one plus. January 15, 1932: *Gruskin Reaction*—very faintly positive, slightly stronger than on December 17, 1931. Dr.

Gruskin thinks he may be starting on a recurrence of his carcinomatous lesion. March 20, 1932: *Gruskin Reaction*—positive reaction, plus one. May 16, 1932: *Gruskin Reaction*—positive, plus one. June 15, 1932: *Gruskin Reaction*—positive, plus two. *Blood Count*—hemoglobin, 74 per cent red blood cells 4,010,000, white blood cells 8450. *Sedimentation Rate*: almost horizontal line. Feels stronger, is able to be at work for a few hours daily. Weight 118 pounds. Appetite good. No digestive complaints. Fluoroscopic examination discloses no delay in the passage of the barium meal and consequently no recurrence with obstructive phenomena. August 3, 1932: *Gruskin Reaction*—plus two. Complaints of weakness. Appetite fair. Weight 117 pounds. September 21, 1932: Had two weeks vacation and feels stronger; complaint now is not of weakness but of fatigability on exertion. Appetite good. No digestive discomforts if he eats small meals. Weight 118 pounds. Gruskin reaction same.

The persistence of a positive Gruskin reaction in this case is in all probability due to lymph node involvement. The regional lymphatic structures are large factors in the treatment of gastric carcinoma. To quote Balfour¹³: "There are two facts of great importance regarding enlarged lymph nodes in cancer of the stomach: (1) enlargement does not necessarily mean involvement by cancer, and (2) a patient may be cured even if all involved lymph nodes are not removed. The first fact is well known and undisputed and its practical importance is that it impels the surgeon to avoid the mistake of assuming

incurability because of marked and extensive enlargement of regional nodes, a fact to which W. J. Mayo early drew attention. The second point is less easily substantiated, but sufficient examples are found in this series of cases of cured patients, in which the surgeon considered the resection only palliative because of incomplete removal of an involved chain of lymph nodes. I believe it to be a possibility that in cancer in any situation, removal of the primary growth and of the immediately adjacent lymphatic structures may bring about a permanent cure even if involved lymph nodes are left; the remaining nodes in such cases act as a sufficient barrier to further dissemination of the disease. It is, therefore, occasionally good practice to disregard involvement of lymph nodes if the primary growth can be removed, and to remove the adjacent lymphatic structures as completely as possible."

CONCLUSIONS

1. Our present methods of study are often inadequate for the diagnosis of carcinoma of the stomach in its incipient stage.
2. In the Gruskin reaction we have a test for the diagnosis of malignancy that merits our attention.
3. Carcinoma of the stomach may produce attacks of pain indistinguishable from those of cholelithiasis.

The Poet of Flanders Fields*†

Lieutenant Colonel John McCrae, Canadian Army Medical Corps

By LOUIS H. RODDIS, Lièut. Comdr. Medical Corps, U. S. Navy,
San Pedro, California

THE soldier poet who wrote the most arresting poem of the World War was Canadian, born of Scottish ancestry. He was the second son of David McCrae and Janet Eckford who were married January 21, 1870. The older son Thomas McCrae also became a notable man, a professor of medicine, the relative by marriage of Sir William Osler with whom he collaborated in the production of an encyclopedic treatise on medicine well known to most practitioners.

John was born November 30, 1872. He began his education when scarcely three years of age by learning the Shorter Catechism. This learning of the Catechism in what might almost be termed infancy, was a sort of test applied by many Scottish families to determine if the child were capable of becoming a scholar. If he passed the test successfully he was marked for the university and one of the learned professions, divinity, medicine or the

law. It is said on no less authority than that of Sir Walter Scott that it was the ambition of every Scottish mother to have her son "wag his head in a pulpit", and failing that to become a physician or an advocate.

Having passed the Catechism test, and having no doubt learned from it at so early an age that "He should renounce the devil and all his works, the pomps and vanities of this wicked world", as that noble and earnest document recommends for us to do, he in due time went to the grammar school and the high school. In 1888 he entered the University of Toronto with a scholarship, and graduated from the Faculty of Arts in 1894 with the Bachelor of Science degree, his major being in biology. He graduated in medicine and surgery in 1898, a gold medallist, with a scholarship in physiology and pathology. He entered immediately upon his internship in Toronto General Hospital. He had spent the previous summer between his junior and senior year at the Garrett Children's Hospital in Mt. Airy, Maryland. In 1899 he went to Johns Hopkins Hospital as a resident physician and then to McGill University as an assistant in pathology and assistant pathologist to the Montreal General Hospital.

At this point, however, his work was

*Received for publication December 15, 1932.

†This is the fifth of a series of portraits of medical poets. Those which have previously appeared in the ANNALS OF INTERNAL MEDICINE are:

DR. McCRAE AND BONNEAU

interrupted by the Boer War. In addition to medicine he had two other major interests, poetry and military life. His father had been a militia officer, and at fourteen years of age John had joined the Guelph Highland Cadets. Now as a lieutenant of Canadian Artillery and a section commander he went out to South Africa on the

Laurentian. Here is one of his first letters from the war:

Van Wyks Vlei
March 22, 1900

Here I am with my first command. Each place we strike is a little more God-forsaken than the last, and this place wins up to date. We marched last week from Victoria west to Carnovan, about eighty miles. We stayed there over Sunday, and on Monday my sec-

tion was detached with mounted infantry, I being the only artillery officer. We marched fifty-four miles in thirty-seven hours with stops; not very fast, but quite satisfactory. My horse is doing well, although very thin. Night before last on the road we halted, and I dismounted for a minute. When we started I pulled on the lines but no answer. The poor old chap was fast asleep in his tracks, and in about thirty seconds too.

This continuous marching is really hard work. The men at every halt just drop down in the road and sleep until they are kicked up again in ten minutes. They do it willingly too. I am commanding officer, adjutant, officer on duty, and all the rest since we left the main body. Talk about the Army in Flanders! You should hear this battalion. I always knew soldiers could swear, but you ought to hear these fellows. I am told the first contingent had got a name among the regulars.

Here is another note of war and of a commander whose name is a byword in the British Army.

We were inspected by Lord Roberts. The battery turned out very smart, and Lord Roberts complimented the Major on its appearance. He then inspected, and afterwards asked to have the officers called out. We were presented to him in turn; he spoke a few words to each of us, asking what our corps and service had been. He seemed surprised that we were all Field Artillery men, but probably the composition of the other Canadian units had to do with this. He asked a good many questions about the horses, the men, and particularly about the spirits of the men. Altogether he showed a very kind interest in the battery.

At nine took the Presbyterian parade to the lines, the first Presbyterian service since we left Canada. We had the right, The Gordons and the Royal Scots next. The music was excellent, led by the brass band of the Royal Scots, which played extremely well. All the singing was from the psalms and paraphrases: "Old Hundred" and "Duke Street" among them. It was very pleasant to hear the old reliables once more. "McCrae's Covenanters" some of the officers

called us; but I should not like to set our conduct up against the standard of those austere men.

A veteran of the South African War, and with the Queen's Medal with clasps, he returned to Montreal to resume his practice, his place as a promising young pathologist, his teaching, his military drill, and his poetry. He was appointed physician to the Alexandria General Hospital, assistant physician to the Royal Victoria Hospital and a lecturer at the University. Eventually he became a fellow of the Royal College of Physicians and built a solid reputation as both a pathologist and an internist. He published a number of papers and at the time the World War began was finishing the revision of Adami's great *Textbook of Pathology*.

As early as 1894 he had begun to publish poetry, when two short poems "The Shadow of the Cross" and "The Hope of My Heart" appeared in the *Varsity*. In 1895 "Unsolved" was contributed to *The Canadian Magazine*. From then on until his death, *The Spectator*, *University Magazine*, *The Canadian Magazine* or the *West Minister* published nearly every year some verse by him. His contributions were not many, scarcely one or two a year, all short, and all similar in form and character. The usual or most common verse form was one called by the student of prosody the rondeau, and McCrae studied and experimented with this form until he was letter perfect in its use as a vehicle of poetic expression. The themes of his poetry were death, duty, and regret for lost love and life. It is possible that he was influenced by Houseman whose "Shropshire Lad", "that wonderful burst of song" as someone has called it, had

appeared in 1896. The elegiac note, the lament for loss is particularly a prominent feature of both poets.

One of the best of the poems is "Quebec" published in the *University Magazine* in 1908 on the occasion of the Tercentenary of the City.

QUEBEC

1608 1908

Of old, like Helen, guerdon of the strong—

Like Helen fair, like Helen light of word,—

"The spoils unto the conquerors belong.

Who winneth me must win me by the sword".

Grown old, like Helen, once the jealous prize

The strong men battled for in savage hate,

Can she look forth with unregretful eyes,

Where sleep Montcalm and Wolfe beside her gate?

"The Oldest Drama" from the *University Magazine* of 1907, "Upon Watts' Picture 'Sic Transit'", *University Magazine* 1904, "Isandlwana", *University Magazine* 1910, represent some of the best of his poetic work during the years of busy professional life.

He was a member of the Pen and Pencil Club of Montreal, a group of young writers and artists. He was popular socially and went about to social gatherings. He went fishing on his vacation and he made a number of journeys to Europe and the United States. How a fine looking and successful young doctor, five feet eleven inches tall, weighing one hundred and eighty pounds, and a poet, in fact in every respect the most eligible of bachelors, contrived to remain a bachelor during these years is difficult to understand, but he managed to do so, and in fact never married.

When the World War began in 1914 McCrae was in England but he at once

returned to become Brigade Surgeon to the First Artillery Brigade. Nearly his whole service before the World War, including the South Africa War, had been as a combat officer of artillery and he never quite got over a desire to continue as a line officer. He had plenty of war, however, as a medical officer, as these notes from two of his letters indicate:

Sunday, April 25, 1915.

On the front field one can see the dead lying here and there, and in places where an assault has been they lie very thick on the front slopes of the German trenches. Our telephone wagon team hit by a shell; two horses killed and another wounded. I did what I could for the wounded one, and he subsequently got well. This night, beginning after dark, we got a terrible shelling, which kept up till two or three in the morning. Finally I got to sleep, though it was still going on. We must have got a couple of hundred rounds, in single or pairs. Every one burst over us, would light up the dugout, and every hit in front would shake the ground and bring down small bits of earth on us, or else the earth thrown into the air by the explosion would come spattering down on our roof, and into the front of the dugout. Col. Morrison tried the mess house, but the shelling was too heavy and he and the adjutant joined Cosgrave and me, and we four spent an anxious night there in the dark. One officer was on watch "On the bridge" (as we called the trench at the top of the ridge) with the telephones.

Thursday, May 27, 1915.

Day cloudy and chilly. We wore our greatcoats most of the afternoon, and looked for bits of sunlight to get warm. About two o'clock the heavy guns gave us a regular "blacksmithing". Every time we fired we drew a perfect hornet's nest about our heads. While attending to a casualty, a shell broke through both sides of the trench, front and back, about twelve feet away. The zigzag of the trench was between it and us, and we escaped. From my bunk the moon looks

down at me, and the wind whistles along the trench like a corridor. As the trenches run in all directions they catch the wind however it blows, so one is always sure of a good draught. We have not had our clothes off since last Saturday, and there is no near prospect of getting them off.

Here is one with an observation by the poet doctor that was later to appear in "Flanders Fields":

and in the sky
The larks, still bravely singing, fly
Scarce heard amid the guns below.

Monday, April 26, 1915.

Another day of heavy actions, but last night much French and British artillery has come in, and the place is thick with Germans. There are many prematures (with so much firing) but the pieces are usually spread before they get to us. It is disquieting, however, I must say. *And all the time the birds sing in the trees over our heads.*

His horse's name was Bonfire and his dog's Bonneau. He wrote clever little notes as if from these animals, and signed those from the horse with a horseshoe as "Bonfire His Mark". References to animals and to trees and flowers are frequent in his letters and show his great interest in them.

"In Flanders Fields" appeared in *Punch* in the spring of 1915. Major General E. W. B. Morrison, who was in command of the brigade in which Major McCrae was serving, has in a letter described so well the actual circumstances under which the poem was written that his description is reproduced here:

"This poem", General Morrison writes, "was literally born of fire and blood during the hottest phase of the second battle of Ypres. My headquarters were in a trench on the top of the bank of the Ypres Canal, and John had his dressing station in a hole dug

in front of the bank. During periods in the battle men who were shot actually rolled down the bank into his dressing station. Along from us a few hundred yards were the headquarters of a regiment, and many times during the sixteen days of battle, he and I watched them burying the dead whenever there was a lull. Thus the crosses, row on row, grew into a good-sized cemetery. Just as he describes. We often heard in the mornings the larks singing high in the air, between the crash of the shell and the reports of the guns in the battery just beside us. I have a letter from him in which he mentions having written the poem to pass away the time between the arrival of batches of wounded, and partly as an experiment with several varieties of poetic meter. I have a sketch of the scene, taken at the time, including his dressing station; and during our operations at Passchendaele last November, I found time to make a sketch of the scene of the crosses, row on row, from which he derived his inspiration."

Here is the poem:

IN FLANDERS FIELDS

In Flanders fields the poppies blow
Between the crosses, row on row,
That mark our place; and in the sky
The larks, still bravely singing, fly
Scarce heard amid the guns below.

We are the Dead. Short days ago
We lived, felt dawn, saw sunset glow,
Loved and were loved, and now we lie
In Flanders fields.

Take up our quarrel with the foe;
To you from failing hands we throw
The torch; be yours to hold it high.
If ye break faith with us who die
We shall not sleep, though poppies grow
In Flanders Fields.

In the early summer after the sec-

ond battle of Ypres, the poet, now made famous overnight, was detached from the First Artillery Brigade and ordered for duty as Chief of the Medical Service at No. 3 General Hospital at Boulogne. At about this time also he was recommended for promotion to Lieutenant Colonel. He had many regrets at leaving the guns, but his services as an internist were of much greater value, and every medical man with specialist training was needed in the hospital now filled with sick and wounded after the desperate winter of 1915. He remained as Chief of Medicine until 1918 when he was selected to command General Hospital No. 1, but before he could assume this command it was proposed that he should be appointed "Consultant Physician to the British Army in the Field". He was never to receive either appointment. He contracted pneumonia and died at General Hospital No. 14 after an illness of only five days.

Each great war has furnished the inspiration for some great poem. There is little doubt but that "In Flanders Fields" is the poem of the World War that will linger longest in the minds of men. Its title, its simplicity, its easy measure, and its combination of elegy and call to duty are reasons for its sudden and wide publicity. With a music hall song, "It's a Long Long Way to Tipperary", it shares the honor of expressing best in fewest words the World War atmosphere and mood.

McCrae's scientific papers are well written, and his editing of Adami's Pathology well done. But there is one

short piece of prose that is more than well written and constitutes a fitting tribute to himself as well as being worthy to be considered beside the three other great tributes to the medical profession, namely the self-imposed Oath of Hippocrates with its lofty ethics, the well known eulogy by Robert Louis Stevenson, and Sir William Osler's address in which he refers to medicine as "a calling not a trade". Compare these with John McCrae on the legend from Watts' picture "Sic Transit", the subject of one of his earlier poems, and it stands the test well. Here is what he says of this profession: "What I spent I had: What I saved I lost: What I gave I have." "It will be in your power every day to store up for yourselves treasures that will come back to you in the consciousness of duty well done, of kind acts performed, things that having given away freely you yet possess. It has often seemed to me that when in the Judgment those surprised faces look up and say, 'Lord, when saw we Thee anhungered and fed Thee; or thirsty and gave Thee drink; a stranger, and took Thee in; naked and clothed Thee'; and there meets them that warrant-royal of all charity, 'Inasmuch as ye did it unto one of the least of these, ye have done it unto Me,' there will be amongst those awed ones many a practitioner of medicine."

BIBLIOGRAPHICAL NOTE

Most of the material for this article was obtained from Sir Andrew Macphail's tribute to Colonel McCrae, written in 1919, to accompany a collected edition of his poems.

Editorial

CERTAIN FACTORS IN THE LOCALIZATION OF DISEASE

The individuality of the various clinical forms of disease depends largely upon the tendency each exhibits to localize differently in the human tissues. The external specificity of symptoms and signs observed by the clinician corresponds to an internal specificity of pathological lesions or of functional disturbances. The factors entering into the determination of the specific localization of disease are to a large extent still obscure though from the earliest times they have been the subject of medical investigation.

In recent years there has been a renewal of activity in the study of the influence of heredity on the occurrence of disease. In addition to the well known hereditary anatomical anomalies it has been shown that certain of the heredo-familial degenerative diseases of the nervous system and certain metabolic disturbances such as pentosuria and alkaptonuria can be definitely followed as gene-determined characteristics. The list of such diseases is a large and important one. The lesions, especially in the diseases of the sense organs of the central nervous system, are as a rule exquisitely localized. Heredity is then an important factor which by as yet unknown mechanisms localizes disease of endogenous origin to specific sites in the tissues of the body.

Less definite in its findings has been the modern reinvestigation of the effects of constitution upon disposition to the various diseases. Borchardt defines constitution as the status of the organism as conditioned by both heredity and environment. It is the aggregate of those characteristics, anatomical, physiological, and psychical which constitute the total individual. Various types of constitution have been described such as the slender or asthenic type and the broad or pyknic type. These separate types of constitution have been shown to exhibit a difference in their disposition to many diseases such as tuberculosis, gout, diabetes, gall-stones, asthma, peptic ulcer, etc. In some instances these variations in disposition seem to be linked with variations in physiological functions which might be causative. For the most part, however, constitutional pathology does not offer explanations of its findings. It is in the descriptive rather than in the elucidative phase of its development. We may accept the fact that constitution to some extent determines the localization of disease in the body.

The study of these more general phenomena, heredity and constitution, has been accompanied in our day by an attack on the problem of disease localization carried on from quite a different angle. The investigations to which we refer have dealt with the more intimate mechanisms by which

local tissue immunity or susceptibility are determined. These studies have been concerned chiefly with the problems connected with the localization of the infectious diseases, and with the localized effects of toxins, drugs, and poisons.

The degree to which bacteria are invasive has long been conceded to be the result of a balance between two opposing factors: the "virulence" of the bacterial species and the resistance of the host.

Virulence is at best a vague, all inclusive term used to cover the sum total of all the harmful effects of a bacterial species. Included in it is the power of a particular strain to attack successfully highly localized areas within the body of the host. To an increasing extent in recent years this specificity of effect of certain bacterial strains has won recognition and the bitter opposition which met Rosenow's pioneer work in this field has to some extent died away. The problem of bacteriology is now to determine in how far tissue specificity shown by pathogenic organisms is related to the specificity of the types into which the bacterial species in vitro can be subdivided. These types until recently could be considered specific only upon the basis of specific immunologic responses incited by their injection. The brilliant researches of Avery and his co-workers have given us evidence in the case of the pneumococcus, that type specificity and virulence are alike functions of the capsule of the organism, and that the capsule of each type of pneumococcus contains a polysaccharide which is chemically and immunologically distinct from that contained in the capsule of

the other types. Such light thrown upon the nature of type specificity within the bacterial species must serve in time to enlarge our understanding of the mechanism of tissue specificity of bacterial action in the body, with a consequent expansion of our knowledge of the factors in the localization of the bacterial diseases.

The relationship of the chemical constitution and physical state of a substance introduced into the body to the localization of this substance in the organs of the body was studied intensively by Ehrlich and led directly to his bold conception of union by chemical affinity between protoplasm and the injected drug or dye or toxin. He was led by this conception to search for specific drugs which would be toxic to parasites and possess a strong chemical affinity for them, while showing only a weak chemical affinity for the tissues of the host. Such a substance could be administered in sufficient dosage to kill the infecting organism and leave the host unscathed. The enunciation of the theory of chemotherapy has been enormously valuable because of the stimulation it gave to the synthesis of large series of new chemical compounds and to their trial as therapeutic agents. The attempt to explain their distribution and action on the basis of chemical affinities has met with difficulties which have somewhat blurred the simple outlines of the original theory. A further difficulty and disappointment of the chemotherapeutic era has been the repeated demonstration of the fact that the parasitocidal action of a chemical substance in vitro very often does not correspond to its action on the parasite in the animal body. The orig-

inal compound introduced may be altered by oxidation, reduction, or synthesis in the body and it may be only the end product of such reactions that is available for chemotherapeutic action. It has been found also that the effectiveness of certain drugs seems to be as an adjuvant to the immune reactions of the host and that the optimum dose for this joint action lies well below the maximal dose which would be tolerated. Perhaps the essence of the difficulty in chemotherapeutic research lies in the fact that whereas the chemical constitution of the prepared remedy is known, the nature of the physicochemical medium in which it must act, and the chemical nature of the parasitic or host protoplasm with which it is intended to join, are both still obscure. A large measure of empiricism must prevail in chemotherapy while it still deals with such unknown factors. It may be that the separation of the chemical fractions of microorganisms, a line of investigation which in the hands of Heidelberger and others has revealed the chemical compounds responsible for the type characteristics of the pneumococci, will eventually simplify the task of chemotherapy by indicating the precise nature of the substance on which the chemical remedy must act. A sound theory of the nature of the affinity which localizes the action of a drug or a toxin must await further knowledge.

These investigations which are attempting to reduce to terms of chemical constitution and physical state the attributes of bacteria and of drugs which give specificity to their biological behavior have been supplemented by studies bearing upon the variations in

resistance of the various tissues and organs of the host.

It is apparent that the exterior of the body of the host offers in different areas a variable degree of resistance to invasion, the basis of which lies in structural differences. The toughness and impermeability of the skin as compared to the delicacy and absorptive power of the mucous membranes, the heat and moisture in the folds of axillae and groins as compared with the hands, the differing degrees of exposure to trauma and friction, all such structural and functional differences in the exterior of the body are no doubt important factors in determining the localization of the portals of entry of the infections.

When the infection is within the body, however, and in process of dissemination through the blood stream, the factors which determine its secondary localizations in certain sites while leaving other parts uninvolved offer fascinating problems. It is reasonable to suppose that once within the closed system of the circulation, bacteria, drugs, toxins, or other foreign material will pass out again into the tissues at the points where the vascular wall is most readily permeable. The capillary wall towards the venous end of the capillary has been shown to be the most permeable portion of the vascular system. The nature of this permeability, and its control by the autonomic system, by hormonal action, and by the physicochemical constitution of the blood and tissues, have been intensively studied in recent years. Burrows has recently summarized our present knowledge of how local changes in

capillary permeability may lead to localization of disease, and has cited a vast number of experimental and clinical observations which indicate the actual importance of this factor.

The advance of our knowledge of capillary permeability has depended largely upon two methods: The visualization of the capillaries and the use of injections of dyes which by the greater intensity of staining make manifest the area in which permeability has been increased. By a combination of these methods it has been shown that increased permeability of capillaries may be quite independent of dilatation and even of stasis. Local inflammation, local ischemia, local increase in hydrogen ion concentration, local disturbance of vascular innervation, local action of histamine-like substances, may be accompanied by a local increase in capillary permeability as shown by a localization of injected dyes. Moreover, it has been shown that the capillaries in such an area may remain more than normally permeable for some time after the inciting cause has disappeared. These experimental observations with dyes throw light on the mechanism involved in certain further experimental studies dealing with the localization of disease.

The tendency of blood-borne infections to localize in traumatized areas has been repeatedly proven by experimental methods and corresponds closely to similar localizations of injected dyes. The normal brain and spinal cord always remain free from dye injected intravenously, but Macklin and Macklin found that if rats were injected with trypan blue and then given blows on the head this trauma was sufficient

to localize the dye in the brain as shown by a pronounced staining of the tissues. Okuneff applied a hot water bag to the abdomen of a rabbit and then gave an intravenous injection of trypan blue. As a result not only was the belly wall where it had been in contact with the hot water bag strongly colored, but so also were the subjacent coils of intestine. Ebbecke has reported that if trypan blue or trypan red be injected into the general blood stream and a wheal be then produced in the skin, the dye will discolor the wheal. Similarly Chesney, Turner and Halley excised pieces of skin from the backs of rabbits and later gave intravenously 0.1 c.c. of a testicular emulsion of active treponemes. At periods varying from nineteen to sixty-seven days subsequent to these injections every one of the dorsal scars became affected with indurated syphilitic lesions, whereas no other cutaneous lesions occurred. In humans the tendency for secondary syphilitic eruptions to be more intense about old scars, chronic ulcers, and areas of irritation has been repeatedly noted. The tendency of the lesions to be most numerous about old tattooing is especially striking. Krause injected cultures of tubercle bacilli intravenously into rabbits and then wrenched a joint. In one-half of these rabbits the injured joints became tuberculous. In septicemia due to typhoid bacilli, pneumococci, or staphylococci, secondary localizations at sites of trauma, of pressure, or even of hypodermic injections have been very frequently reported. In the experimental studies of the virus diseases various forms of irritation as a means of localizing the disease have been repeatedly employed

by many investigators. The virus of vaccinia when intravenously given will produce a vaccinal eruption wherever the skin has been traumatized. Flexner and Amoss found that infection of the nervous system with poliomyelitis virus given intravenously could only be obtained if enormous doses were employed. If, however, an intraspinal injection of foreign serum had been made twelve or eighteen hours beforehand, infection was readily established by giving virus intravenously.

A mass of experimental work, from which these few illustrative examples are drawn, points strongly towards the dominant rôle of local variations in capillary permeability as a factor in the localization of blood-borne diseases.

Beyond the capillaries lie the extracellular tissue fluids and the tissue cells. It is not sufficient that a noxious agent permeate the capillary endothelium; it must also exert its effect upon the extravascular tissues before evidence of

a localized lesion appears. Gay has discussed the variable resistance of the tissues to such invasion. Theoretically, he points out, successful local resistance might be due to local formation of antibody, or to a local accumulation of antibody formed elsewhere. He sets aside both hypotheses, however, and inclines to believe that local resistance is not humoral but chiefly cellular in character. In this connection he has brought forward evidence that a particular type of macrophage, the clasmatoocyte, plays the chief rôle in local defense reactions and he suggests that the varied susceptibility to infection of different tissues depends chiefly upon the distribution among them of this macrophage.

Necessarily in this brief review many aspects of the localization of disease have not been mentioned. Enough perhaps has been said to indicate some of the recent lines of attack upon this fundamental problem of human pathology.

Reviews

Intracranial Tumors. By PERCIVAL BAILEY, Professor of Surgery, University of Chicago. xx plus 475 pages, with 155 illustrations. Charles C. Thomas, Springfield, Illinois, 1933. Price, \$6.00.

This book comes at a very opportune time for students and those interested in the subject of intracranial tumors, because it is the first of its kind to present the whole subject from a much needed clinico-pathologic viewpoint. The material is presented in the readable style of informal clinics, which were amplified for publication. Fifty-nine illustrative cases from the author's clinic form the basis of the text.

The opening chapters include a discussion of the problem of tumors in general, the

modern classification of intracranial tumors, and valuable analytic tables. The more fundamental anatomic and physiologic conceptions are also reviewed. Each type of intracranial tumor is presented from the clinico-pathologic viewpoint, with emphasis on the latter. The author correctly stresses the view that it is no longer sufficient to know that a patient has a brain tumor and its location, but the histological type as well. Several clinical cases are given to illustrate each histological type. From case histories the clinical story of each individual type of tumor is developed. The general characteristics, the age incidence, the common location of the tumor, the gross appearance, and the microscopic anatomy are discussed. The his-

tory of the developing neoplasm is given by detailed review of symptoms and the resultant neurologic signs. Each tumor is described in the location in which it is most commonly found, with a discussion of the neurologic syndromes which result from neoplastic invasion of each cerebral subdivision. In the chapter on medulloblastoma, for instance, the syndrome of the vermis cerebelli is outlined; in connection with hypophyseal adenomas, acromegaly and the hypopituitary syndrome are discussed. Regional physiology and anatomy are included in the discussion of the neurologic signs and symptoms of each syndrome. A brief note concerning the accepted treatment is given for each tumor. Chapters on general diagnosis, differential diagnosis, and general treatment of intracranial tumors conclude the book.

The text is printed on dull paper and adequately illustrated with 155 pen-and-ink drawings. While reading is made easier by the use of dull paper, this is done at the expense of eliminating the usual and preferable half-tones. Photomicrographs would have added to the illustrations. The bibliography contains some four hundred references which serve as a valuable guide for supplementary reading. The book is exceptionally well done and deserves a place in the library of any one interested in intracranial tumors.

J. G. A., JR.

Diseases of the Heart. By SIR THOMAS LEWIS. 297 pages. The Macmillan Company, New York. 1933. Price, \$3.50.

This book is written in the author's usual clear and succinct style. It is purposely designed for use by practitioners and students, and will be of little value to one who is already primarily concerned in diseases of the heart. The subject is approached largely from the point of view of bedside observations, and these are clearly stated. The author has a particularly sane and common sense attitude toward the limitations of the usefulness of digitalis and toward the handling of patients suffering with essential hypertension. Many cardiologists would be more optimistic in regard to the usefulness of quinidine in the therapy of auricular fibrillation. There is perhaps too little discussion of the information to be obtained from

electrocardiography and other mechanical methods, and too great stress placed upon somewhat unreliable clinical methods. The reviewer certainly cannot agree with the following statement: "The fingers should be trained to recognize a high tension pulse; for a pressure meter can hardly be used as a routine in general practice." The discussion of those patients with complaints referred to the heart and who present no evidence of heart disease is inadequate. Such patients, both in their diagnostic and therapeutic implications offer serious problems for the practitioner. The author has dealt with them in a very short chapter on the "Effort Syndrome," and a paragraph or so on the occurrence of heart pain in neurasthenia, which latter term is apparently used as a sort of catch-all for neurotic invalidism. The reviewer sees little reason for not dealing with the "Effort Syndrome" in a chapter devoted to the psychoneuroses. However, because of its clarity and lack of extensive theoretical discussions, and because of the author's excellent clinical observations, and his conservative and common-sense approach to the whole subject, this should prove a valuable book for the general practitioner.

W. S. L., JR.

Outline of the Cranial Nerves. By JOHN FAVILL, A.B., M.D., F.A.C.P., Associate Clinical Professor of Neurology, Rush Medical College of the University of Chicago. Cloth. 120 pages. The University of Chicago Press, Chicago, Illinois. 1933.

This little book should be of decided value to the medical student or to any one interested in the study of Neurology. Each cranial nerve is treated under five headings: anatomy, function, tests, pathology and localization, thus bringing together facts that are usually not found under one classification. The chapter relating to the eighth nerve is especially good—giving a full account of the vestibular tests and their significance.

Considered as a whole, this is an excellent summary of our present day knowledge of the cranial nerves.

A. C. G.

Clinical Aspects of the Electrocardiogram. By HAROLD E. B. PARDEE, M.D. Third edition, revised. 295 pages. Paul B. Hoe-

ber, Inc., New York. 1933. Price, \$5.50.

The third edition of this book has been revised and somewhat amplified. The author has accepted the newer views in regard to the localization of premature ventricular beats and of the myocardial lesions giving rise to bundle branch block and has revised his terminology accordingly. The chapters on changes in the electrocardiogram due to myocardial disease, and the clinical significance of abnormal waves should be of general interest. The author happily points out that while certain of such changes undoubtedly mean temporary or permanent serious myocardial disease, and others probably indicate abnormalities of the myocardium, one is not justified in making a prognosis upon the electrocardiogram alone. One too often sees patients who have been frightened unjustifiably by a diagnosis of myocardial disease based upon slight deviations of uncertain meaning from the normal electrocardiogram. Ventricular axis deviation and the arrhythmias are adequately covered and there is a clear exposition of the theory of the electrocardiogram. The two types of electrocardiograph are described and the technic of their use explained. The book should be readily understood by the practitioner of medicine and should be of value also to those primarily interested in heart disease.

W. S. L., JR.

Procedure Book of the Methodist Episcopal Hospital. 2nd Edition. Brooklyn, New York, 1932.

This small volume is a paper bound book of two hundred and one printed pages, containing twenty-five chapters and an index. Between each chapter there are six blank pages for additional notes. Its size, 6 x 9 inches, precludes the possibility of its being carried about in the pocket.

Originally prepared to serve the undergraduate nurses of the Methodist Episcopal Hospital, the book has been expanded in this edition to be of service also to the interne staff. All printed procedure books are of interest to the superintendents, heads of training schools, chiefs of services, and house officers of other hospitals. They contain much valuable information which can be taken over to serve in the construction of

new procedure books. This little volume is quite complete and contains a vast amount of useful data. One strange omission is the lack of any mention of blood transfusions. It is also of interest, though not important, that though the junior nurses are specifically forbidden to sing, whistle, or play musical instruments, no mention of the rules as to smoking is made.

M. J. A.

Diseases of the Eye. By HOFER ERNST FUCHS. Revised by MAXIMILIAN SALZMAN. Translated by E. V. L. BROWN. Tenth English Edition. 255 illustrations and 41 colored figures. J. B. Lippincott Company, Philadelphia. 1933. Price, \$7.00.

This volume, which constitutes the tenth English edition of Fuchs' famous *Textbook of Ophthalmology*, has been reduced approximately one-third in the number of pages as compared with recent editions. The lessened size is due largely to the elimination of Part I of the former work consisting of Chapter one (Objective Examination of the Eye) and Chapter two (Functional Testing), Part III which took up anomalies of Refraction and Accommodation, and Part IV which gave a concise description of the various operations upon the eye and its adnexae.

There has also been a considerable rearrangement of the subject matter. Part I treats of the Lids and Conjunctiva; Part II, Diseases of the Tunica Fibrosa (Cornea and Sclera); Part III, Diseases of the Uvea; Part IV, Diseases of the Retina and of the Optic Nerve; Part V, Diseases of the Lens, Zonule and Vitreous; Part VI, Diseases of the Eyeball as a Whole; Part VII, Diseases of the Orbit and Part VIII, Diseases of the Nerves of the Eye.

While the rearrangement of material may be an advantage and the elimination of Parts I, III, and IV may be gratifying to the undergraduate, these changes certainly will not be pleasing to the postgraduate student who has looked upon his Fuchs' as his Ophthalmic Bible.

It would seem that greater attention should have been directed to the use of the slit-lamp in determining microscopic changes in the living tissues, as an aid to diagnosis. The reviewer also believes that greater attention should have been given to the therapeutic use

College News Notes

of tuberculin in the treatment of the various tuberculous lesions. The modern conception and treatment of retinal detachments could also be made more explicit.

In spite of the somewhat limited scope, the book is still a very valuable work upon the diseases of the eye.

C. A. C.

Criteria for the Classification and Diagnosis of Heart Disease. By The Criteria Committee of the Heart Association, New York Tuberculosis and Health Association, New York. 131 pages. 1932. One can only be in sympathy with the purpose of this publication. It should serve as an important step towards the adoption of a uniform nomenclature for heart disease, and uniform criteria for using such nomenclature. The book deals with etiological, anatomical and physiological diagnosis, and the functional state of the heart. In the appendix are sections on electrocardiography and radiography. It is not a clinical exposition of heart disease, but as an aid in classifying cases it should prove most valuable to any physician interested in internal medicine.

W. S. L., JR.

The Doctrine of the Healing Power of Nature Throughout the Course of Time. By MAX NEUBURGER, M.D., Ph.D., Professor of History of Medicine of the University of Vienna. Translated by LINN J. BOYD, M.D., F.A.C.P., Professor of Pharmacology, The New York Homeopathic Medical College and Flower Hospital. Paper. 184 pages. 1933.

To those interested in the history of medicine, particularly from its philosophical aspects, this monograph by one of the world's greatest medical historians should be of considerable interest. The doctrine of the healing power of nature has occupied the attention of the physician for thousands of years. Today, it is probably of greater importance than at any time in the past. Our studies of the internal secretions and of immunity have brought the matter to the forefront. Dr. Neuburger traces the history of this subject from the days of Hippocrates, when the occurrence of spontaneous healing was established as a fact for the first time, through the ages down to modern times.

Dr. Boyd's translation is excellent.

A. C. G.

College News Notes

Acknowledgment is made of the following gifts to the College Library of publications by members:

Dr. W. R. Brooksher (Fellow), Fort Smith, Ark.—2 reprints;
Maj. Leon A. Fox (Fellow), Washington, D. C.—2 reprints;
Dr. Hyman I. Goldstein (Associate), Camden, N. J.—1 reprint;
Dr. Oliver T. Osborne (Fellow), New Haven, Conn.—1 reprint.

Dr. Arthur L. Bloomfield (Fellow) has been appointed Acting Dean of Stanford University School of Medicine, San Francisco. Dr. Bloomfield is also Professor of Medicine and Secretary of the School.

Dr. John Severy Hibben (Associate), Pasadena, Calif., has been appointed Chairman of a Special Committee on Physical Therapy of the California State Medical Association to survey the present practice of physical therapy with reference to education and practice, and to report on it at the next meeting of the State Medical Association.

Dr. Walter L. Bierring (Fellow), Des Moines, Iowa, has been appointed State Health Commissioner for Iowa, beginning July 1.

Dr. Maxim Alexander Oginsky (Fellow), formerly Medical Director and Pathologist to the Saratoga Hospital at Saratoga Springs, N. Y., was appointed April 1, 1933, as Di-

rector of Laboratory and Pathologist to the Woman's Hospital, Detroit, Mich.

Dr. James A. Lyon (Fellow), Washington, D. C., and Dr. Lewis C. Ecker (Associate), Washington, D. C., are President and Vice-President, respectively, of the Washington Heart Association.

Dr. Lawrason Brown (Fellow), Saranac Lake, N. Y., was recently reelected President of the Saranac Lake Society for the Control of Tuberculosis.

Dr. William S. Rude (Fellow), Ridgetop, Tenn., was recently elected one of the Vice-Presidents of the Tennessee State Medical Association.

OBITUARIES

DR. MARTIN JAMES LARKIN

Dr. Martin James Larkin (Fellow), Toledo, Ohio, died March 11, 1933; aged 39 years. On the evening of July 9, 1932, while on his way to the Mercy Hospital, he was apprehended by a man who demanded his car. While he was in the act of leaving his car, the gunman opened fire on him. The bullet entered the left side of the face, fractured the mandible, passed through his mouth and lodged in the neck, opposite the transverse processes of the second and third cervical vertebrae. Dr. Larkin recovered from the wound; the fractured mandible united and he apparently returned to normal, so that he returned to practice on January 3, 1933. On January 18, he complained of pain in the cervical region. Two days later an abscess was evacuated, and one week later the bullet was removed. Several days later he gave signs of cerebral irritation and of bloodstream infection. His condition became progressively worse, and he expired on March 11, 1933.

Dr. Larkin was a graduate of St. John's University, Toledo, receiving the degree of A.B. in 1915. He received his medical education at St. Louis University School of Medicine, graduating in 1919. For two years

thereafter, he served on rotating services of the St. Louis City Hospital, and then entered general practice in Toledo. His work had been devoted chiefly to Internal Medicine and Tuberculosis since 1924. His appointments included Director of the Department of Medicine, Mercy Hospital; Assistant Director of the Department of Medicine, Lucas County Hospital. He was a member of the Toledo and Lucas County Academy of Medicine, the Ohio State Medical Association and the American Medical Association. He became a Fellow of the American College of Physicians on March 22, 1931.

DR. EDWARD W. MEIS

Dr. Edward W. Meis (Fellow), Sioux City, Iowa, died December 7, 1932, of carcinoma of the stomach.

Dr. Meis received his medical degree from the University of Iowa College of Medicine in 1900. At the time of his death, he was Senior Examiner for the Prudential and Missouri State Life Insurance Companies; a member of the Sioux City Chest Clinic; a member of the staff of St. Joseph's Mercy Hospital.

He was a member of the Woodbury County Medical Society, the Iowa State Medical Association and the

American Medical Association. He became a Fellow of the American College of Physicians on February 24, 1920, and had served actively throughout his entire membership.

DR. FRANKLIN E. MURPHY

Dr. Franklin E. Murphy (Fellow), Kansas City, Mo., died, February 20, 1933, of heart disease; aged, 67 years.

Dr. Murphy was born November 21, 1866, at Reddington, Ind., the son of a physician. His family moved successively from Reddington to Independence, Mo., and then to Kansas City, where he received his secondary school training in the Central High School. Dr. Murphy continued his studies at the Philadelphia College of Pharmacy, graduating in 1888. After acting as a pharmacist for one year, he entered the University of Pennsylvania School of Medicine, from which he graduated in 1893. From 1896 to 1901, he was Secretary of the Kansas City Medical College; from 1901 to 1903, he pursued postgraduate work in the Universities of Göttingen, Jena, Berlin and Vienna. Shortly after his return to this country, he became Professor of Clinical Medicine in the University of Kansas School of Medicine, serving in this capacity from 1905 to 1933.

Dr. Murphy was President of the Jackson County (Mo.) Medical Society, a member of the Missouri State

Medical Association and a Fellow of the American Medical Association. He had been a Fellow of the American College of Physicians since 1920. He was a member of the Staffs of the Bell Memorial, Research, Wesley and General Hospitals.

"His record shows the career of a man who chose his profession with a full knowledge of its difficulties and trials, and steadily pursued his course of primary, professional and postgraduate instruction. This is evidence of his determination of character, as he had to earn his own way. His professional ability was recognized by members of the profession, and he was appointed to responsible positions as a teacher of medicine and elected to executive responsibilities in medical organizations."

". . . Franklin E. Murphy was a man of positive character. No one, friend or enemy, was ever heard to speak of him except in terms of respect. He always took his work seriously and was a hard, patient and methodical worker. His patients all respected him and those with whom he came in intimate contact loved him." Dr. Murphy was a man who could always be relied upon to support the best traditions of the profession.

(Furnished by A. COMINGO GRIFFITH, M.D., F.A.C.P., Governor for Missouri.)
